ABSTRACT BOOK

Abstract Book

SETAC Europe 34th Annual Meeting

Table of Contents

This book compiles the abstracts from the 35th annual meeting of the Society of Environmental Toxicology and Chemistry – Europe (SETAC Europe), conducted from 11–15 May 2025 in Vienna, Austria.

The abstracts are reproduced as submitted by the author and accepted by the scientific committee. They appear in order of abstract code and alphabetical order per presentation type. The poster spotlight abstracts are included in the list of poster abstracts. The presenting author of each abstract is high-lighted in bold.

The information in this abstract book reflects the status of the abstracts as was on 14 April 2025.

PRINT ISSN 2309-8031 - ONLINE ISSN 2310-3043

About SETAC

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists, biologists, chemists, toxicologists, managers, engineers or others interested in environmental issues. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in North America in 1979 to fill the void and quickly saw dynamic growth in the Society's membership, meeting attendance and publications.

A unique strength of SETAC is its commitment to balance the scientific interests of government, academia and business. The Society by-laws mandate equal representation from these three sectors for officers of the World Council and Geographic Unit Boards of Directors and Councils, and in the composition of committees and other society activities. The proportion of members from each of the three sectors has remained nearly equal over the years.

The Society is concerned about global environmental issues. Its members are committed to Environmental Quality Through Science®, timely and effective communication of research, and interactions among professionals so that enhanced knowledge and increased personal exchanges occur. Therefore, SETAC publishes two globally esteemed scientific journals and convenes annual meetings around the world, showcasing cutting-edge science in poster and platform presentations. Because of its multidisciplinary approach, the scope of the science of SETAC is broader in concept and application than that of many other societies.

SETAC's growth is reflected in the founding of Geographic Units around the world. SETAC Europe was established in 1989 as an independent organisation, followed by SETAC Asia-Pacific in 1997 and SETAC Latin America in 1999. In 2002, the four existing organisations joined together under the governance of the SETAC World Council. SETAC Africa is the most recent Geographic Unit, which was adopted in 2012. As evidence of international acceptance of the SETAC model and of the great interest at the local level, regional chapters and branches have emerged in a number of countries.

SETAC publishes two journals, *Environmental Toxicology and Chemistry* (ET&C) and *Integrated Environmental Assessment and Management* (IEAM). ET&C is dedicated to furthering scientific knowledge and disseminating information on environmental toxicology and chemistry, including the application of these sciences to risk assessment. Integrated Environmental Assessment and Management focuses on the application of science in environmental decision-making, regulation and management, including aspects of policy and law, and the development of scientifically sound approaches to environmental problem solving. Together, these journals provide a forum for professionals in academia, business, government and other segments of society involved in the use, protection and management of the environment for the enhancement of ecological health and human welfare.

SETAC books provide timely in-depth reviews and critical appraisals on scientific subjects relevant to understanding a wide range of contemporary topics pertaining to the environment. These include any aspect of environmental chemistry, toxicology, risk assessment, risk management or environmental policy.

SETAC has two administrative offices, in Pensacola, Florida, USA, established in 1992, and in Brussels, Belgium, established in 1993.

Track 1. Environmental and Human Toxicology: From Molecules to Organisms, From Omics to in Vivo

1.01 Unveiling Long-Term Ecological Impacts: From Epigenetic Biomarkers to Multigenerational and Chronic Effects of Environmental Contaminants Including Their Mixtures

1.01.T-01 PFAS Across Generations: Developmental Exposure in Zebrafish Drives Behavioural, Transcriptomic and Epigenetic Disruptions

Manon Fallet[1]*, Michela Di Criscio*[2]*, Jonas Zetzsche*[1]*, Adeolu Ogunleye*[2]*, Coralie Yon*[1]*, Amina Agic-Alijagic*[1]*, Rudolf Aro*[1]*, Daniel Duberg*[1]*, Leo Yeung*[1]*, Tuulia Hyotylainen*[1]*, Philipp Antczak*[3]*, Nikolai Scherbak*[1]*, Joelle Ruegg*[2] *and Steffen H. Keiter*[1]*, (1)orebro University, Sweden, (2)Uppsala University, Sweden, (3)University of Cologne, Germany,*

Understanding how environmental pollutants impact organisms across generations is critical to addressing global ecological challenges. Perfluoroalkyl substances (PFAS), widely used in industrial and consumer products, pose significant risks due to their persistence and potential to induce heritable changes through epigenetic modifications. This study examines the multigenerational effects of perfluorooctane sulfonic acid (PFOS) and its replacement, perfluorobutane sulfonic acid (PFBS), on zebrafish, focusing on behavior, fertility, gene expression, and epigenetic alterations. While PFOS is notorious for its environmental toxicity and bioaccumulation, PFBS is less studied despite its growing use as an alternative. We exposed zebrafish embryos to environmentally relevant concentrations of PFOS, PFBS, or control conditions from 2 to 28 days post-fertilization, followed by a depuration period, after which the fish were raised in clean water. The exposed generation (F0) was analyzed for fertility, morphology, behavior, lipidomics, and transcriptomics, while the unexposed F1 and F2 generations were assessed for behavioral, transcriptomic, and DNA methylation changes. Our results revealed that PFOS exposure reduced fertility and adversely affected growth, organ development, and behavior in both larvae and adults of the F0, with sex-specific effects observed in behavior. PFBS also caused behavioral changes, albeit less severe. The transcriptomic analysis results showed disruptions in lipid and sugar metabolism, neurotransmission, and synaptic organization. Lipidomic findings indicated disruptions in hormone biosynthesis and fatty acid metabolism, explaining fertility reductions and behavioral alterations. Multi- and transgenerational effects were also observed on the F1 and F2 generations with behavioral changes persisting in both F1 and F2, correlating with gene expression modifications in the visual system and muscle function pathways. Epigenetic analysis identified DNA methylation changes in genes linked to neurodevelopment and neuronal function, providing evidence of heritable impacts of PFOS and PFBS. Our findings provide critical insights into the mechanisms by which PFAS exert long-term biological and ecological impacts, from immediate phenotypic changes to heritable epigenetic modifications. These results underscore the urgent need for further research and informed policy-making to mitigate the risks of PFAS exposure on ecosystems and public health.

1.01.T-02 Multigeneration Responses of *Daphnia magna* to Short Chain Per- and Polyfluorinated Substances (PFAS)

Ge Xie[1]*, Cornelis A.M. van Gestel*[1]*, J. Arie Vonk*[2] *and Michiel Kraak*[2]*, (1)Vrije Universiteit Amsterdam, Netherlands, (2)Universiteit van Amsterdam, Netherlands*

Short chain per- and polyfluorinated substances (PFAS) have been widely used as replacements for long chain PFAS, and are therefore ubiquitously distributed in the environment. However, they remain largely unregulated owing to insufficient information on their environmental fate and effects. Moreover, due to their highly persistent and bioaccumulative nature, organisms living in contaminated ecosystems are chronically exposed to these short chain PFAS over multiple generations. Yet, in ecotoxicity experiments such chronic effects have barely been addressed, which are consequently overlooked in environmental risk assessment. Therefore, in this study, the ecotoxicity of perfluorobultane sulfonic acid (PFBS) and its precursor perfluorobutane sulfonamide (FBSA) to the aquatic invertebrate Daphnia magna was assessed under continuous exposure for six consecutive generations, following OECD guideline 211, with adult survival, reproduction, and population growth rate as endpoints. The observed effects were related to both the external (test medium) and internal PFAS concentrations in the daphnids. Over six generations, both PFBS and FBSA showed intensified ecotoxicity, increasing by 1.8 to 3.0, and 3.6 to 6.4 times, respectively. PFBS ecotoxicity increased as a result of elevated compound accumulation over generations, indicating a narcotic mode of action, whereas FBSA exerted specific reproductive toxicity, resulting in a more pronounced worsening of adverse effects over time. Compared to PFBS, FBSA was around 100 times more toxic in F0 (EC50_reproduction of 856 and 7.08 mg L-1 for PFBS and FBSA, respectively), escalating to over 435 times more toxic in F5 (EC50_reproduction of >478 and 1.10 mg L-1 for PFBS and FBSA, respectively), and also showed a higher bioaccumulation potential (BAF of 7.76 and 16.4 L kg-1 for PFBS and FBSA, respectively). These findings highlight that the conventional single-generation ecotoxicity tests underestimate PFAS ecotoxicity during multigeneration exposure, and that the environmental risks of PFAS cannot reliably be assessed by the current limited subset of studied compounds. This research was supported by the Open Technology Programme of the Dutch Research Council (NWO) [grant number 18725]

1.01.T-03 Multigenerational Reproductive Toxicity of Arsenic in Zebrafish (*Danio rerio*)

*Som Niyogi, Mahesh Rachamalla, Francisco Carlos da Silva Junior and **Markus Hecker**, University of Saskatchewan, Canada*

Arsenic causes reproductive toxicity in animal models via endocrine disruption, however, whether the toxicity persists beyond one generation (F0) is largely unknown. Our study was designed to investigate whether the multigenerational reproductive effects of arsenic occur via maternal or paternal lineage and to gain insights into the potential underlying epigenetic mechanisms. Adult zebrafish (F0 generation) were exposed to environmentally relevant doses of arsenic via diet [0 (control), 30 (low), 60 (medium), and 100 (high) g/g dry weight, as arsenite] for 90 days. Following exposure, arsenic-treated females were crossed with control males, and vice versa, to assess the reproductive effects of sex-specific arsenic exposure. Arsenic exposure in females resulted in a dose-dependent decrease in fecundity and fertilization rate. In contrast, arsenic exposure in males induced similar reproductive effects predominantly at the high arsenic exposure dose. Subsequently, F1 generation larvae from different maternal and paternal arsenic treatments were raised to adulthood in clean water and diet, and males and females from the same treatment were then bred to evaluate the reproductive effects of maternal and paternal arsenic exposure. Maternal arsenic exposure decreased fecundity and fertilization success, even at the low dose, whereas the same reproductive effects were recorded only at medium and high doses with paternal arsenic exposure. In addition, the genes involved in the hypothalamus-pituitary gonad liver (HPGL) axis were consistently downregulated in F0 females directly exposed to arsenic as well as in F1 males and females maternally exposed to arsenic, irrespective of dose levels. On the other hand, the HPGL axis genes were downregulated in F0 males exposed directly to medium and high arsenic doses and in F1 generation males and females paternally exposed to the same arsenic doses. Furthermore, we also found that arsenic exposure led to hypermethylation of the promoter region of key HPGL axis genes, specifically steroidogenic factor-1 in the brain and cyp19a1a in the gonads in F0 and F1 males and females. This indicated that the downregulation of critical HPGL axis genes was mediated by arsenic-induced DNA hypermethylation. Overall, our study demonstrated that arsenic exposure causes multigenerational reproductive toxicity in zebrafish by disrupting the HPGL axis via epigenetic alterations, and these effects occur via both maternal and paternal lineages.

1.01.T-04 New Insights Into Cadmium Sub-Lethal Effects on *Daphnia magna*

***Albano Pinto**[1], Ines PE Macario[1], Guilherme Jeremias[1], Sergio Marques[1], Joana Lourenco[1], Ana Rita Guimaraes[1], Sofia Marques[1], Gabriela Moura[1], Jana Asselman[2], Patricia Pereira[1] and Joana Luisa Pereira[1], (1)University of Aveiro, Portugal, (2)Ghent University, Belgium*

The rise in the production and use of electrical and electronic products leads to the increase in usage of cadmium, increasing the risk of exposures to this metal and justifying its inclusion in the list of restricted hazardous substances by the European Union. Despite the plethora of studies available, the full toxicity spectrum and the mechanisms behind cadmium toxicity in aquatic biota still need further clarification. The present study contributes to such clarification, by characterizing the sub-lethal effects of an exposure (7 days) to the EC20 concentration of cadmium (4.527 µg L-1) in the freshwater keystone species Daphnia magna. A holistic approach across multiple levels of biological organization was applied, starting at a molecular level with epigenetic endpoints (total 5-mC DNA methylation and total DNA methyltransferases activity) and transcriptomic analysis (RNA-Seq), then working up to higher levels of biological organization by evaluating phenotypic effects at the sub-cellular and individual level. Exposure to cadmium caused global genome hypomethylation and altered activity of DNA methylation related enzymes. These changes in the epigenome were accompanied by significant gene transcription modulation, with 253 up- and 157 down-regulated genes, some of them in biological processes and pathways that correlate with the responses found for phenotypic endpoints A significant increase of antioxidant enzymes, lipid peroxidation levels and DNA damage was recorded, alongside a reduction on physiological functions and somatic growth in exposed organisms. These findings provide insights into cadmium adverse outcome pathways considering DNA methylation as molecular initiating events. JL was funded by national funds (OE), through FCT, in the scope of the framework contract foreseen in Decree- Law 57/2016 changed by Law 57/2017. PP is funded by National funds (OE) through FCT [CEECIND/01144/2017; DOI: https://doi.org/10.54499/CEECIND/01144/2017/CP1459/CT0009].

1.01.T-05 Beyond Exposure: Investigating the Transgenerational Effects of Bisphenol S in Zebrafish
Marta Ribeiro[1]*, Janan Gawra*[2]*, Susana Barros*[3]*, Antonio Nogueira*[3]*, Marlene Pinheiro*[3]*, Nelson Alves*[1]*, Brigidar Pinho*[4]*, Jorge Oliveira*[4]*, Andrea Estevez*[5]*, Rosario Rodil*[5]*, Jose Quintana*[5]*, Laia Navarro-Martin*[2]*, Miguel M. Santos*[1] *and Teresa Neuparth*[3]*, (1)CIIMAR/FCUP, Portugal, (2)IDAEA-CSIC, Spain, (3)CIIMAR, Portugal, (4)UCIBIO/i4HB, Portugal, (5)IAQBUS, Spain*
Bisphenol S (BPS), a commonly used substitute for Bisphenol A (BPA), has been detected in surface waters at increasing concentrations (from ng/L to low µg/L), primarily due to its widespread industrial applications, especially in the production of polycarbonate plastics and epoxy resins. As current knowledge regarding the toxicity of BPS in non-target organisms is limited, therefore, this study aims to evaluate the ecological risks of BPS in aquatic ecosystems through a transgenerational bioassay with Danio rerio (zebrafish) as a model organism. The first generation (F0) was exposed to environmentally relevant concentrations of BPS (0.4, 2, and 10µg/L direct exposure) and subsequent generations, F1 and F2, were grown in clean water (intergenerational and transgenerational, respectively). We characterized physiological, biochemical and molecular responses to disclose cause-effects relationships and contribute to the understanding of the underlying mechanisms behind the adverse physiological responses. In F0, a significant decrease in the fertilization rate was observed and several biochemical biomarkers (i.e. catalase, glutathione S-transferase and acetylcholinesterase) were altered by the lowest and highest concentrations, in both males and females brains. Parental BPS exposure altered several endpoints in non-directly exposed zebrafish (F1 and F2), by affecting their growth, heart rate, behaviour and other physiological parameters such as Fulton s condition factor, gonadosomatic and hepatosomatic indexes. To better understand the observed effects described so far, we began by performing a transcriptomic analysis (RNA-seq) on F1 embryos at 24 hpf. F1 embryos descendant from parental exposure to 0.4 µg/L of BPS, were the ones that revealed the largest number of altered genes compared to the control group. The majority of those were downregulated and 8 KEGG pathways were affected, such as oxidative phosphorylation, RNA degradation, ribosome, cardiac muscle contraction and PPAR signalling pathway. Results so far suggest that BPS, at environmentally relevant concentrations, was capable of inducing several direct, inter and transgenerational effects in different biological processes in zebrafish. Therefore, with this conceptual approach, we also hope to promote the assessment of the environmental hazards and risks of this compound. This study is supported by the project TRANSEPIC (2022.02922.PTDC, doi: 10.54499/2022.02925.CEECIND/CP1728/CT0004) and the author Marta Ribeiro acknowledges the portuguese Fundação para a Ciência e Tecnologia for her PhD grant (2022.12763.BD)

1.01.P Unveiling Long-Term Ecological Impacts: From Epigenetic Biomarkers to Multigenerational and Chronic Effects of Environmental Contaminants Including Their Mixtures

1.01.P-Tu001 Sub-lethal Effects of Cadmium and Ciprofloxacin in Freshwater Green Microalgae: Epigenetic and Phenotypic Responses
Ines PE Macario[1]*, Tania Vidal*[1]*,* ***Joana Santos***[1]*, Albano Pinto*[1]*, Fatima Brandao*[1]*, Sergio Marques*[1]*, Silja Frankenbach*[1]*, Joana Lourenco*[1]*, Jana Asselman*[2] *and Joana Luisa Pereira*[1]*, (1)University of Aveiro, Portugal, (2) Ghent University, Belgium*
Anthropogenic activities often lead to contamination of waters with harmful substances such as metals, pharmaceuticals and other exogenous chemicals. As epigenetic mechanisms shape gene-environment interactions, the study of the epigenetic alterations in these organisms can provide clues to better understand how they face environmental challenges and how to protect them. Assuming the importance of microalgae as producers in freshwater food chains, we assessed the effects in Parachlorella sp. of exposure (10 days) to sublethal levels of cadmium, a legacy environmental contaminant, and ciprofloxacin, an antibiotic that has been recognised as an emerging contaminant in freshwater (yield EC20 after testing according to the OECD guideline no. 201; 90.3 µg Cd/L and 7.68 mg ciprofloxacin/L). We comparatively followed total DNA methylation and several phenotypic endpoints, namely DNA damage (comet assay), physiological (growth, efficiency of photosystem II and oxygen production were assessed) and biochemical biomarkers (oxidative stress and damage). Cadmium tended to induce hypomethylation and ciprofloxacin hypermethylation of the microalgae genome. Both chemicals induced a slight decrease in biomass yield but there were no effects or slight stimulation in photosystem II efficiency and oxygen

production. Both chemicals caused mild oxidative stress and genotoxicity. Whole transcriptome analysis (RNAseq) and assessment of DNA methylation at the cytosine level (EM-seq) are ongoing, which should provide evidence on the mechanistic behind the phenotypic effects noticed and changes promoted by cadmium and ciprofloxacin in DNA methylation patterns. The molecular basis for adverse outcome pathways of toxicity caused by stressors such cadmium and ciprofloxacin in microalgae will certainly be better characterized, allowing a feasible selection of appropriate biomarkers for improved ecological risk assessment and the consequent protection of microalgae. This work was developed under the scope of project EPIBOOST, funded by the EU - Grant 101078991. AP is funded by FCT - 2022.10817.BD. JL was funded by national funds (OE), through FCT - framework contract foreseen in Decree-Law 57/2016, changed by Law 57/2017. 1.01.P-Tu002 Impact of Endocrine Disrupting Chemicals on Reproduction and Intergenerational Inheritance of Epigenetic Traces in the Freshwater Snail *Biomphalaria glabrata*

Elisabeth Simboeck[1]*, Katharina Wiessner*[1]*, Anna Pavlicek*[2]*, Linda Prahauser*[1]*, Lia Hergolitsch*[1] *and Vanessa Pap*[1]*, (1)UAS Technikum Wien, Austria, (2)University of Natural Resources and Life Sciences, Austria*

Endocrine disrupting chemicals (EDCs) are found ubiquitously in the environment, as anthropogenic deposition has increased immensely in recent decades. They mimic or inhibit endogenous hormones and negatively impact the health of an organism through various modes of action. For example, EDCs have been shown to affect epigenetic mechanisms, which cause phenotype changes and inheritance of traits not associated with DNA sequence alteration. In this study, we investigated the effects of acute and chronic as well as direct and indirect endocrine disruption on the reproduction of the pulmonate freshwater snail Biomphalaria glabrata in two consecutive generations. A putative impact of estrogenic disruption in molluscs is of particular interest as this phylum has developed a distinct sexual hormone system. Nevertheless, it belongs to one of the largest classes within the animal kingdom being exposed to estrogenic substances. Biomphalaria glabrata individuals of the F0 generation were exposed to different concentrations of the endocrine active substance 17?-estradiol and changes on reproduction were determined. Transcriptome analysis revealed distinct sets of differentially expressed genes in ovotestes (gonads) after a short (24 hours) and a long (28 days) exposure, while global DNA methylation was not significantly changed in this tissue. Next, long-term effects of endocrine disruption and putative intergenerational inheritance of epigenetic changes were determined. The offspring (F1) of the exposed F0 individuals were either raised without or with continuous exposure to 17?-estradiol. Development and reproductive fitness as well as global DNA methylation of both cohorts were determined and revealed a significant negative effect of both, a direct and indirect 17?-estradiol exposure, on the F1 generation. In summary, our data suggest that the freshwater snail Biomphalaria glabrata is sensitive to estrogenic disrupting chemicals and that intergenerational adverse effects could be explained by a changed DNA methylome.

1.01.P-Tu003 Multigeneration Responses of *Folsomia candida* to Short Chain Per- and Polyfluorinated Substances (PFAS)

Ge Xie[1]*, Michiel Kraak*[2]*, J. Arie Vonk*[2]*, Thimo Groffen*[3] *and Cornelis A.M. van Gestel*[1]*, (1)Vrije Universiteit Amsterdam, Netherlands, (2)Universiteit van Amsterdam, Netherlands, (3)Universiteit Antwerpen, Belgium*

Due to the high persistence of per- and polyfluorinated substances (PFAS), organisms living in contaminated environments are chronically exposed to these chemicals over multiple generations. Yet, such chronic effects have barely been addressed in ecotoxicity experiments. Moreover, existing data on PFAS ecotoxicity is strongly biased towards the aquatic environment and to long-chain compounds, although short-chain PFAS have been widely used as substitutes for long-chain PFAS, resulting in high emissions into the environment. Therefore, this study aimed to assess the ecotoxicity of the short-chain PFAS perfluorobutane sulfonic acid (PFBS) and its precursor perfluorobutane sulfonamide (FBSA) to the soil invertebrate Folsomia candida (Collembola) over five consecutive generations, with adult survival, reproduction and population growth rate as endpoints. The tests followed OECD guideline 232, with slight modifications. In the multigeneration tests, PFBS did not significantly affect adult survival and population growth rate at the highest test concentration (1160 mg kg-1 dry soil), but had a mild effect on reproduction, with EC50 values for reproduction of 700, 866 and 710 mg kg-1 dry soil for the F0, F2, and F4 generation, respectively. FBSA was substantially more toxic than PFBS. Full concentration-effect relationships were obtained for all test endpoints for the F0 generations exposed to FBSA, with an LC50 of 10.3 mg kg-1 dry soil, an EC50 of 1.43 mg kg-1 dry soil for reproduction and an EC50 of 1.89 mg kg-1 dry soil for population growth rate. Since F. candida exposed to 9.64 and 92.7 mg kg-1 dry soil FBSA went extinct in the F0, springtails in the following generations were exposed to FBSA concentrations up to 1.06 mg kg-1 dry soil. An EC50 of 1.10 mg kg-1 dry soil was obtained for reproduction in the F1 generation, but no significant adverse effect was observed on any endpoint in any other generation. It was speculated that F. candida could biotransform the FBSA into PFBS, but a potential biotransformation capacity threshold lies between 1.06 and 9.64 mg kg-1 dry soil. It is concluded that PFBS is not very toxic to F. candida, but FBSA is more than 100 times more toxic, with concentration-response relationships turning into an all-or-nothing effect at a specific threshold. The comparatively high ecotoxicity of the barely tested precursor FBSA challenges the environmental risk assessment of PFAS, which is currently based on a limited number of compounds. This research was supported by the Open Technology Programme of the Dutch Research Council (NWO) [grant number 18725]

1.01.P-Tu004 Neurobehavioral Impairments in the Sea Bass (*Dicentrarchus labrax*) Chronically Exposed to Cadmium and Ciprofloxacin Contaminated Diets

*Juliette Bedrossiantz[1], **Janan Gawra**[1], Nerea Sanchis[2], Paula Medina[2], Demetrio Raldua[1], Joana Luisa Pereira[3], Mercedes Blazquez[2] and Laia Navarro-Martin[1], (1)Institute of Environmental Assessment and Water Research, Spain, (2)Institute of Marine Sciences (ICM-CSIC), Spain, (3) University of Aveiro, Portugal*

Environmental contamination by heavy metals and pharmaceuticals poses significant risks to marine ecosystems, as they can alter the behavior and survival of aquatic organisms. Cadmium (Cd) is a heavy metal recognized for its high neurotoxicity even at low concentrations such as those found in natural ecosystems. Ciprofloxacin (CIP) is a fluoroquinolone antibiotic that is increasingly detected in aquatic environments and could alter microbial communities, affecting the gut health of fish and interfering with neuronal functions through the microbiota-gut-brain axis. This study focuses on understanding the sublethal effects of these two environmental contaminants in the juvenile model of European sea bass Dicentrarchus labrax after 21 days of dietary exposure. For each compound, two concentrations belonging to the environmental ranges (Cd: 10 mg/kg and 100 mg/kg; CIP: 1 mg/kg and 10 mg/kg) were chosen. After exposure, we evaluated D. labrax behavior with a battery of behavioral tests including the social preference test (SPT), the shoaling test (ST), the light-dark test (LDT) and the group exploratory test (ET). Exposure to Cd and CIP caused significant dose-dependent behavioral alterations. In the SPT, fish exposed to higher concentrations showed less social interaction, with a reduction in the distance travelled in the conspecific compartment. In the ST, a tendency towards cohesion was observed, significant in animals exposed to the highest concentration of Cd. In the LDT, we found a pattern of anxiogenic response concomitant with depression as indicated by the prolonged time in the illuminated zone. The time in the illuminated zone increased significantly when this test was repeated as a group in the ET. Finally, we found in all cases a significant decrease in basal locomotor activity and an increase in freezing episodes.

Reduced swimming activity, changes in social behavior and alterations in exploratory and decision-making behaviors indicate that dietary exposure to Cd and CIP, even at environmentally relevant concentrations, could affect the survival and ecological fitness of the species. These results underscore the need to add sublethal endpoints in toxicological monitoring studies to preserve marine environments. Further analysis will evaluate transcriptomic and epigenetic responses and link effects at the molecular level to behavioural impairment caused by exposures to Cd and CIP.

1.01.P-Tu005 Effects of Cadmium in *Acartia tonsa*: Epigenetic and phenotypic responses

*Ana Beatriz Rodrigues[1], Ilias Semmouri[2], Albano Pinto[1], Ines PE Macario[1], Sergio Marques[1], Joana Lourenco[1], Ines Domingues[1], **Joana Luisa Pereira**[1] and Jana Asselman[2], (1)University of Aveiro, Portugal, (2)University of Ghent, Belgium*

Increasing anthropogenic activities are significantly impacting aquatic ecosystems, leading to contamination and potential deleterious effects in organisms. Cadmium, a trace metal with no essential biological role known, is particularly harmful due to its high toxicity, persistence, and bioaccumulation potential. Herein, we assessed the potential link between DNA methylation and different phenotypic endpoints as a response to short-term (48 h) cadmium exposure (238.8 µg/L, corresponding to the pre-estimated immobilization EC20) of the marine copepod Acartia tonsa, a zooplanktonic marine species with important ecological role and established as a model organism in ecotoxicology. Epigenetic changes were assessed through quantification of global 5-mC DNA methylation. Biomarkers of oxidative stress and damage were assessed by measuring glutathione S-transferases (GSTs) activity and the extent of lipid peroxidation, through the TBARS method, while genotoxicity was analyzed by inspecting DNA damage using the comet assay. Additionally, post-exposure swimming behavior of A. tonsa was analyzed by automated video-tracking. Global 5-mC DNA methylation levels slightly decreased among exposed copepods, suggesting a global hypomethylation trend. Phenotypically, this corresponded to a significant

increase in genotoxicity, a significant increase in GST activity accompanied by an increase in oxidative damage. Regarding copepods behavior, including swimming distance and swimming speed, an impairment can be noticed, but only at concentrations higher than the EC20, thus higher than those provoking recognizable effects in the other tested biomarkers. This approach supports a better understanding of cadmium s effects on marine copepods, by following adverse outcomes initiated with epigenetic mechanisms at the molecular, biochemical and individual level. As the present work becomes complete with currently ongoing whole epigenome and whole transcriptome analysis, molecular basis for adverse outcome pathways for toxicity caused by stressors such cadmium in copepods will certainly be characterized, which should clarify further the interconnection of the responses found in the present work.
Project EPIBOOST, funded by the EU through Grant 101078991; CESAM by FCT/MCTES (UIDP/50017/2020 + UIDB/50017/2020 + LA/P/0094/2020); AP by FCT - 2022.10817.BD. JL by national funds (OE), through FCT - framework contract foreseen in Decree- Law 57/2016, changed by Law 57/2017.

1.01.P-Tu006 DNA Methylation and Ocean Acidification: Insights from *Patella caerulea* at the Natural CO2 Vent Systems of Ischia Island

Silvia Giorgia Signorini[1]*, Camilla Della Torre*[1]*, Marco Giulio*[2]*, Marco Munari*[3]*, Fabio Crocetta*[4]*, Lara Nigro*[5]*, Ilaria D'Aniello*[3] *and Alexandra Anh-Thu Weber*[2]*, (1)University of Milan; Stazione Zoologica Anton Dohrn, Italy, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Stazione Idrobiologica Umberto d Ancona, University of Padova, Italy, (4)Stazione Zoologica Anton Dohrn, Italy, (5)University of Milan, Italy*

Ocean acidification (OA) represents one of the major threats to marine biota, especially to calcifying organisms. Within this context, CO2 vent systems, which are naturally acidified sites by volcanic CO2 emitted from the seafloor, represent a perfect window into the future, where it is possible to investigate the effects of OA on marine organisms exposed to this environmental disturbance for their entire life cycle, allowing to take into consideration any potential acclimation and/or adaptation strategies. In particular, there is evidence that epigenetic modifications, such as DNA methylation, might play a fundamental role in organisms adaptation to stress, since they can contribute to physiological plasticity but they could also promote genetic adaptation. In view of this, DNA methylation was investigated in populations of the calcifying species Patella caerulea collected in both winter and summer seasons from the natural pH gradient of the Castello Aragonese vent systems (Ischia Island) (N1: ambient pH = 8.1; N2: intermediate pH = 7.7; N3: very low pH = <7.4) and from the ambient pH site San Pietro (SP: ambient pH = 8.1). Genomic DNA was extracted from foot tissue of 15 individuals per site, and whole genome enzymatic methyl-seq (EMseq) libraries were constructed and sequenced on the Illumina NovaSeq 6000 sequencer. Reads were aligned to the P. caerulea reference genome and methylation at CpG sites was extracted using MethylKit R package. Pair-wise comparisons carried out inside the Castello Aragonese vent systems revealed that few sites were differentially methylated, indicating no difference in DNA methylation among ambient and acidified sites. Furthermore, the analysis related to seasonality (winter vs summer) within site, showed that 184 CpGs were differentially methylated in San Pietro, while inside the vent systems, the number of differentially methylated cytosines drastically reduced to 11 in N1, and to 0 in both the acidified sites N2 and N3. Previous research has highlighted that higher epigenetic plasticity might induce a greater metabolic cost to the organism. Considering that, these results could suggest that limpets living in the acidified sites of the vent may not be able to modulate DNA methylation in response to OA. Alternatively, it could be that further mechanisms are involved, such as differences in gene expression, or other epigenetic mechanisms (histone modifications, chromatin accessibility).

1.01.P-Tu007 Investigating the Effects of Glyphosate Exposure on Survival, Reproduction, and Development in *Drosophila melanogaster*

Tolulope Ajayi *and Caitriona Collins, Technological University of the Shannon Midlands: Midwest (Athlone), Ireland*

The need for global food security has led to a reliance on chemical pesticides and their heavy use has led to severe declines in insect populations over the last 30-years. Biodiversity loss disrupts delicate ecosystems and has far-reaching consequences. Glyphosate, the active compound in widely used herbicides Gallup and Roundup, is effective, but persists in soil and water, posing acute and chronic exposure risks to humans and non-target species. Sublethal concentrations of glyphosate have been shown to have negative effects on insect development and fertility, sublethal doses reduce egg viability, alter spermatogenesis and disrupt embryonic development. This study aims to investigate the molecular mechanisms of glyphosate-based herbicide (GBH) toxicity on insect fertility and development using the fruit fly, Drosophila melanogaster as a model. Wild-Type Oregon-R flies are orally exposed to sublethal concentrations of GBHs. Egg development was assessed by tracking the progress of eggs laid on contaminated medium. Fertility was etermined by crossing exposed virgin flies with control virgin flies and scoring progeny over 15-days. For adults, the LC50 values for GBH Gallup were determined as 6.53mg/mL for female and 6.97mg/mL for male flies. Similarly, the LC50 for GBH Roundup was determined as 5.9mg/mL for female and 5.65mg/mL for male flies. Exposure of laid eggs to sublethal doses (0.01-5mg/mL) of Gallup and Roundup led to dose dependent declines in egg and larval survival. With 5mg/mL concentrations leading to 100% and 61% lethality respectively and 1mg/mL concentrations leading to 75% and 35% lethality respectively. Furthermore, exposure to sublethal doses of GBHs during development produced adults with impaired fertility. Females exposed to 1mg/mL Gallup or Roundup during development have 34 and 40% declines in their fertility rates. Similarly exposed males have 75 and 57% reductions in their fertility rates. Sublethal doses of GBHs have significant effects on Drosophila development and fertility. The formulation Gallup has a higher toxicity than that of Roundup and there are sex-specific differences in response rates to GBH exposure. Ongoing experiments aim to identify the molecular mechanisms of this reproductive toxicity. This study improves our understanding of glyphosate-induced reproductive effects and the potential effects of sublethal doses of these pesticides on insects. This Project is Currently Funded by the TUS Presidential Doctoral Scholarship.

1.01.P-Tu008 Terrestrial Ecotoxicity Evaluation of Rock Powders Used in Agriculture in Brazil: Preliminary Results with *Enchytraeus crypticus* and *Folsomia candida*

Cristina Sisinno[1]*, Julia Niemeyer*[2]*, Fabrielle Paixao*[2]*, Andressa Buch*[3]*, Andrea Rizzo*[1] *and Claudia Cunha*[1]*, (1)Center for Mineral Technology, Brazil, (2)Santa Catarina Federal University, Brazil, (3)Fluminense Federal University, Brazil*

In alignment with the principles of the Circular Economy, there is a growing expectation that waste generated in the mineral sector will not only be properly managed but also be repurposed into new production cycles. However, many materials from this sector contain naturally occurring chemicals from rocks that may pose potential toxicity. Rock powders, derived from rock extraction activities, are approved for agriculture application in Brazil as fertilizers or secondary materials. Despite this, ecotoxicological tests are not mandate under Brazilian legislation, and studies on their ecotoxicity remain limited. This lack of information is particularly concerning due to the potential long-term effects and impacts throughout the food chain. This study aims to conduct preliminary ecotoxicological tests of rock powders deemed for agriculture use, employing terrestrial organisms Enchytraeus crypticus and Folsomia candida, in accordance with ABNT standards NBR ISO 16387:2012 Soil quality Effects of pollutants on Enchytraeidae (Enchytraeus sp.) Determination of effects on reproduction and survival, and ABNT NBR ISO 11267:2019 Soil quality Inhibition of reproduction of Collembola (Folsomia candida) by soil pollutants. The materials were ground and sieved to ensure that at least 50% of particles were less than 0.3 mm in size. The major oxide composition included SiO_2, Al_2O_3, and Fe_2O_3. Tests were conducted by mixing the rock powder samples with Tropical Artificial Soil (TAS) at the concentrations of 0%, 0.1%,1.0%, 10%, and 100%. Preliminary testing of three samples (SC, MG, and GE) sourced from different mining operations in Brazil (Santa Catarina, Minas Gerais and Rio de Janeiro) revealed no chronic toxicity for E. crypticus in any samples. However, at concentration of 100%, samples MG and GE exhibited significant chronic toxicity for F. candida ($p<0.05$), with a reduction in reproduction (ANOVA followed by Dunnett s test). Complementary chemical analyses and other ecotoxicological tests need to be performed. These screening and preliminary findings highlight the importance of appropriate application rates for rock powders and integrating biological indicators into the registration process for all agricultural fertilizers and inputs in Brazil. Such measures are vital to prevent potential adverse effects on biotic communities in agricultural ecosystems while ensuring that sustainability and safety principles are upheld in the reuse of these materials. Center for Mineral Technology (CETEM/MCTI); National Council for Scientific and Technological Development (CNPq) for PCI-DA Scholarship from the Ministry of Science, Technology and Innovation (MCTI) of Brazil.

1.01.P-Tu009 Linking Molecular and Phenotypic Endpoints in Zebrafish Larvae Exposed to Ciprofloxacin and Cadmium

Janan Gawra[1]*, enia Correia*[2]*, Bruna Vieira*[2]*, Joana Luisa Pereira*[2]*, Ines Domingues*[2] *and Laia Navarro-Martin*[1]*, (1)Institute of Environmental Assessment and Water Research, Spain, (2)Centre for Environmental and Marine Studies & University of Aveiro, Portugal*

The EPIBOOST project aims at validating the epigenetic modifications caused by chemicals as biomarkers of relevance which can support more accurate environmental risk analysis. For this, a multiparametric approach is pursued by looking at the effects of chemicals from the individual and biochemical levels to the genetic and epigenetic levels, establishing a link between phenotypic and molecular endpoints. In this work, taking ciprofloxacin (CIP) and cadmium (Cd) as a case study, 96 hours zebrafish larvae were exposed to sublethal concentrations of the CIP (ranging from 10 to 50 mg/L) and Cd

(0.24 to 24 ?g/L) for 24 hours. Endpoints analysed included mortality, development, swimming behaviour (swimming distance and path angles), biotransformation enzymes (glutathione-s-transferase (GST)), antioxidant enzymes (catalase (CAT), and glutathione reductase (GR)), neurotoxicity markers (acetylcholinesterase (ChE)), transcriptomics and DNA methylation. For Both chemicals, at concentrations tested no effects on survival or development (delays or anomalies) were observed. CIP induced an activation of the antioxidant system which seemed to have occurred as suggested by the increase in the CAT activity. In contrast to Cd which decreased the CAT activity. In the same direction, an increase in ChE activity was also observed in eleutheroembryos exposed to CIP, while Cd induced a reduction in the ChE activity suggesting neurotoxicity elicited by the tested Cd concentration. The study of swimming behaviour indicated an alteration of the swimming pattern, where zigzag movements and high-speed movements increased suggesting an anxiety-like behaviour of larvae exposed to the antibiotic. Molecular analyses are underway to further elucidate transcriptomic changes and DNA methylation profiles associated with these phenotypic and biochemical alterations.

1.01.P-Tu010 Effects of Bisphenol S (BPS) in the Threespine Stickleback (*Gasterosteus aculeatus*): Exploring the Links Between Biomarker and Life History Traits Responses

*Blanche Goddyn[1], Anne Bado-Nilles[1], **Ugo Iaria**[1], Cleo Bodin[2], Cyril Turies[1] and Remy Beaudouin[1], (1)UMR-I 02 SEBIO, INERIS, URCA, ULHN, France, (2)INERIS, Experimental Toxicology and Modeling Unit, France*

Chemical pollutants in aquatic environments disrupt biomarkers, affecting growth, reproduction, and survival. Bisphenol S (BPS), a substitute for bisphenol A (BPA), has been linked to reproductive impairments, metabolic disruptions, oxidative stress, and immune dysfunction in fish. This study investigates BPS effects on biomarkers and life-history traits in three-spined stickleback (Gasterosteus aculeatus) to establish mechanistic links across biological scales. Three experiments were conducted: (1) a 6-month mesocosm study exposing fish to BPS (0, 1, 10, 54 ?g/L) in artificial streams, assessing biomarkers like immune parameters, respiratory burst, and organ mass; (2) a 21-day caging study in mesocosms examining reproductive and oxidative stress biomarkers; and (3) a 40-day laboratory study (BPS: 0, 1, 10, 100 ?g/L) assessing biomarkers and linking them to life-history traits such as stickleback nest construction in males and oocyte maturation in females. The mesocosm experiment revealed altered respiratory burst, reduced immune cell counts, and impaired phagocytic function in both sexes, suggesting immunosuppression, with females also exhibiting cells necrosis. In the 21-day study, both sexes showed signs of altered antioxidants, with females showing effects at low doses (1 ?g/L). Laboratory experiments revealed significant effects on reproduction, metabolism, and links between biomarkers and life history traits. Dose-dependent effects included reduced gonado-somatic index (GSI) and sperm count in males, alongside increased nephrotic-somatic index (NSI) and variability in nest characteristics (weight, surface area). In females, hepatosomatic index (HSI) increased significantly, while mature oocyte count and GSI increased at higher doses. The study revealed effects of BPS on reproduction, metabolism, oxidative stress, respiratory burst and phagocytic activity, and allow to etablish link biomarkers to life-history traits. This approach aims to model population-level impacts and extrapolate findings to other pollutants, enhancing environmental risk assessment. This project has also received funding from the European Union s Horizon Europe research and innovation programme under Grant Agreement No 101057014 (The European Partnership for the Assessment of Risks from Chemicals; PARC).

1.01.P-Tu011 Embryonic Exposure to the Endocrine Disrupting Chemical, TBCO, Causes an Intrageneration Decrease in Reproductive Performance of Female Japanese medaka (*Oryzias latipes*) by Impairing Oocyte Maturation

*Sodiq Aremu Olawoore and **Steve Wiseman**, University of Lethbridge, Canada*

Vitellogenesis and oocyte maturation are the final two steps of oogenesis in fish. Most studies of reproductive toxicity focus on the disruption of vitellogenesis leading to decreased fecundity, with very little focus on oocyte maturation, the final stage of oogenesis that gives rise to a fertilizable oocyte. Previous studies from our group demonstrated that reduced fecundity of Japanese medaka exposed as embryos to maternally transferred TBCO, a brominated flame retardant, was caused by impairment of maturation-inducing hormone (MIH)–induced oocyte maturation. However, the molecular mechanism(s) of this effect are unknown. The objective of this research is to investigate the molecular basis of decreased oocyte maturation leading to reduced fecundity in Japanese medaka exposed as embryos to maternally deposited TBCO. F0 generation fish were fed a 100 or 1000 ugTBCO/g diet for 21 days. F1 generation embryos collected during the final week of the exposure were reared to sexual maturity in clean water without any additional exposure to TBCO. At sexual maturity, reproductive performance was assessed in a standard 21-day reproduction assay, after which an ex-vivo oocyte maturation assay was performed. To elucidate mechanisms of decreased oocyte maturation, high-throughput RNA sequencing and enzyme-mediated methyl sequencing were used to compare the transcriptome and methylome of the oocytes that failed to mature and those that matured from control and TBCO-exposed female fish. Exposure to a maternally transferred TBCO caused a concentration-dependent decrease in fecundity and oocyte maturation. In progeny of fish given the 1000 ugTBCO/g diet, the decrease in fecundity was 31.4% and the decrease in oocyte maturation was 22.3%. Transcriptomics analysis showed that genes responsible for regulating mitochondrial energy generation and non-genomic signal transduction were altered in oocytes that failed to mature. Enzyme-methylated sequencing is being used to determine if changes in DNA methylation might alter the gene expression that regulates oocyte maturation. This research will advance the understanding of how early life-stage exposure to environmental chemicals can impact the reproductive performance of fish. This research was supported by a Tier II Canada Research Chair in Aquatic and Mechanistic Toxicology, and a Discovery Grant from the Natural Science and Engineering Research Council (NSERC) of Canada, to Steve Wiseman.

1.01.P-Tu012 Two-Generation Toxicity Assessment of the Antioxidant Propyl-Propane Thiosulfonate (PTSO)

Antonio Cascajosa-Lira[1], Remedios Guzman-Guillen[1], Silvia Pichardo[1], ***Cristina Plata-Calzado[1]****, Alberto Baños[2], Jose M. de la Torre[2], Nahum Ayala-Soldado[3], Rosario Moyano-Salvago[3], Isabel Ortiz-Jaraba[3], Ana Camean[1] and Angeles Jos[1], (1)Universidad de Sevilla, Spain, (2)DMC Research Center, Spain, (3)Universidad de Cordoba, Spain*

Propyl-propane thiosulfonate (PTSO), an antioxidant organosulfur compound found in the Allium genus, shows promise as a natural additive for food and feed, as well as a biopesticide for plant pest control. To ensure its safety for livestock, consumers, and the environment, a comprehensive toxicological assessment is essential. This study aimed to evaluate the potential reproductive toxicity of PTSO in mice, following OECD guideline 416 as part of a broader risk assessment. Spanning two generations, the study assessed possible reproductive, teratogenic, and genetic impacts. A total of 80 CD1 mice per sex per generation were exposed to PTSO through feed at three dose levels (14, 28, and 55 mg PTSO/kg body weight/day) across premating, gestation, and lactation phases. The study observed no clinical changes or mortality linked to PTSO exposure. While some variations in body weight and food intake occurred, they were neither dose-dependent nor sex-specific. Both parental generations (F0 and F1) exhibited normal reproductive outcomes, and offspring (F1 and F2) were born without abnormalities. Sexual hormone levels (progesterone, testosterone, estradiol, follicle-stimulating hormone, and luteinizing hormone) remained within normal ranges. Although sperm analysis showed significant changes in the F0 group, no such variations were observed in F1, and no fertility impairments were noted. Additionally, organ weights (absolute and relative) and detailed histopathological examinations revealed no significant differences across both genders and generations. In conclusion, under the tested conditions, PTSO does not exhibit reproductive or developmental toxicity in mice, supporting its favorable safety profile for potential use in the agrifood industry. This research was funded by Junta de Andalucía (Project P18-TP-2147), and by the Spanish Ministerio de Universidades through the FPU grant (FPU2019-01247) awarded to Antonio Cascajosa Lira.

1.02.P The Chemical Defensome: Novel Insights into the Mechanisms of Defense Allowing Species to Cope with Environmental Pollution

1.02.P-Tu013 Evolution of the Chemical Defensome in Marine Mammals

Anders Goksoyr[1]*, Bram Danneels[1], Diogo Oliveira[2], Raquel Ruivo[2], Filipe Castro[2], Sofie Soderstrom[1], Fekadu Yadetie[1] and Odd Andre Karlsen[1], (1)University of Bergen, Norway, (2) University of Porto, Portugal*

Many marine mammals such as whales, seals, and polar bears, are top-predators, feeding high in the food chain, resulting in a high intake of persistent, bioaccumulating pollutants with the potential to cause harm to the organism. The chemical defensome comprises an integrated network of gene families and pathways that together function to sense, metabolize and eliminate harmful compounds. Although highly conserved, notable evolutionary adaptations are observed through mammalian evolution, most notably in cetaceans. The absence of functional nuclear receptors PXR and CAR in cetaceans, and their presence in polar bears, pinnipeds and sirenia, make the case for an interesting comparison of how these different marine mammal species sense and respond to environmental toxicants targeting these receptors. Our main hypothesis is that the genomes of marine mammals can be decoded into a functional understanding of the responses and susceptibility to toxicants of these animals. Publicly available genomes (NCBI/Ensembl) were used for genome mining, targeting the genes representing the chemical defensome of 40 selected marine mammal species and 28 close relatives. A specific focus is on defensome gene complements, functional gene networks, phylogenetic relationships, gene gain/loss and implications for evolutionary adaptations. The functional defensome gene inventory was then compared between marine mammal lineages and their close relatives. Our analysis revealed large scale loss of defensome genes in cetaceans compared to closely related species. A total of 101 defensome genes were estimated to be lost compared to the reference gene sets. Gene losses are found across the whole spectrum of defensome genes, ranging from transcription factors (NR1I2 and NR1I3), oxygenases (CYP2 family) and reductases (NQO1), to transferases (UGT, GST) and transporters (ABC, OATP/SLCO). Marine mammals that have not lost PXR and CAR (pinnipeds and sirenia), do not show these wide-spread defensome losses. However, both lineages show losses in oxygenases (CYP2 family and FMO) and transferases (GST, SULT). Overall, our results suggest a significant remodelling of the chemical defensome in cetacea. Sporadic gene loss events were also observed in pinnipeds and sirenia. The obtained dataset will serve as a genomic framework to comparatively address the convergent and divergent susceptibilities towards chemical pollution across marine mammals. The authors thank the Research Council of Norway for funding the Marma-detox project (Whales and polar bear in a petri dish: decoding marine mammal toxicology through in vitro and in silico approaches, RCN project #334739).

1.02.P-Tu014 Exploring the Role of the Defensome in Endocrine Disruption: Interspecies Differences in Sensitivity to Thyroid System Interference

Daniel Bruce Pickford*, Lyubomira Tankisheva and Tara Miller, (2)Syngenta, United Kingdom*

Thyroid homeostasis can be affected by increased hepatic clearance of circulating thyroid hormones, in response to upregulation of phase I and II metabolising enzymes. Induction of these enzymes is often mediated by xeno-sensor receptors e.g. CAR/PXR, but there appears to be variation among taxa in the presence, role and specificity of these receptors. In the context of EU regulations, forbidding registration of pesticidal active substances with endocrine disrupting (ED) properties, the status of this mode of action for thyroid disruption is ambiguous. The criteria for identifying EDs state that adverse effects that are non-specific secondary consequences of other toxic effects shall not be considered ... We interrogated the database of substances subject to Tier 1 determinations under the US EPA Endocrine Disruptor Screening Programme (EDSP), for evidence that liver-mediated effects on the thyroid system in human health models correlate with thyroid activity in the amphibian metamorphosis assay (AMA). We categorised AMA endpoints, and effect patterns indicative of thyroid activity were established based on responses to known thyroid disrupters in the OECD validation of the AMA test guideline. These responses were then compared to thyroid responses in male and female pubertal assays, and responses of in vitro assays for CAR/PXR activation conducted under the US EPA ToxCast program. Among the 39 substances assessed, it was concluded that 13 affected the thyroid axis: 2 affected amphibians only, while 9 only affected mammals. Another 2 affected amphibians and mammals, though it should be noted that one of those did not exhibit a clearly thyroidal response pattern in the AMA. Among the 9 affecting thyroid parameters in mammals only, 6 did so indirectly, secondary to induction of liver enzymes. None of those substances were negative in ToxCast screens for CAR/PXR activation. None of those 6 substances elicited thyroid effects in the AMA. These data indicate that the AMA model is rather insensitive to perturbations of the thyroid axis consequent to CAR/PXR-mediated liver enzyme induction. This suggests that, in relation to thyroid disruption, read-across from amphibians to mammals will be less protective than the converse, if liver-mediated thyroid insufficiency should be regarded as a specific effect. This assumes greater importance given current interest in developing new approach methodologies to support ED identification while reducing animal use.

1.02.P-Tu015 Biochemical Responses of *Danio rerio* and *Daphnia magna* to pharmaceuticals Isoeugenol and Altrenogest

Madalena Vieira*, Diana Isabel Oliveira Carneiro, Susana Loureiro and Maria D Pavlaki, Centre for Environmental and Marine Studies & University of Aveiro, Portugal*

Industrial discharges, intensive agriculture, and improper waste disposal contribute to the presence of harmful chemicals, including pharmaceuticals, in aquatic environments. These substances, originally designed for specific purposes, can interfere with physiological and biochemical processes in non-target organisms. This study investigates the effects of two pharmaceuticals identified as priority substances by the European Medicines Agency, Isoeugenol (ISO) and Altrenogest (ALT), on the aquatic species Danio rerio and Daphnia magna, by assessing alterations in enzymatic biomarkers. Enzymatic biomarkers are early indicators of physiological stress and biochemical disturbances in organisms exposed to pollutants.

ISO, a natural organic compound known for its anti-infective properties, and ALT, a synthetic progestin used in veterinary medicine, represent two pharmaceuticals with differing mechanisms of action, enabling a comparative analysis of their ecotoxicological impacts. The concentration range for the tests was based on previous acute toxicity data, from which LC50 values were derived for both species. For D. rerio, concentrations of 0.09 to 1 mg/L were used for ALT, and 0.37 to 7 mg/L for ISO, with a 120-hour exposure period. For D. magna, the concentration ranges were 0.04 to 0.27 mg/L for ALT and 0.14 to 2.62 mg/L for ISO, with a 21-day exposure period. A battery of biomarkers was selected for a comprehensive assessment of the ecotoxicological effects. From the antioxidant defence mechanism, Catalase (CAT), Glutathione Peroxidase (GPx), and Glutathione Reductase (GR) were chosen to evaluate the organism s ability to combat oxidative stress. Additionally, Glutathione S-Transferase (GST), a key enzyme in phase II biotransformation, was selected to assess detoxification processes. Lipid Peroxidation (LPO) was measured to evaluate oxidative damage to cellular membranes. Exposure to ISO and ALT caused significant oxidative stress in the tested organisms, as indicated by alterations in the activities of CAT, GPx, GR and GST. The changes in these key antioxidant and detoxification enzymes suggest a weakened ability to neutralize free radicals and process toxins, compromising cellular defences. Increased LPO further suggests damage to cell membranes, highlighting the potential of both compounds to cause cellular damage and disrupt biological functions, particularly in antioxidant systems and cellular integrity.

1.02.P-Tu016 Defense Mechanisms of Sulforaphane Against Environmental Toxins and Contaminants: A Systematic Review

*Antonio Cascajosa-Lira, Ana I. Prieto, Silvia Pichardo, **Cristina Plata-Calzado**, Angeles Jos and Ana Camean, Area of Toxicology, Faculty of Pharmacy, Universidad de Sevilla, Spain*

Sulforaphane (SFN) is a biologically active isothiocyanate found in cruciferous vegetables, particularly those from the Brassica genus, and is derived from the precursor compound glucoraphanin. Known for its numerous health benefits, SFN acts primarily as an inducer of nuclear factor erythroid 2-related factor 2 (Nrf2), a key regulator of antioxidant response. As a result, SFN has demonstrated a variety of protective effects, including anticancer properties and the ability to shield against toxic agents. This systematic review aimed to examine and synthesize the existing evidence on SFN s protective role, particularly in relation to toxic substances and contaminants, and to explore the underlying mechanisms through which it exerts these effects in various organs and systems. The review found that SFN s protective activities are most pronounced in the liver and nervous system, both of which are highly susceptible to damage from oxidative stress, a hallmark of many liver and neurodegenerative diseases. However, its protective effects are not limited to these organs; SFN has also been shown to benefit other systems, such as the lungs, heart, kidneys, immune system, and endocrine system. The mechanism by which SFN exerts these effects involves the activation of the Nrf2 pathway, which enhances the body's antioxidant defenses, reduces oxidative stress, and modulates the expression of protective genes. Additionally, SFN has been shown to reduce inflammation by decreasing the production of pro-inflammatory cytokines like interleukins and to inhibit apoptosis by preventing caspase-3 activation while increasing the levels of anti-apoptotic proteins like Bcl-2. These multifaceted mechanisms suggest that SFN can effectively counteract the detrimental effects of various toxic agents. Despite its promising potential as a chemoprotective agent, further studies are needed to establish safe and effective dosages for human use and to better understand its long-term effects in clinical settings. This research was funded by Junta de Andalucía (Project P18-TP-2147), and by the Spanish Ministerio de Universidades through the FPU grant (FPU2019-01247) awarded to Antonio Cascajosa Lira.

1.02.P-Tu017 Polymorphisms of the Metallothionein 2A Gene in Relation to Heavy Metal Levels in a Colombian Population

***Belkis Palacio**, Maria Cecilia Garcia, Leonor Cervantes and Barbara Julia Arroyo, Universidad de Cartagena, Colombia*

Genetic variations can be considered as internal factors contributing to the susceptibility of individuals to heavy metal-related toxicities. Metallothioneins are highly conserved, cysteine-rich, low molecular weight metal-binding proteins with multiple cellular functions. Metallothioneins are involved in metal homeostasis and transport and have antioxidant and anti-inflammatory properties. Their synthesis can be induced by essential elements such as Zn and Cu, heavy metals, chemical agents and stress-producing conditions. MTs suppress heavy metal toxicity by binding to these metals. 24 SNPs have been identified in the MT2A gene and three of them have been shown to be associated with metal concentrations in the body of healthy and diseased individuals. This study aimed to investigate the association of single nucleotide polymorphisms rs28366003, rs1610216 and rs10636 of the Metallothionein 2A (MT2A) gene and arsenic, cadmium, mercury and lead levels in blood samples from 95 Colombian adult subjects. 95 healthy subjects from the department of Bolivar were enrolled. Whole blood samples were taken to quantify the levels of four elements (arsenic, cadmium, mercury and lead) by ICP-MS. TaqMan® probes were used for polymorphism analysis in real-time PCR systems. Single nucleotide polymorphisms (SNPs) were genotyped in blood samples using TaqMan allelic discrimination assays. The genotype distribution of MT2A rs28366003, rs1610216 and rs10636 conforms to Hardy-Weinberg equilibrium. Statistically significant associations were detected between metallothionein 2A (MT2A) SNPs and metal and metalloid levels in the study population. These results suggest that MT2A rs28366003, rs1610216 and rs10636 polymorphisms increased the risk for adverse health effects from heavy metal exposure in the Colombian population.

1.02.P-Tu018 Effects of Oxyfluorfen on Biochemical Activities in Non-Target Aquatic Invertebrate Organisms

*Gulsum Batmaz Erismis[1], **Pinar Arslan Yuce**[1] and Aysel Caglan Gunal[2], (1) Çankırı Karatekin University, Turkiye, (2)Gazi University, Turkiye*

Herbicides are chemical substances used to control weeds in agricultural fields. Oxyfluorfen (OXY) is herbicide used in agricultural processes of crops such as soybeans, rice fields, and peanuts. Freshwater pollution from agricultural activities causes various effects on aquatic organisms. The present study evaluated the effect of acute exposure of OXY on non-target aquatic invertebrate. For this purpose, freshwater mussels (Unio delicatus) were divided into 7 groups and exposed to OXY at concentrations of 500, 1000, 1500, 2000, and 2500 ?g/L for 96 hours. There were negative and solvent control groups. After weight and shell length measurements (mean weight of 40.1 ± 6.9 g and mean shell length of 66.9 ± 3.5 mm), gill and digestive gland samples were taken from the mussels. Superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione (GSH), and malondialdehyde (MDA) antioxidant parameters were investigated. Although no lethal effects were observed in mussels exposed to OXY, biochemical effects were observed. The antioxidant defense system showed significant activation of SOD and MDA in mussels exposed to OXY ($p<0.05$). On the other hand, there was no significant change in CAT, GPx and GSH levels in OXY exposure. Integrated Biomarker Response (IBRv2) was obtained lower in the digestive gland than in the gill tissue. The increase in SOD and MDA in the gill and digestive gland tissues of mussels exposed to OXY indicates that oxidative stress has begun in the organism and that superoxide radicals and lipid peroxidation are at the forefront. On the other hand, the fact that GPx, CAT and GSH did not show any change may suggest that the antioxidant defense mechanisms of the mussels give a limited or delayed response. Higher IBRv2 in gill tissue indicates that the organism is facing more intense stress in this tissue and that defense mechanisms are more activated. This may be related to direct exposure of the gills to environmental toxicants. Lower IBRv2 in the digestive gland may indicate that this tissue is less exposed to environmental stress or is able to cope more effectively. As a result, it was revealed that OXY herbicide caused oxidative stress in freshwater mussels in all applied dose ranges. The study was funded by Gazi University Scientific Research Unit (Project number: SPD-2024-9697). Gulsum Batmaz Erismis was supported by TUBITAK 2211-A Domestic Doctoral Scholarship Program 2022/1.

1.02.P-Tu019 The Evaluation of the Effect of Sublethal Diflubenzuron on Antioxidant Enzyme Systems in Freshwater Mussels

*Aysenur Okatan[1], Pinar Arslan Yuce[2] and **Aysel Caglan Gunal**[3], (1)Gazi University, Graduate School of Natural and Applied Science, Turkiye, (2) Çankırı Karatekin University, Turkiye, (3)Gazi University, Turkiye*

The use of pesticides in agriculture, domestic and municipal areas is increasing day by day. Diflubenzuron (DFB) is an insecticide used as an insect growth regulator in agricultural applications and is used especially in cotton, apple and pear cultivation. Additionally, in some developed countries it is used on mosquito larvae to prevent diseases spread by mosquitoes. In this way, intensive use harms ecosystems and populations in these ecosystems. These chemicals mixed into aquatic ecosystems cause undesirable effects on aquatic organisms. In the current study, we evaluated the effects of DFB, one of the common insecticides, on antioxidant enzyme systems of freshwater mussels. The freshwater mussels (Unio delicatus) were divided into control and sublethal DFB-exposed (1.24 mg/L and 12.4 mg/L) groups for 48 hours and 7 days. After measuring the weight and shell length of the mussels (mean weight 32.91±1.29 g and mean shell length 4.94±0.11 mm), digestive gland and gill tissues were collected from the mussels and antioxidant enzyme biochemical parameters were examined. Inhibition of superoxide dismutase activity in digestive gland and gill tissues was observed in long-term exposure to sublethal DFB concentrations. On the other hand, an increase in glutathione peroxidase activity was observed in digestive gland tissue during both exposure periods of mussels to DFB concentrations. There was no change in tissue catalase activity in both exposure times and DFB concentrations. The findings suggest that DFB has a toxic effect on mussels, leading to changes in tissue antioxidant enzyme parameters. The study provides information on environmental risks associated with pesticides such as DFB, highlighting the importance of using freshwater mussels as an alternative model organism for toxicity assessments. The study was funded by Gazi University Scientific Research Unit (Project number: FYL-2022-7938).

1.02.P-Tu020 Surviving in the Sediment: Behavioral and Toxicological Effects of Nano-biocides on the Marine Gastropod *Gibbula umbilicalis*

Caio Cesar-Ribeiro[1] *and Roberto Martins*[2]*, (1)University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies & University of Aveiro, Portugal*

Antifouling (AF) biocides, such as DCOIT, and corrosion inhibitors with biocidal activity, such as MBT, are widely used to prevent (micro)biofouling but pose significant risks to non-target marine organisms. Their nanoencapsulation in silica nanocapsules (SiNC), with or without silver impregnation (SiNC-Ag) for dual biocidal effect (SiNC-Ag-DCOIT), has been proposed to control the biocides release over time, reducing their toxicity while maintaining the AF effectiveness. However, the toxicity of such novel nanoadditives toward marine species is still not thoroughly investigated, particularly in benthic species. Therefore, the present study evaluates the acute toxicity (48 h) of DCOIT and MBT, both in their soluble and nanostructured forms, using the marine gastropod Gibbula umbilicalis as a model organism that plays a crucial ecological role in nutrient cycling and sediment stabilization in saltmarshes. Sediment toxicity tests were conducted at concentrations of 1, 10, and 100 mg/kg (n=3, five gastropods per replicate). Avoidance of contaminated sediment and mortality were assessed to determine the No Observed Effect Concentration (NOEC) and Lowest Observed Effect Concentration (LOEC) and to compare the toxic effects of tested chemicals. The results indicated that SiNC alone was non-toxic, with mortality rates of up to 13% at the highest concentration tested (100 mg/kg). DCOIT exhibited high toxicity with a LOEC = 1 mg/kg for both behavioral and mortality endpoints. Encapsulation of DCOIT in SiNC and SiNC-Ag partially reduced toxicity at lower concentrations, but failed to prevent 100% mortality at 100 mg/kg. SiNC-DCOIT and SiNC-Ag-DCOIT caused similar lethal effects, indicating limited effects linked to the silver coating. In contrast, soluble MBT was more toxic than DCOIT, with a mortality of 80% as low as 1 mg/kg (LOEC) and 93 100% at higher concentrations. Encapsulation (SiNC-MBT) failed to mitigate MBT toxicity. These findings highlight that MBT is more toxic than DCOIT to Gibbula umbilicalis. These findings underscore the need for further optimization of the encapsulation strategies. This study advances our understanding of the environmental risks posed by biocides and emphasizes the importance of developing tailored nanoencapsulation approaches for safer and more environmentally sustainable antifouling technologies. This research was funded by the São Paulo Research Foundation (FAPESP), grant number 2024/01138-0. 1.03.P Developing Science-Based Metrics to Quantify Fashion and Apparel's Chemical and Biodiversity Impacts on Nature

1.03.P-Tu021 Textile Case Study for Integrated Chemicals and Waste Management

Alexis Michael Bazzanella[1]*, Anna Isabel Becker*[1] *and Mariella Noto*[2]*, (1)International Sustainable Chemistry Collaborative Centre, Germany, (2)ZDHC Foundation, Netherlands*

This paper presents a case study from the textile sector on economic and industry sector engagement and sectorial actions, adressing climate change, biodiversity loss and pollution. It is put into context of a discussion note entitled Development of Global Framework on Chemicals (GFC) implementation programmes to advance integrated chemicals and waste management: National systems, industry engagement, and sustainable development linkages. The textile sector is as one of the key economic and industry sectors for fostering early engagement and for creating momentum. It has strong impacts on all three dimensions of the triple planetary crisis, making it a prime target for integrated action. ISC3 builds on multi-stakeholder cooperation with textile initiatives and organisations such as the ZDHC Foundation who themselves are working on textile solutions in a multi-stakeholder approach. A key output of the multistakeholder consultation and interactions has been the ZDHC Manufacturing Restricted Substances List (MRSL), a list of chemicals banned from intentional use in the processing of textile materials, leather, rubber, foam, adhesives and trims used in textiles, apparel, and footwear industry. ISC3 in a collaboration with ZDHC aims at strengthening outreach and capacity building, and finally have started working on a concept supporting the transfer of the MSRL to other sectors such as consumer electronics. In relation to promoting innovative solutions of sustainable chemistry in the textile sector, the ISC3 Innovation Hub is supporting start-ups working on innovative sustainable chemistry solutions for the textile sector around the globe. The identified innovative examples have a high potential for transforming distinct steps in the textile value chain. Combining and integrating key innovations developed by different start-ups and large corporates along the textile value chain can and will further enhance the impact of these more sustainable solutions. It is therefore of high importance to facilitate these connections and to build-up business partnerships. As one step towards this goal, ISC3 is currently facilitating a corporate challenge with a frontrunner in sustainable textile and fabrics manufacturing and supply to find start-ups offering innovative low-carbon bio-based and less hazardous alternatives to the traditional textile chemicals.

1.03.P-Tu022 Development of a Rapid Screening Method for Detection of Hazardous Additives in Textiles

Alyssa Wicks[1], *Anthony M Miller*[1], *Ornella Joseph*[1], *Kenneth Brown*[2] *and Graham F. Peaslee*[1], *(1)University of Notre Dame, United States, (2)Hope College, United States*

Flame retardants (FRs), per- and polyfluoroalkyl substances (PFAS), antimicrobials, and dyes are intentionally added to textiles to provide protection from fire, stain/water resistance, odor control, and color. However, these additives pose a number of health concerns, including reproductive health risks, skin irritation, and increased risk of cancer. When these classes of chemicals are added to textiles used in uniforms that must be worn regularly, such as those of first responders, school children, flight attendants, postal workers, military personnel, food service and hospitality workers, they represent a public health or occupational health threat that is largely unstudied in the United States. Traditional analyses for the presence of PFAS, metals, and flame retardants in textiles typically require separate, specific extraction protocols and analysis using multiple instruments. In an effort to save analysis time and resources, the current work has developed a rapid screening methodology to identify hazardous additives in textiles, and applied the methodology to a variety of samples, including firefighter station wear. First, samples underwent the ex-vacuo techniques of particle-induced gamma-ray emission (PIGE) and particle-induced x-ray emission (PIXE) spectroscopy to perform nondestructive elemental analysis. In three minutes per sample, textiles were screened for F, Cl, Br, Cr, Zn, and Cu as a surrogate for the presence of PFAS, flame retardants, toxic dyes, or antimicrobials. Due to the presence of Br or Cl being from a FR or dye, samples shown to contain these elements then underwent a secondary thin layer chromatography screening method to differentiate dyes from FRs. A subset of samples then underwent the following analyses to validate the screening methods: targeted LC-MS/MS analysis for PFAS, GC-MS analysis for FRs, HRMS for brominated/chlorinated dyes, and ICP-OES to confirm presence of metals. Preliminary results confirm a variety of concerning chemicals can be identified rapidly in firefighter station wear and other textiles.

1.03.P-Tu023 Impact of Microfibre Emissions from Textile Industries

Ishrat Badruddin[1], *Paul Kay*[1], *Richard Blackburn*[1], *Ben Parker*[2] *and Joseph Houghton*[1], *(1)University of Leeds, United Kingdom, (2)University of Exeter, United Kingdom*

Dyed cellulosic fibres (natural and regenerated) account for 80% of microfibres found in seafloors, raising concerns over their impacts on the environment. Most research into microfibres concentrates on laundry and identifies it as a major cause of microfibre leakage into the environment; however, this typically ignores microfibre shedding during the various stages of textile manufacturing. Microfibres are typically <5 mm, which increases their potential to enter the food chain where they are consumed and entangle as clots, causing blockages within the gut of aquatic organisms. Fibres in the form that they occur in plants may not be harmful to flora and fauna, but the use of textile auxiliaries, strong alkali, detergents, oxidising agents, dyes, and finishes during textile processing changes the cellulose polymer crystal structure and chemistry, and covalently bonds compounds to the fibres, all of which permanently changes fibre structure and chemistry from that observed in nature. Attached chemistry also has the propensity to be released into the environment during degradation, the effects of which are unknown. Therefore, mitigation strategies at every step of textile manufacturing should by implemented to reduce microfiber emissions. From our study, during the dry process- the use of ring, compact, and air-jet spinning have potential to release less microfibres during fibre spinning. For knitting and weaving- laser cut rib filament knit, and unprocessed twill filament or plain spun weave would shed less microfibres. During dyeing, the use of dope dyeing, supercritical CO2 dyeing, and cold pad-batch dyeing have potential for positive impact on the environment to reduce microfibre emissions. Effluent treatment using combination of membrane bioreactor and biological catalysis, or ultrafiltration with crossflow module and reverse osmosis, or acoustic technology are improved industrial wastewater treatment practices that could be used to prevent the unintended release of microfibres. The microfibres recovered from the textile effluents can further have applications in fibre-to-fibre recycling, fillers in bio-composites, or 3-D printing. To conclude, implementing better-by-design interventions, using economically viable and scalable models for industries at manufacturing stage along with increasing consumer awareness will help tackle the microfibre

challenges. This work was funded by the National Environment Research Council (NERC) as listed by UKRI, Future Fibres Networking Grant, NE/Y003985/1.

1.03.P-Tu024 Forest Biodiversity Indicators for Sustainability Reporting in the Wood-Based (Regenerated Cellulose) Fiber Industry for Fashion

***Andreas Barth**[1], Lea Ranacher[1], Franziska Hesser[1], Kurt Christian Schuster[2] and Tobias Stern[3], (1)Wood K plus, Austria, (2)Lenzing Aktiengesellschaft, Austria, (3)University of Graz, Austria*

Most studies on assessing the environmental sustainability of apparel are primarily focused on pressure indicators like air emission, water pollution or land use. However, to assess biodiversity, state indicators are also required, and it is advisable to collect information on these at the site of the ecosystem intervention. The wood fiber-based fashion industry heavily depends on wood as a raw material, which poses potential risks to forest biodiversity. As sustainability becomes increasingly important, companies are applying science-based environmental targets, driven by regulations such as the Corporate Sustainability Reporting Directive (CSRD). Among other topics, this regulation requires companies to disclose their impacts and dependencies on biodiversity. However, currently available biodiversity indicator sets tend to be generic and only deal superficially with different economic sectors. Science-based indicators and goals can help companies make informed biodiversity commitments. Collaboration among stakeholders, including regulatory experts, researchers, and businesses, is essential to align corporate actions with biodiversity goals. We therefore want to utilise results of forest biodiversity research for practical application in corporate sustainability reporting. This study uses a Delphi survey to identify and evaluate forest biodiversity indicators suitable for corporate sustainability reporting in the wood fiber-based fashion industry. The indicators should be used to assess the impact on biodiversity at the point of wood procurement. Experts from the fields of sustainability regulatory and biodiversity research are consulted to propose relevant indicators and assess their practical application. The goal is to provide businesses with knowledge to better integrate biodiversity considerations into their sustainability strategies. Initial findings suggest that while meaningful indicators are available, access to timely and spatially accurate data remains a challenge. Further research is needed to develop sector-specific indicators that meet the requirements of sustainability reporting.

1.03.P-Tu025 Embryonic Exposure to Alizarin Yellow Dye Alter Embryonic Development and Behavior in Zebrafish (*Danio rerio*)

***Luis Terrazas Salgado**[1], Justin Dubiel[1], Carter Langevin[1], Lauren Zink[2], Natalia de Farias[3], Gisela de Aragão Umbuzeiro[3] and Steve Wiseman[1], (1)University of Lethbridge, Canada, (2)University of British Columbia, Canada, (3)Universidade de Campinas, UNICAMP, Brazil*

In recent years the use of synthetic dyes has increased significantly, however, little is known about their ecotoxicological effects. Among different classes of dyes, the azo dyes are used in great quantities and are known to break down into carcinogenic amines. One amine of interest is alizarin yellow. This dye is water soluble and has various applications, including in the coloring of textiles, leather, and plastics and the manufacture of paints and lacquers. Given the widespread use of this dye, it has been considered a major contaminant of aquatic environments, and bodies of water contaminated with this dye are some of the most difficult to treat due to the complex aromatic structure of the dyes, which makes them more stable and difficult to biodegrade. However, little is known about the toxicity of alizarin, including toxicity to early life stages of fish. In this study, freshly fertilized zebrafish embryos were microinjected with either a DMSO control or with 38, 190, 950, 4750 ng/g egg of alizarin yellow before gastrulation, and effects on survival, hatching success, and malformations were assessed until 14 days post-fertilization. Heart rate was quantified at 48 hours post-fertilization, and a behavioral assay to quantify locomotion was performed on larvae at 5 days post-fertilization. Alizarin yellow caused dose-dependent increases in mortality, with an EC50 of 3129 ng/g egg. There was a significant decrease in mean heart rate in the highest treatment (178 beats per minute) compared to the control (170 beats per minute) at 48 hours post-fertilization. Dose-dependent increases in the occurrences of malformations were observed, including a significant reduction in the length of the larva, a significant decrease in the eye area, curvature of the spine, pericardial edema, and yolk sac edema were also observed. The occurrence of each malformation was significantly higher at the highest dose of alizarin yellow. Overall, embryonic exposure of zebrafish to alizarin yellow dye affected the embryonic development of zebrafish which may have ecotoxicological implications. Additional research is being performed to understand the mechanisms of toxicity and the risk that alizarin yellow may pose to aquatic organisms.

1.03.P-Tu026 Measuring So We Can Manage: The Current Landscape of Textile Chemical Impacts on Biodiversity and Ecological Health

***Catherine A Rudisill**[1] and Scott Echols[2], (1)Safer Chemistry Advisory, United States, (2)Stichting ZDHC*

Foundation, Netherlands
The interconnected crises of climate change, pollution, and biodiversity loss, as highlighted by the United Nations Environment Programme (UNEP), underscore the urgency of addressing chemical pollution. Within the textile and apparel industry, harmful chemical emissions significantly impact biodiversity and water ecosystems, yet data and methodologies to measure these impacts remain insufficient. This research examines the current landscape of chemical pollution in the textile supply chain, focusing on its ecological consequences and the gaps in data, tools, and methodologies. A comprehensive review of scientific literature, industry reports, and non-governmental organization (NGO) assessments identified critical challenges and gaps, particularly the lack of standardized metrics connecting chemical emissions to biodiversity outcomes. Current tools, such as geographical risk tools, provide valuable insights but lack the granularity needed to inform mitigation strategies specific to textile industry pollutants. Collaboration between chemical and ecological disciplines is essential to bridge these gaps. This study highlights the necessity for developing practical, scientifically robust indicators to track chemical footprints in line with emerging disclosure frameworks such as the EU Corporate Sustainability Reporting Directive (CSRD). By documenting ongoing initiatives and fostering cross-sector collaboration, efforts like the Zero Discharge of Hazardous Chemicals (ZDHC) program aim to operationalize solutions, reduce research redundancy, and enhance resource allocation. The findings underscore the need to establish reliable impact metrics and frameworks that not only address immediate challenges but also support long-term goals for safer chemical practices and sustainable biodiversity management. Documenting existing efforts will reduce redundancy, encourage cross-sector collaboration, and optimize resource use for future research.

1.04.A Molecular Ecotoxicology and Omics Perspectives: Advancing Mechanistic Understanding for Environmental Risk Assessment

1.04.A.T-01 Exploring Mechanisms of Chemical Toxicity Using *Chlamydomonas reinhardtii* Mutants Library

Tim Godec[1]*, Carissa Robyn Bleker*[1]*, Tina Elersek*[1]*, Marusa Kerencic*[1]*, Katja Stare*[1]*, Milena Horvat*[2]*, Tina Kosjek*[2] *and Anze Zupanic*[1]*, (1)National Institute of Biology, Slovenia, (2)Institute Jozef Stefan, Slovenia*
The molecular mechanisms underlying chemical toxicity and stress response are often poorly understood. Functional genomics, which links genetic determinants to phenotypic outcomes, provides a high-throughput approach to uncover genes and pathways involved in chemical susceptibility and tolerance. Using a library of ~11,000 Chlamydomonas reinhardtii gene knockout mutants, we investigated responses to 15 chemicals, including herbicides, heavy metals, and a cyanotoxin. By identifying mutants with altered growth under chemical exposure, we aimed to elucidate key molecular mechanisms of toxicity. Following three days of exposure to chemicals, DNA barcodes identifying each mutant were sequenced and analyzed. Logarithmic fold change of growth was calculated and gene set enrichment analyses were performed using various functional gene sets. Across treatments, mutations more often increased susceptibility than tolerance. The number of tolerant mutants across treatment ranged from 2 (microcystin) to 192 (glyphosate), while susceptible mutants ranged from 10 (atrazine) to 2,076 (silver). Some genes consistently influenced responses across treatments; e.g., Cre06.g278116 conferred tolerance in 10 treatments, while Cre17.g741150 caused susceptibility in 14. Tolerance was not enriched for specific processes, but susceptibility was associated with genes involved in mating and early zygote formation. Certain mutants exhibited opposing responses depending on the treatment. For instance, Cre17.g722150 (a Type III polyketide synthase) conferred susceptibility to seven chemicals but tolerance to six, while Cre17.g702150 (a thioredoxin-like protein) mostly mediated resistance to metals but susceptibility to herbicides and microcystin. Chemical-specific responses were also observed, such as cation transporter Cre02.g093700 s role in paraquat tolerance and microcystin-related genes involved in cGMP/cAMP regulation. We employed multiple strategies to analyse our functional genomics dataset, including GSEA, manual exploration of top-responsive genes, and overrepresentation across all chemicals and specific chemical groups. While we have identified several genes with known and unknown functions that have an important role in tolerance and susceptibility to chemical exposure, the limited annotation of plant genes, particularly regarding their functional roles, makes it challenging to pinpoint the precise mechanisms of toxicity.

1.04.A.T-02 Tipping Points in the Lipidomes of Arctic Zooplankton Under Global Change

Mathieu Lutier[1]*, Bethanie R. Edwards*[2]*, Jiwoon Hwang*[2]*, Nele Thomsen*[3]*, Helena C. Reinardy*[3]*, Katrine Borga*[1]*, Janne E. Soreide*[4] *and Khuong V. Dinh*[1]*, (1)University of Oslo, Norway, (2)University of California Berkeley, United States, (3)Scottish Association for Marine Sciences, United Kingdom, (4)The University Centre in Svalbard, Svalbard and Jan Mayen*
Human activities induce extremely rapid environmental changes. This could exceed physiological tipping

points beyond which environmental changes have drastic impacts on organism s physiology. Tipping points have never been studied in the lipidome of organisms exposed to environmental changes. Yet, the lipidome plays a crucial role in the functioning of organism s physiology and ecosystems. Amongst the most striking example are Arctic copepods such as Calanus glacialis. Indeed, they store enormous lipid reserves, up to 60% of their body mass, and migrate to the deep sea to survive the winter in a state of metabolic dormancy, the diapause. Due to their energy-rich lipid composition, they play a key role in trophic food webs. Moreover, the winter migration of such lipid-rich organisms sequestrates huge quantity of carbons in the deep ocean. The success of diapause is tightly related to changes in the lipidome. The Arctic ocean experiences Ocean Acidification (OA) four times faster than the global ocean. Changes in the lipidome and metabolic dormancy have been suggested to protect organisms when OA exceed tipping points. Thus, the lipidome lies at the interaction between diapause and the response to OA. Any changes in the lipidome of copepods would have consequences on the overwintering of copepods as well as on the functioning of Arctic ecosystems. Here we determine lipidome tipping points of organisms exposed to environmental changes. For that purpose, we exposed C. glacialis, a diapausing Arctic species, to 15 pH conditions for several weeks. In parallel, we exposed Metridia longa, a non-diapausing species that stays active over the winter. We expect the lipidome of M. longa to be affected only by OA while C. glacialis lipidome would reflect the interacting influences of diapause and OA. The lipid of the two species were analysed using targeted tandem mass spectrometry (MS/MS) liquid chromatography. We annotated ~500 lipid compounds using a combination of LOBSTAHS and MS-DIAL lipidomic pipelines. We then search for tipping points in the lipidome of both species using Weighted Gene Co-expression Network Analysis (WGCNA) and piecewise linear regressions. We also compare the lipidome reaction norms of both species using delta ranks to detect evolutionary mechanisms related to diapause. The method we develop will be applicable to a wide range of stressors and species and will be of broad interests for ecotoxicologists interested in lipids and contaminants.

1.04.A.T-03 Development of an In Vivo High Throughput Screening Approach for Mechanism-Based Toxicity Assessment of Plastic Additives Chemicals Using *Caenorhabditis elegans* Transcription Factor RNAi Library

***Siyeol Ahn**, Elizabeth Dufourcq Sekatcheff and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of*

Identifying the toxic effects of brominated flame retardants (BFRs) contained in consumer products is crucial for accurately informing decision-makers in regulatory policies. RNA interference (RNAi) technology in Caenorhabditis elegans has been developed as a rapid and powerful screening method for identifying the toxicity pathways of various chemicals. Therefore, this study aims to facilitate the mechanistic understanding and identification of the toxic effects of BFRs using C. elegans RNAi high-throughput screening. In the first step, RNAi screening was performed for 384 C. elegans transcription factors (TFs). RNAi-fed worms were exposed to TBBPA, and their locomotion behavior was measured. The biological pathways triggered by the TFs that significantly led to either rescued or exacerbated toxicity were analyzed using KEGG and Reactome. Next, the toxicity pathways were validated using gene expression or mutants of C. elegans exposed to BFRs. Finally, a potential AOP with BFRs as stressors was constructed by utilizing the toxicological mechanisms associated with BFR exposure and the AOP Wiki. Among the 384 transcription factors that were screened for potential effects of TBBPA on C. elegans locomotion, 19% showed significant alterations in locomotion (45 genes; p-value < 0.05, $2 <$ p-fold < 0.5). The associated pathways of these 45 transcription factors affected by TBBPA were revealed to be mostly involved in the nuclear receptor (NR) transcription pathway and retinoic acid signaling. The expression of NR transcription pathway-related genes, such as nhr-69, nhr-8, and unc-55, showed a statistically significant increase in C. elegans exposed to different concentrations of BFRs. To apply BFRs toxicity to an AOP framework, we aligned information on BFRs toxicity mechanisms, NR transcription pathway and retinoic acid signaling, with existing key events and adverse outcomes based on the AOP Wiki.
In this study, we identified potential mechanisms of toxicity of BFRs using C. elegans RNAi library screening, This method has great potential as a fast and efficient screening method for mechanism -based toxicity assessment of chemicals, including flame retardants. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through 'Core Technology Development Project for Environmental Diseases Prevention and Management', funded by Korea Ministry of Environment (MOE) (2021003310005).

1.04.A.T-04 Impact of Simvastatin on *Gammarus locusta*: Metabolomic Measurement of Direct and Transgenerational Effects

***João Rodrigues**[1], Raquel Chaves[2], Miguel M. Santos[3], Teresa Neuparth[2] and Ana Gil[1], (1)Department of Chemistry and CICECO Aveiro Institute of Materials, University of Aveiro, Portugal, (2)CIIMAR/CIMAR-*

LA - Interdisciplinary Centre of Marine and Environmental Research, Group of Endocrine Disruptors and Emerging Contaminants, University of Porto, Portugal, (3)CIIMAR/CIMAR-LA - Interdisciplinary Centre of Marine and Environmental Research, Group of Endocrine Disruptors and Emerging Contaminants, University of Porto; FCUP Department of Biology, Faculty of Sciences, University of Porto, Portugal
Simvastatin (SIM), a pharmaceutical widely prescribed for the treatment of hypercholesterolemia, is considered a contaminant of emerging concern based on its occurrence in aquatic systems and potential adverse effects in the environment and human health. Previous studies have already linked SIM inter/transgenerational exposure to disruption of neuroendocrine regulation pathways, concomitantly with reduced reproduction and growth in Gammarus locusta. To better understand the mechanistic into SIM´s adverse effects and modes of action, metabolomics is presented as a powerful tool, offering valuable insights into organism s early molecular responses to stressors. In this study, untargeted 1H NMR metabolomics was applied to assess the impact of SIM (at an environmentally relevant concentration) on the metabolism of Gammarus locusta males and females, considering both direct and transgenerational exposure. Results revealed the important gender-dependent nature of each of these effects. Directly exposed males showed enhanced glucose catabolism and tricarboxylic acid (TCA) cycle activity, in tandem with adaptations in osmotic regulation and glyoxylate metabolism. Exposed females exhibited only a small osmoregulatory effect. It is suggested that the response of exposed males may reflect previously reported high levels of methyl farnesoate hormone and alterations in apical factors, namely decreased growth. Conversely, transgenerational effects were identified only in females, with impact on energy metabolism (glycolysis and TCA cycle enhancement) and osmoregulatory response. This expresses the ability of female gametes to transmit the effects of direct SIM exposure. Such effects were putatively related to reported delayed maturation and transcriptomic deviations impacting on carbohydrate and lipid metabolisms, possibly specifically engaging phenylalanine/tyrosine in the catecholamine pathway. These findings highlight the importance of gender on the ability of responding and transmitting the effects of SIM through generations, offering critical information to improve hazard and risk assessment of biologically active compounds. The authors acknowledge TRANSEPIC ? 1.04.P-We006 Cellular Handling, Transformation Pathways and Metabolic Disturbances of Mercury in Freshwater Phytoplankton

***Vera Slaveykova**[1], Joao Santos[1], Remy Millet[1], David Amouroux[2] and Arturo Keller[3], (1)University of Geneva, Switzerland, (2)Institut des Sciences Analytiques et de Physico-chimie pour l'Environnement et les materiaux, France, (3)University of California, Santa Barbara, United States*
Mercury, a priority pollutant, raises significant environmental concerns. While numerous studies have investigated mercury bioaccumulation and its impact on aquatic organisms, there is a gap in the understanding concerning its cellular handling and transformations, and disturbances of the metabolic pathways of phytoplankton species at the bottom of the food web. In such a context, this study aims to elucidate the mechanisms governing the cellular transformations and responses of phytoplankton to mercury exposure. The green alga Chlamydomonas reinhardtii and diatom Cyclotella meneghiniana were selected as representatives of major phytoplankton groups. These algae were exposed to 10 and 100 nM inorganic mercury (Hg(II)) and methylmercury (MeHg) for 72h. Mercury uptake, sub-cellular distribution, and physiological effects such as oxidative stress and photosynthetic yield were assessed. Simultaneously, over 90 metabolites, spanning antioxidants, amines, organic acids/phenolics, nucleobases/sides/tides, amino acids, sugars/sugar alcohols, and fatty acids, were quantified using liquid chromatography mass spectrometry. Cellular transformation including methylation/demethylation, reduction and oxidation as well as formation of HgS nanoparticles have been explored using double isotope Hg spiking (199Hg(II) and 201MeHg). Results demonstrated that C. meneghiniana exhibited higher mercury accumulation than C. reinhardtii at the same exposure concentrations. Subcellular distribution of mercury differed between the two species, with C. reinhardtii concentrating mercury predominantly in organelles, while the diatom exhibited mercury in both organelles and heat-stable peptides. Both algal species significantly demethylate methylmercury, whereas no measurable methylation of the inorganic mercury was found. A reduction of Hg(II) to Hg(0) were also found in both phytoplankton species. Physiological data matched metabolomic results, revealing substantial alterations in various pathways, including amino acids, nucleotides, fatty acids, the tricarboxylic acid cycle (TCA), and antioxidant metabolism. The findings reveal species-specific and concentration-dependent responses, providing new insights into mercury handling and

metabolic reprogramming in phytoplankton. Understanding these processes is essential for assessing mercury's impact on aquatic primary producers and its potential trophic transfer, especially in contaminated environments. The authors thank Swiss National Science Foundation grants 175721 and 180186 for the financial support.

1.04.P-We007 Towards Mechanistic Understanding of Reduced Cell Proliferation: An RNA- and RIBOseq Approach

Sven Mosimann[1]*, Barbara Jozef*[1]*, Miha Tome*[2]*, Anze Zupanic*[2] *and Kristin Schirmer*[1]*, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)National Institute of Biology, Slovenia*

Fish are a highly diverse and ecologically important group of organisms that are exposed to a wide range of anthropogenic substances. While effects of toxic chemicals include both acute and chronic adverse outcomes, the latter seems to prevail in the natural environment. Therefore, ecotoxicological risk assessment is particularly interested in understanding the effects of prolonged chemical exposure to fish. One of the most often studied endpoints is organism growth. However, the assays usually conducted are not only under ethical scrutiny but also labour and time demanding. Therefore, new methods are desperately needed. While the OECD TG 249 already provides an alternative for the assessment of acute fish toxicity using the rainbow trout gill cell line, RTgill-W1, there is no such assay for chronic toxicity. However, building on the observation that larger animals have more cells instead of bigger ones, researchers from our group could demonstrate excellent predictive powers of the same cell line by taking cell number as proxy for organism size for a set of both structurally and functionally different chemicals. Nevertheless, the underlying molecular mechanisms and especially the points at which the different initially triggered biochemical pathways converge and lead to an arrest of the cell cycle remain unclear. To investigate the underlying molecular mechanisms, we exposed RTgill-W1 cells to a set of six different substances: 2-mercaptobenzothiazole, methimazole, propiconazole, tebuthiuron, topramezone and trifloxystrobin. While all six chemicals induced reduced cell proliferation, we found that derived EC50s correlate well with baseline toxicity QSARs. Next, to shed light on the underlying molecular mechanisms of reduced cell proliferation, we designed an experiment to analyse the transcriptome and translatome. Gene ontology and pathway analysis using KEGG revealed a regulation of the cell cycle after an only one-day long exposure to the two chemicals already fully assessed. Specifically, gene ontology analysis of the RNAseq data showed that the cell cycle is affected during mitosis or at the G2/M checkpoint. Further, we identified several genes that were regulated differently at the level of transcription and translation. Altogether, the results will not only help us deciphering the mechanisms of reduced cell proliferation upon chemical insult but will also test the predictive powers of cell-line based assays.

1.04.P-We014 An Integrative Omics Approach for the Development of Conceptual Adverse Outcome Pathways: A Case Study Map[ing Metabolic Syndrome in Tributyltin-Exposed Adipocytes

Dayna Schultz[1]*,* ***Fotini Nikiforou***[1]*, Ilias Frydas*[1]*, Nafsika Papaioannou*[1]*, Thanasis Papageorgiou*[1]*, Katerina Gabriel*[1]*, Spyros Karakitsios*[1] *and Denis Sarigiannis*[2]*, (1)Aristotle University of Thessaloniki, Greece, (2)National Hellenic Research Foundation, Greece*

Metabolic syndrome (MetS) is a condition distinguished by co-occurring symptoms that is increasingly attributed to exposure to endocrine-disrupting chemicals (EDCs). It is characterised by cardiometabolic irregularities and is associated with increased risk of cardiovascular disease (CVD), non-alcoholic fatty liver disease (NAFLD), and type 2 diabetes (T2D). Using an adverse outcome pathway (AOP) framework, this study leverages an integrated multi-omic approach using both univariate and multivariate techniques, as well as network and clustering analysis, to better visualise the intricate relationships between perturbed features (PFs), pathways, and disease associations. More specifically, Simpson-Golabi-Behmel syndrome (SGBS) pre-adipocytes were exposed to tributyltin (TBT), a known lipogenic substance, to assess metabolite and transcript dysregulation. Cells were grown to near confluence, incubated in differentiation medium for 4 days, and cultivated in maintenance medium for 6 days. The differentiation medium of TBT-exposed cells was additionally supplemented with 25nM TBT during the initial 4 days. On day 10, TBT-exposed cells and differentiated controls were compared. Samples for untargeted metabolomics were analyzed using Reversed Phase (RP) and Hydrophilic Interaction (HILIC) Liquid Chromatography in positive and negative ionization modes. Transcriptomic analysis was performed using Agilent microarrays to determine differentially expressed genes (DEGs). All data analyses took place in R. Data preprocessing, batch correction, and statistical analyses were conducted using xcms, IPO, PMCMRplus, and xMSannotator packages for metabolomics, and limma for transcriptomics. Pathway analysis was performed using KEGG, WikiPathway, and RaMP-DB databases in clusterProfiler and MetaboAnalystR while disease associations utilised DisGeNet. Cluster analysis using the Jaccard Similarity index was performed to group diseases and pathways based on their PF fingerprints. Six conceptual AOPs (cAOPs)

were developed that link disruptions in widespread pathway-level perturbances to adverse outcomes like xanthomatosis, bone remodeling disorders, cardiac outcomes, NAFLD, and insulin resistance. The resulting AOPs were also supported by recent literature findings. This method will be applied in future studies to explore environmental exposures and their contributions to various disorders, ultimately aiding in risk assessment and the development of targeted interventions.

1.04.B Molecular Ecotoxicology and Omics Perspectives: Advancing Mechanistic Understanding for Environmental Risk Assessment

1.04.B.T-01 Comparative Assessment of the tPOD of Tamoxifen in Zebrafish Embryos with Chronic Endpoints from a Two Generation Study

***Matthias Teigeler**, Fabian Essfeld, Steve Uwa Ayobahan, Julia Alvincz, Benedikt Ringbeck, Christoph Schafers, Elke Eilebrecht and Sebastian Eilebrecht, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany*

The transcriptomic Point of Departure (tPOD) is gaining attention in ecotoxicology as a method for deriving quantitative endpoints from RNA-Seq data. In fish, the zebrafish embryo model is emerging as a promising New Approach Methodology (NAM), recognized under EU Directive 2010/63/EU as an alternative to traditional animal testing. Sublethal transcriptomic profiles in zebrafish embryos have been linked to various Modes of Action (MoA), with tPOD values from Fish Embryo Toxicity (FET) tests generally being protective and comparable, though often lower, than the No Observed Effect Concentration (NOEC) from chronic fish studies. However, there is a limited database to robustly suggest tPOD as a predictive tool for chronic endpoints derived from long-term fish tests. This study aimed to determine the tPOD for tamoxifen, an estrogen receptor modulator, in zebrafish embryos and compare it with endpoints from the Zebrafish Extended One Generation Reproduction Test (ZEOGRT). In the ZEOGRT, for the most sensitive endpoint for tamoxifen, the NOEC was determined to be 0.20 µg/L. Zebrafish embryos were exposed to tamoxifen concentrations (0.026 to 5.8 µg/L), covering the NOEC/LOEC obtained from the ZEOGRT. After 96 hours post-fertilization, RNA sequencing and differential expression analysis (DESeq2) were performed. The DRomics pipeline was used to identify the tPOD through transcriptomics benchmark dose (BMD) analyses in R. Significant concentration-dependent gene expression changes were observed, particularly in genes related to the endocrine system, such as Wnt signaling, MAPK signaling, and steroid hormone biosynthesis. Based on 64 responsive genes, tPOD values for tamoxifen were 10 ng/L (10th percentile) and 90 ng/L (maximum 1st peak), with the latter being slightly more sensitive than the ZEOGRT NOEC. These findings support the use of tPOD in the zebrafish FET test as a NAM for estimating the NOEC of tamoxifen, a pharmaceutical with endocrine activity. The slightly lower effect concentrations from this study compared to the NOEC from the ZEOGRT are in line with previous research and support that the tPOD is more conservative than apical points of departure. This study affirms that tPOD in the zebrafish embryo model could be a cost-effective, protective method for estimating NOECs, particularly for endocrine-disrupting chemicals, and supports the 3Rs principles in regulatory testing.

1.04.B.T-02 Sex Hormone Disruption of Biodegradable Plastic Extracts in Comparison with Conventional Plastics: Observations in H295R Cells and Adult Male Zebrafish

***Eunhye Kim**[1], Mike Williams[2] and Kyungho Choi[1], (1)School of Public Health, Seoul National University, Korea, Republic of, (2)Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia*

Biodegradable plastics are generally considered a safer alternative to petroleum-based plastics. However, their endocrine-disrupting effects in comparison to those replaced remain unclear. We chose several plastic products with direct human contact, and assessed the endocrine-disrupting potential of biodegradable plastics using human adrenocortical carcinoma (H295R) cells and adult zebrafish. Eight products, including two with conventional plastics, were chosen, and their acetone extracts were used for exposure. In H295R cells, decreased testosterone (T), increased estradiol (E2), and upregulated cyp19a1, were observed following the exposure, suggesting anti-androgenic effects of most products. For in vivo observation, two samples with the highest in vitro responses were selected: a polybutylene adipate terephthalate (PBAT) + polylactic acid (PLA) sanitary bag and a high-density polyethylene (HDPE) sanitary bag as a control. Following a 21-day exposure to selected plastic extracts, adult male zebrafish exposed to PBAT+PLA extracts showed reduced 11-ketotestosterone (11-KT) levels, elevated E2 levels, and higher E2/11-KT ratios, supporting anti-androgenicity of these products. Gene expression analysis revealed upregulated cyp11a1, supporting enhanced estrogen synthesis, and upregulated fshr and lhr genes, indicating compensatory activation of the hypothalamic-pituitary-gonadal axis. The present observations in both in vitro and in vivo experiments clearly show that biodegradable plastics generally exhibit the same directions of sex hormone disruption as conventional plastics. These findings underscore the need for stricter safety evaluations of biodegradable plastics of direct human contact to mitigate potential adverse health consequences. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through Core Technology Development Project for Environmental Diseases Prevention and Management, funded by Korea Ministry of Environment (MOE) (RS-2022-KE002173)

1.04.B.T-03 Disturbance in the Metabolic Pathways of Tree Frogs Living in the Chernobyl Exclusion Zone: From Gene, Protein Expression Patterns to Metabolic Enzyme Activity and Body Condition Index

Lea Dasque[1], Luc Camoin[2], Marie-Laure Delignette-Muller[3], Damien Roussel[4], Car Clement[5], Stephane Audebert[2], Samuel Granjeaud[2], Emilie Baudelet[2], Andre Gilles[6], Jean Armengaud[7], Nathalie Mondy[4], Jean-Marc Bonzom[1], Olivier Armant[1] and ***Sandrine Frelon****[8], (1)French Institute of Radiation Protection and Nuclear Safety, France, (2)CNRS UMR7258 CRCM MAP, France, (3)CNRS LBBE Vet Agro Sup, France, (4)UMR-CNRS 5023 LEHNA Universite Lyon 1, France, (5)IRSN, France, (6)UMR RECOVER Universite Aix-Marseille, France, (7)CEA LI2D, France, (8)French Institute of Radiation Protection and Nuclear Safety / Laboratory of ecology and ecotoxicology of radionuclides, France*

While wildlife is chronically exposed to various sources and levels of ionizing radiation in the environment, studies regarding the long-term impact of long-lived radio-contaminant released in case of accident, are still scarce, patchy, and sometimes contradictory. To increase such data, crucial to bring more realism to Ecological Risk Assessment, IRSN recent studies were performed on the tree frog Hyla orientalis living in the Chornobyl Exclusion Zone (CEZ) for ~15 generations. Analyses of genetic diversity and transcriptomics studies showed a high rate of mitochondrial mutations, a modulation of genes relative to energy metabolism, and, a small population size with a higher affiliation rate for those living in the most radio-contaminated areas. This raises questions on the ability of populations to maintain themselves and on their health status. In that way, to go further, proteomic analyses of frog muscles of the same individuals were performed and analyzed by two complementary methodologies, including dose-response curves. In addition, the activity of two enzymes involved in the energetic metabolism, i.e. citrate synthase (aerobic metabolism) and lactate dehydrogenase (anaerobic metabolism), was measured. All results were analyzed in relation to individual total dose rates (ITDR), distributed over five orders of magnitude. GO enrichment after proteomic analysis highlighted four significant enriched pathways (FDR 5%) i.e. Carboxylic acid metabolic process , Cellular lipid catabolic process , Fatty acid beta-oxidation and Small molecule catabolic process . Regarding enzyme activities, results showed a tendency of LDH activity decrease and a significant increase of the ratio between LDH and CS with increasing ITDR. All the results seem to confirm by two further approaches a disturbance in the metabolic pathways, notably the ones linked to fatty acids (?-oxidation, catabolism). Investigations will be carried on deciphering the biological pathways involved in long term effects of radiocontamination to draw hypotheses on the cascade of events leading to adverse outcome and conclude on CEZ tree frog health status.

1.04.B.T-04 Exploration of Transcriptomic Data with Over-Representation Analysis (ORA) Enhanced by Aggregated Biological Prior Knowledge

Ellis Franklin*[1], Elise Billoir[2], Philippe Veber[3], Jeremie Ohanessian[2], Marie-Laure Delignette-Muller[3] and Sophie Prud'homme[2], (1)Universite de Lorraine, CNRS, LIEC; Universite de Lyon, CNRS, VetAgro Sup, LBBE, France, (2)Universite de Lorraine, CNRS, LIEC, France, (3)Universite de Lyon, CNRS, VetAgro Sup, France*

In the context of transcriptomics, analyses yield extensive transcript lists that require impractical manual literature reviews. To address this, functional enrichment analysis, also known as pathway enrichment analysis, has become the standard approach. This method condenses large gene lists into more manageable and interpretable sets of biological functions or pathways (e.g. GO terms or KEGG pathways). One of the most common enrichment methods is the Over-Representation Analysis (ORA), which tests whether a biological function F contains a disproportionately large number of deregulated genes compared to sampling a random sample of expressed genes. In this case, the function F is considered as enriched. Enrichment analyses, while advantageous in highlighting certain functions, have the drawback of limiting interpretation to only a subset (often small) of the list of deregulated genes, specifically those involved in the enriched functions. We developed Cluefish (CLUstering, Enrichment and FISHing), a free, semi-automated workflow for exploring transcriptomic data. The workflow applies ORA to pre-clustered protein-protein interaction networks constructed from the STRING database, using clusters as anchors to identify smaller and more specific biological functions. Additionally, with steps for cluster merging and the retrieval of genes with shared biological context, Cluefish enables the inclusion of a larger portion of deregulated genes in the interpretation, providing a more comprehensive view of transcriptomic data. Using zebrafish embryos as an in vivo model, we investigated the dose-dependent transcriptional effects of dibutyl phthalate (DBP). By comparing our approach with traditional methods, we demonstrated that Cluefish allows for the interpretation of a larger portion of the data and reveals disrupted biological pathways that would otherwise be overlooked. Coupled with sensitivity thresholds and dose-response curves derived from DRomics, Cluefish outputs enabled the formulation of hypotheses supported by multiple concordant elements, which are not only biologically coherent but also of significant scientific interest.

1.04.P-We008 Metabolomic and Transcriptomic Changes in Larval Zebrafish After Developmental Exposure to Aroclor 1254

Corey S Green[1], *Jason Tyler Magnuson*[2], *Ana Alonso*[3], *Jean-Christophe Cocuron*[3], *Michel Gielazyn*[4], *Claire Lay*[5], *Rachel Leads*[6], *Lisa Rosman*[7], *Daniel Schlenk*[8] *and Aaron P Roberts*[3], *(1)Eastern New Mexico University, United States, (2)United States Geological Survey, Columbia Environmental Research Center, United States, (3)University of North Texas, United States, (4)National Oceanic and Atomospheric Administration, Assessment and Restoration Division, United States, (5)Abt Global, United States, (6)Michigan State University, United States, (7)National Oceanic and Atmospheric Administration, Assessment and Restoration Division, United States, (8)University of California Riverside, United States*

Polychlorinated biphenyls (PCBs) are long-lived synthetic compounds that were widely used until 1979. The neurotoxicity of Aroclor 1254, a commercial mixture of PCBs, has been well documented within mammalian species, however, the underlying mechanisms of toxicity have not been fully characterized, particularly in aquatic organisms. Previous research has shown that developmental exposure to Aroclor 1254 induced dose dependent tremors in the eyes of larval zebrafish (Danio rerio), indicating novel neurotoxic effects. Here, we used targeted metabolomics and transcriptomic profiling to investigate the neurotoxicological effects of Aroclor 1254 exposure at nominal concentrations of 500 µg/L to embryonic zebrafish for 96 h. There were significant differences between controls and Aroclor 1254 treated zebrafish larvae in proline, glutarate, asparagine, glycerol 3-phosphate, sucrose, threonine, and fructose 6-phosphate levels. Metabolites involved in neurotransmitter signaling pathways, such as glycine, tyrosine, and glutamine, had significantly different levels in Aroclor 1254 treated larvae, with top enriched pathways involved in lipid metabolism and xenobiotic response. Bioinformatic analyses utilizing transcriptomic data found that exposure to Aroclor-1254 consistently resulted in disruptions of pathways and networks related to visual function, nervous system function, protein synthesis, and other pathways related to embryonic development. These underlying pathways were supported by eye tremor phenotypes that were present in Aroclor 1254 exposed larvae. These results suggest that changes in the levels of metabolites involved in neurotransmitter function and dysregulations in genes within visual function pathways are likely responsible for the underlying eye tremor behavior and may serve as novel biomarkers in early life stage fish exposed to PCBs.

1.04.P-We009 Ecotoxicogenomic Hazard Assessment of the Artificial Sweetener Sucralose

Alexandra Loll[1], *Annika Heinrich*[1], *Christoph Schafers*[1], *Henner Hollert*[2] *and Sebastian Eilebrecht*[1], *(1)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Goethe University Frankfurt, Germany*

The intensive consumption of artificial sweeteners has led to a global market revenue of more than 21 billion USD in 2021 and is expected to rise further. Mainly used as food additives, the high stability and water solubility of artificial sweeteners makes them perfect candidates as sugar alternatives. While the stability that comes with being calorie-free is an advantage in this case, it also makes them a potential threat to the environment due to the lacking degradation in waste water treatment plants. Consequently, they are released into the aquatic environment where they have proven to be persistent and mobile. Although researchers have described them as emerging contaminants for more than a decade, environmental hazard assessment data are still lacking. The few studies that have been carried out already revealed some ecotoxic effects such as neurotoxicity in zebrafish embryos caused by acesulfame or altered swimming behaviour of daphnids caused by sucralose. EFSA is currently re-evaluating the safety of artificial sweeteners, including environmental aspects. The use of OMICs for the required environmental hazard assessment offers many advantages, including time savings, insight into modes of action and reduction of animal testing. This project aims to gather data on the ecotoxicogenomic effects of the four most common artificial sweeteners sucralose, acesulfame, saccharin and cyclamic acid, using ecotoxicological model organisms from different trophic levels. First results showed that sucralose significantly altered gene expression of the aquatic plant Lemna minor, both, at the highest exposure of 100 mg/L and at the environmentally relevant concentration of 10 µg/L. Also, functional analysis provided hints on adverse effects caused by the substance. The Crustacean Daphnia magna and the teleost fish Danio rerio (embryo) were neither morphologically, nor molecularly affected by sucralose exposure in our experiments. The authors thank the German Federal Environmental Foundation for funding.

1.04.P-We030 Investigating the Effects of N-alkyl Dimethyl Benzyl Ammonium Chloride (ADBAC) on the Fathead Minnow (*Pimephales promelas*) Proteome, in a Two-Phase Approach and as Part of a Whole-Ecosystem Study

***Raina Mackenzie Kerr Hubley*[1]*, Theresa Warriner*[1]*, Lauren Timlick*[2]*, Vince Palace*[3] *and Denina B.D. Simmons*[1]*, (1)Ontario Tech University, Canada, (2)International Institute of Sustainable Development-Experimental Lakes Area, Canada, (3)International Institute of Sustainable Development-Experimental Lakes Area & University of Manitoba, Canada*

N-alkyl dimethyl benzyl ammonium chloride (ADBAC) is a chemical disinfectant often integrated into household personal care products, surface cleaners, and cosmetics. Consumer ADBAC usage has significantly increased due to the ongoing COVID-19 pandemic. Individuals discharge these chemicals into wastewater, where the contaminants persist and become a threat to aquatic organisms. Although researchers have identified ADBACs in environmental water samples at ug/L concentrations, few studies have examined their toxicological effects on fish. When fish are exposed to contaminants, they may develop molecular changes within their tissues and biofluids. Scientists can utilize proteomics to determine the effects of contaminants on protein abundance, and they can examine potential protein biomarkers that are tied to adverse outcome pathways. We aimed to utilize a proteomic approach to determine the effects of an ADBAC mixture on the fathead minnow (Pimephales promelas). We exposed 330 fathead minnows to 4 concentrations of a benzalkonium chloride mixture (0.02ug/L, 0.2ug/L, 2ug/L, and 20ug/L) and solvent control (0ug/L) over a 28-day period. Following the ADBAC exposure, we anaesthetized the fish with 100 mg/L pH buffered tricaine methanesulfonate. Then, we collected mucus, plasma, and tissue samples. Next, proteins were sequenced with liquid chromatography-tandem mass spectrometry. Simultaneously, the International Institute of Sustainable Development Experimental Lakes Area (IISD-ELA) is conducting a multi-year, whole-lake ADBAC exposure. In this presentation, we will share the methodology from both phases of the study. Additionally, we will highlight the preliminary plasma and gill proteomics results from the laboratory exposure.

1.04.P Molecular Ecotoxicology and Omics Perspectives: Advancing Mechanistic Understanding for Environmental Risk Assessment

1.04.P-We001 Role of Nutritional Status on Arsenic Toxicity in *Daphnia pulex*: A Combined Life History and Multi-Omics Perspective on Individual and Interactive Effects

***Emily Rose DeTemple*[1]*, Priyanka Roy Chowdhury*[2]*, Tom Hampton*[3] *and Joseph Shaw*[4]*, (1)Paul H. O'Neill School of Public and Environmental Affairs, Indiana University, United States, (2)Keene State College, United States, (3)Dartmouth College, United States, (4)Indiana University, United States*

Anthropogenic activities are readily introducing pollutants and altering nutrient availability into freshwater ecosystems. Activities such as mining, smelting, and fossil fuel extraction are releasing environmental pollutants such as arsenic, while degradation leads to alterations in crucial nutrients, such as phosphorus. Phosphorus is a critical nutrient for all organisms and alterations in their levels can lead to eutrophication. Food quantity (hereafter food) is crucial to organism metabolism and can influence toxicity of contaminants. While organisms within these environments experience these stressors simultaneously and influence toxicity of contaminants, there is limited research describing the interactive effect of multiple stressors on aquatic animals. Here we present a combined life history and multi-omics approach to evaluate the individual and interactive effects of food, food quality measured as phosphorus, and arsenic in aquatic keystone species, Daphnia pulex. We used a two-batch design for the multi-omic approach and to assess life history parameters. Batch A exposed D. pulex to arsenic (0.132 mg L?¹), while Batch B served as the control. Each batch was divided into treatments with high (3 mg C L?¹) or low (0.1 mg Carbon L?¹) food levels, and high (50 µmol P L?¹) or low (5 µmol P L?¹) phosphorus levels. Chronic exposure (40 days) to 0.132 mgC L?¹ arsenic under static renewal conditions was used. Differential gene expression analyzed using edgeR (p-value and FDR ? 0.05, log2 fold change ? 2). Gene Ontology (GO) and KEGG pathway analyses were conducted using topGO and our custom Pathway Enrichment Analysis Tool (PEAT). Metabolites were extracted from homogenized Daphnia and analyzed by mass spectrometry for protein identification. Results paralleled the life history and metabolomic findings with phosphorus alone and in conjugation with other factors resulted in the most significant effect. All data agree there was little arsenic effect. The interaction between phosphorus and arsenic exhibited the greatest differential gene expression with genes and pathways enriched for processes that affect development and energy production. There was no significance in the food and arsenic interaction. Our findings support that food, and phosphorus play differential roles in arsenic toxicity. This research demonstrates that coupling life history data with omics data, elucidates the complex connections between individual and sub-individual responses.

1.04.P-We002 Transcriptomic Fingerprinting of Pyriproxyfen and Abamectin Exposure in Zebrafish Embryos and Daphnia: Implications for Species Sensitivity and Risk Assessment

Steve Uwa Ayobahan[1], *Hannes Armin Reinwald*[2], *Julia Alvincz*[1], *Christoph Schafers*[1], *Elke Eilebrecht*[1] *and Sebastian Eilebrecht*[1], *(1)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Bayer AG, Crop Science Division, Germany*

The use of pesticides and biocides in agricultural and industrial applications raises significant concerns regarding their potential detrimental effects on aquatic ecosystems. These active substances can disrupt ecological balance, leading to adverse outcomes for both environmental health and biodiversity. Consequently, comprehensive environmental hazard and risk assessments are essential prior to the registration of any chemical substance. However, traditional risk assessment methodologies frequently overlook the importance of species-specific sensitivities. This oversight can lead to undetected long-term impacts, including developmental and behavioural disruptions. To address these challenges, this study employs transcriptomic analysis to investigate the molecular responses of two pesticides pyriproxyfen, a growth regulator acting as a juvenile hormone analog, and abamectin, a neurotoxic agent in zebrafish embryos and Daphnia, two widely utilized model organisms. Both species were exposed to sublethal concentrations of these pesticides. Although survival and hatching rates remained unaffected, transcriptomic analysis revealed distinct molecular responses. Exposure to pyriproxyfen significantly influenced genes related to hormonal regulation, neuronal development, and cellular processes associated with growth, suggesting potential endocrine disruption and developmental abnormalities. In contrast, abamectin primarily affected genes associated with mitochondrial function, oxidative stress, and neural apoptosis, indicating neurotoxic and metabolic disturbances. Notably, Daphnia exhibited greater sensitivity upon pyriproxyfen exposure compared to zebrafish embryos, underscoring species-specific differences in responses. Highlighting the elevated sensitivity of Daphnia relative to zebrafish embryos, this study advocates for a more refined understanding of pesticide impacts that considers species-specific responses. Such insights are crucial for developing robust risk assessment frameworks that accurately reflect the ecological risks associated with pesticide exposure, ultimately fostering responsible environmental stewardship.

1.04.P-We003 The Potential of OMICs in Anticipating and Differentiating Modes of Action of Fungicides

Fatma Marghany[1], *Steve Uwa Ayobahan*[1], *Christoph Schafers*[1], *Henner Hollert*[2] *and Sebastian Eilebrecht*[1], *(1)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Fungicides are widely applied to control fungal growth in agricultural and medicinal practices. However, due to their wide application, previous studies recorded residual concentrations of fungicides in the environment, making the contact between fungicides and environmental fauna and flora inevitable. Moreover, previous studies highlighted the adverse effects of fungicides with different modes of action (MoA) on non-target organisms. Together, the wide applications of fungicides along with their reported adverse effects on non-target organisms, highlight the importance of developing robust, cost and time-effective fungicidal hazard assessment approaches. In this study, we applied OMICs analysis to identify MoA-specific biomarker candidates, which may act as early indicators for ecotoxic MoA. First, the potential of OMICs approach to differentiate between two different MoAs was revealed by defining substance-specific biomarker candidates for two fungicides with two different MoAs, the sterol biosynthesis inhobitor difenoconazole (apoa1b, gatm, mylpfb and acta1b) and the nucleic acid metabolism inhibitor, metalaxyl (lgals2b, abat, fabp1b.1 and myh9a). Furthermore, we applied the approach to three azole fungicides with the same MoA (sterol biosynthesis inhibition). In addition to sterol biosynthesis inhibition in fungi, previous studies reported the endocrine disrupting effect of azole fungicides in fish. From the detected differentially expressed genes (DEGs), ugdh, gstt1b, pfkfb4b, fkbp5 and pnp4b were selected as biomarker candidates to predict endocrine disruption induced by sterol biosynthesis inhibition fungicide MoA in zebrafish embryos were defined. Additionally, we conducted functional analysis for the detected DEGs and integrated the obtained information to understand the potential ecotoxic MoA of fungicides in non-target organisms and study the relation between the detected molecular responses and the original MoA of the tested fungicide in the target organism according to fungicide resistance action committee (FRAC) classification. The defined biomarker candidates will act as pre-regulatory screening approach to anticipate ecotoxic MoAs of different classes of chemical substances in compliance to the 3Rs principle by providing early indications of the ecotoxic MoAs not approved for application in the European union such as endocrine disruption.

1.04.P-We004 A Transcriptomic Points of Departure Assay for Rainbow Trout Embryos: Comparisons with Fish Acute and Chronic Toxicity Data

Niladri Basu[1], *Emily Boulanger*[1], *Hugo Marchand*[1], *Krittika Mittal*[1], *Ke Xu*[1], *Aylish Marshall*[1], *Rebecca Dalton*[2], *Florence Page-Lariviere*[2], *Doug Crump*[2] *and Jessica Head*[1], *(1)McGill University, Canada, (2)Environment and Climate Change Canada (ECCC), Canada*
There is regulatory, scientific, and ethical interest in the development of alternatives to vertebrate animal toxicity tests. The objective of this study was to establish a high-throughput test method for embryo-larval fish that could yield data comparable to both fish acute (i.e., 96-hr LC50s) and chronic (i.e., long-term, sub-lethal) toxicity tests. Rainbow trout alevins (~1 day post-hatch) were placed in individual wells (24-well plates) and exposed for 24 hr to 12 different concentrations per chemical. To date, 39 chemicals with diverse physical and chemical properties have been studied, including negative controls (fish medium water or 0.5% DMSO). To eliminate the need for a range-finding test, test concentrations were based on a tapered design which included an LC50 push zone (10- and 100-fold higher than the empirical LC50s listed in the U.S. EPA ECOTOX Knowledgebase), transcriptomic point of departure (tPOD) zone (six concentrations below the LC50 range on a half log10 basis), and baseline zone (10- and 100-fold lower concentrations). Using this design, the exposure for ethanol was: 1000, 100, 10, 3, 1, 0.3, 0.1, 0.03, 0.01, 0.001, 0.0001, and 0 mg/L (covering 7 orders of magnitudes). Mortality during transport, rearing, hatching, and experimental phases were all lower than guidance from OECD236. To ensure repeatability of the results, copper sulfate was studied four times and yielded consistent LC50 values. Based on current data, the relationship between LC50 data from our work and that of fish acute studies (from databases) is near 1:1 with a r2 of about 0.9. A tPOD has been derived for six compounds (with sequencing data in hand for 18 more), and in all cases the tPOD concentration seems to be protective (i.e., lower than, or similar to) of values associated with sub-lethal outcomes from chronic bioassays. The findings thus far are promising in terms of establishing a new test method, though work continues to expand our sequencing efforts to yield more tPOD data, test more compounds, and deepen studies into exposure measures (i.e., nominal vs. modeled vs. measured). The work was funded by Genome Canada/Genome Quebec s GAPP program.

1.04.P-We005 Contribution of Dose-Response Modelling for Mechanistic Understanding of (Multi-)Omics Data and Risk Assessment

Elise Billoir[1], *Aurelie Siberchicot*[2] *and Marie-Laure Delignette-Muller*[3], *(1)LIEC, Universite de Lorraine, CNRS, France, (2)LBBE, Universite Lyon 1, CNRS, France, (3)LBBE, VetAgro Sup, Universite Lyon 1, CNRS, France*
Omics technologies has opened new possibilities to assess environmental risks and to understand the mode(s) of action of pollutants from the molecular level. Given their cost, they are usually employed in experimental designs where few conditions (e.g. 2 to 4 exposure concentrations) are compared to a control condition through differential analysis. However, in such studies, the results observed in each condition (up or down-regulations compared to the control, and fold change) are derived independently, hence limiting the relevance for risk assessment. In contrast, when coupled to dose-response experimental designs, omics technologies allow a non-targeted assessment of organism responses along an exposure gradient. Though describing the dose-response relationships on high-throughput data is no easy task, tools are now available for exploiting dose-response omics data (e.g. DRomics, FastBMD, BMDExpress), making use of the information all along the exposure gradient at each step. To begin, (1) they identify the items (e.g. transcripts, metabolites) that are significantly deregulated along the dose/concentration gradient. Then for each deregulated item, they (2) characterize its dose-response relationship using parametric modelling and (3) estimate from this model a sensitivity threshold as a benchmark dose (BMD). Resulting outputs synthesize the responses all along the exposure gradient and are full of meaning for risk assessment. Besides, in the light of biological annotation obtained from databases such as KEGG or Gene Ontology (GO), it is possible to look at pathway-wise points of departure towards a mechanistic understanding of dose-dependent omics data. After presenting the landscape of omics data analysis in (eco)toxicology, we will give an overview of the methodological choices we made in developing the DRomics tool. Our purpose was to rationalize and optimize a strategy to fully exploit dose-response omics data, not only focusing on monotonic responses (increasing, decreasing) but also biphasic responses (U and bell-shape) that are often encountered on omics. We will also illustrate on different case studies some functionalities recently added in DRomics to help the comparison of responses obtained at different experimental levels: different measurement levels (e.g. multi-omics), different exposure histories, time points, etc. Finally, we will discuss pending methodological challenges and open questions.

1.04.P-We006 Cellular Handling, Transformation Pathways and Metabolic Disturbances of Mercury in Freshwater Phytoplankton

Vera Slaveykova[1], *Joao Santos*[1], *Remy Millet*[1], *David Amouroux*[2] *and Arturo Keller*[3], *(1)University of Geneva, Switzerland, (2)Institut des Sciences Analytiques et de Physico-chimie pour l'Environnement et les materiaux, France, (3)University of California, Santa Barbara, United States*

Mercury, a priority pollutant, raises significant environmental concerns. While numerous studies have investigated mercury bioaccumulation and its impact on aquatic organisms, there is a gap in the understanding concerning its cellular handling and transformations, and disturbances of the metabolic pathways of phytoplankton species at the bottom of the food web. In such a context, this study aims to elucidate the mechanisms governing the cellular transformations and responses of phytoplankton to mercury exposure. The green alga Chlamydomonas reinhardtii and diatom Cyclotella meneghiniana were selected as representatives of major phytoplankton groups. These algae were exposed to 10 and 100 nM inorganic mercury (Hg(II)) and methylmercury (MeHg) for 72h. Mercury uptake, sub-cellular distribution, and physiological effects such as oxidative stress and photosynthetic yield were assessed. Simultaneously, over 90 metabolites, spanning antioxidants, amines, organic acids/phenolics, nucleobases/sides/tides, amino acids, sugars/sugar alcohols, and fatty acids, were quantified using liquid chromatography mass spectrometry. Cellular transformation including methylation/demethylation, reduction and oxidation as well as formation of HgS nanoparticles have been explored using double isotope Hg spiking (199Hg(II) and 201MeHg). Results demonstrated that C. meneghiniana exhibited higher mercury accumulation than C. reinhardtii at the same exposure concentrations. Subcellular distribution of mercury differed between the two species, with C. reinhardtii concentrating mercury predominantly in organelles, while the diatom exhibited mercury in both organelles and heat-stable peptides. Both algal species significantly demethylate methylmercury, whereas no measurable methylation of the inorganic mercury was found. A reduction of Hg(II) to Hg(0) were also found in both phytoplankton species. Physiological data matched metabolomic results, revealing substantial alterations in various pathways, including amino acids, nucleotides, fatty acids, the tricarboxylic acid cycle (TCA), and antioxidant metabolism. The findings reveal species-specific and concentration-dependent responses, providing new insights into mercury handling and metabolic reprogramming in phytoplankton. Understanding these processes is essential for assessing mercury's impact on aquatic primary producers and its potential trophic transfer, especially in contaminated environments. The authors thank Swiss National Science Foundation grants 175721 and 180186 for the financial support.

1.04.P-We007 Towards Mechanistic Understanding of Reduced Cell Proliferation: An RNA- and RIBOseq Approach

Sven Mosimann[1], *Barbara Jozef*[1], *Miha Tome*[2], *Anze Zupanic*[2] *and Kristin Schirmer*[1], *(1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)National Institute of Biology, Slovenia*

Fish are a highly diverse and ecologically important group of organisms that are exposed to a wide range of anthropogenic substances. While effects of toxic chemicals include both acute and chronic adverse outcomes, the latter seems to prevail in the natural environment. Therefore, ecotoxicological risk assessment is particularly interested in understanding the effects of prolonged chemical exposure to fish. One of the most often studied endpoints is organism growth. However, the assays usually conducted are not only under ethical scrutiny but also labour and time demanding. Therefore, new methods are desperately needed. While the OECD TG 249 already provides an alternative for the assessment of acute fish toxicity using the rainbow trout gill cell line, RTgill-W1, there is no such assay for chronic toxicity. However, building on the observation that larger animals have more cells instead of bigger ones, researchers from our group could demonstrate excellent predictive powers of the same cell line by taking cell number as proxy for organism size for a set of both structurally and functionally different chemicals. Nevertheless, the underlying molecular mechanisms and especially the points at which the different initially triggered biochemical pathways converge and lead to an arrest of the cell cycle remain unclear. In order to investigate the underlying molecular mechanisms, we exposed RTgill-W1 cells to a set of six different substances: 2-mercaptobenzothiazole, methimazole, propiconazole, tebuthiuron, topramezone and trifloxystrobin. While all six chemicals induced reduced cell proliferation, we found that derived EC50s correlate well with baseline toxicity QSARs. Next, in order to shed light on the underlying molecular mechanisms of reduced cell proliferation, we designed an experiment to analyse the transcriptome and translatome. Gene ontology and pathway analysis using KEGG revealed a regulation of the cell cycle after an only one-day long exposure to the two chemicals already fully assessed. Specifically, gene ontology analysis of the RNAseq data showed that the cell cycle is affected during mitosis or at the G2/M checkpoint. Further, we identified several genes that were regulated differently at the level of transcription and translation. Altogether, the results will not only help us deciphering the mechanisms of reduced cell proliferation upon chemical insult but will also test the predictive powers of cell-line based assays.

1.04.P-We008 Metabolomic and Transcriptomic Changes in Larval Zebrafish After Developmental Exposure to Aroclor 1254

Corey S Green[1]*, Jason Tyler Magnuson*[2]*, Ana Alonso*[3]*, Jean-Christophe Cocuron*[3]*, Michel Gielazyn*[4]*, Claire Lay*[5]*, Rachel Leads*[6]*, Lisa Rosman*[7]*, Daniel Schlenk*[8] *and Aaron P Roberts*[3]*, (1)Eastern New Mexico University, United States, (2)United States Geological Survey, Columbia Environmental Research Center, United States, (3)University of North Texas, United States, (4)National Oceanic and Atomospheric Administration, Assessment and Restoration Division, United States, (5)Abt Global, United States, (6)Michigan State University, United States, (7)National Oceanic and Atmospheric Administration, Assessment and Restoration Division, United States, (8)University of California Riverside, United States*
Polychlorinated biphenyls (PCBs) are long-lived synthetic compounds that were widely used until 1979. The neurotoxicity of Aroclor 1254, a commercial mixture of PCBs, has been well documented within mammalian species, however, the underlying mechanisms of toxicity have not been fully characterized, particularly in aquatic organisms. Previous research has shown that developmental exposure to Aroclor 1254 induced dose dependent tremors in the eyes of larval zebrafish (Danio rerio), indicating novel neurotoxic effects. Here, we used targeted metabolomics and transcriptomic profiling to investigate the neurotoxicological effects of Aroclor 1254 exposure at nominal concentrations of 500 µg/L to embryonic zebrafish for 96 h. There were significant differences between controls and Aroclor 1254 treated zebrafish larvae in proline, glutarate, asparagine, glycerol 3-phosphate, sucrose, threonine, and fructose 6-phosphate levels. Metabolites involved in neurotransmitter signaling pathways, such as glycine, tyrosine, and glutamine, had significantly different levels in Aroclor 1254 treated larvae, with top enriched pathways involved in lipid metabolism and xenobiotic response. Bioinformatic analyses utilizing transcriptomic data found that exposure to Aroclor-1254 consistently resulted in disruptions of pathways and networks related to visual function, nervous system function, protein synthesis, and other pathways related to embryonic development. These underlying pathways were supported by eye tremor phenotypes that were present in Aroclor 1254 exposed larvae. These results suggest that changes in the levels of metabolites involved in neurotransmitter function and dysregulations in genes within visual function pathways are likely responsible for the underlying eye tremor behavior and may serve as novel biomarkers in early life stage fish exposed to PCBs.

1.04.P-We009 Ecotoxicogenomic Hazard Assessment of the Artificial Sweetener Sucralose
Alexandra Loll[1]*, Annika Heinrich*[1]*, Christoph Schafers*[1]*, Henner Hollert*[2] *and Sebastian Eilebrecht*[1]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2) Goethe University Frankfurt, Germany*
The intensive consumption of artificial sweeteners has led to a global market revenue of more than 21 billion USD in 2021 and is expected to rise further. Mainly used as food additives, the high stability and water solubility of artificial sweeteners makes them perfect candidates as sugar alternatives. While the stability that comes with being calorie-free is an advantage in this case, it also makes them a potential threat to the environment due to the lacking degradation in waste water treatment plants. Consequently, they are released into the aquatic environment where they have proven to be persistent and mobile. Although researchers have described them as emerging contaminants for more than a decade, environmental hazard assessment data are still lacking. The few studies that have been carried out already revealed some ecotoxic effects such as neurotoxicity in zebrafish embryos caused by acesulfame or altered swimming behaviour of daphnids caused by sucralose. EFSA is currently re-evaluating the safety of artificial sweeteners, including environmental aspects. The use of OMICs for the required environmental hazard assessment offers many advantages, including time savings, insight into modes of action and reduction of animal testing. This project aims to gather data on the ecotoxicogenomic effects of the four most common artificial sweeteners sucralose, acesulfame, saccharin and cyclamic acid, using ecotoxicological model organisms from different trophic levels. First results showed that sucralose significantly altered gene expression of the aquatic plant Lemna minor, both, at the highest exposure of 100 mg/L and at the environmentally relevant concentration of 10 µg/L. Also, functional analysis provided hints on adverse effects caused by the substance. The Crustacean Daphnia magna and the teleost fish Danio rerio (embryo) were neither morphologically, nor molecularly affected by sucralose exposure in our experiments. The authors thank the German Federal Environmental Foundation for funding.

1.04.P-We010 Sex-Specific Behavioural Ecotoxicology and Transcriptomic Responses to Phenanthrene in the Amphipod *Parhyale hawaiensis*
Ibrahim Lawan*, Alastair Lyndon Robert and Theodore Burdick Henry, Heriot-Watt University, United Kingdom*
Polycyclic aromatic hydrocarbons (PAHs) are pervasive environmental contaminants that disrupt critical biological processes in marine organisms and pose significant risks to ecosystem health. Phenanthrene (PHE), a model PAH, exhibits gender-specific behavioural toxicity, yet the molecular mechanisms underlying these effects remain poorly understood. The objective of this study was to investigate

molecular mechanisms of behavioural ecotoxicity in the model tropical marine amphipod Parhyale hawaiensis. First, we determined the 96-hour LC50 of PHE and assessed the seven-day sublethal gender-specific behavioural impacts of PHE on adult P. hawaiensis. Organisms were subsequently exposed to a sublethal PHE concentration (100 µg/L) alongside solvent (DMSO) and seawater controls for transcriptomic profiling. Whole amphipods of each gender were collected at 0, 1, 4, 8, and 24 hours for RNA sequencing (RNA-seq) and to capture time- and sex-specific gene expression changes. Our findings reveal significant alterations in detoxification enzymes, neurotransmitter receptors, and heat shock proteins, with temporal variations in expression patterns. These results demonstrate the sensitivity of transcriptomics for revealing molecular responses to PHE exposure and their connection to behavioural disruptions. This integrative approach highlights the importance of combining molecular and behavioural analyses to improve ecological risk assessment and develop sensitive biomarkers for PAH toxicity. Lawan, I., was supported by the Petroleum Technology Development Fund (PTDF) Nigeria for academic sponsorship. The funder had no role in study design, data collection and analysis, decision to publish, or abstract preparation.

1.04.P-We011 Metabolomics Analysis for the Investigation of New Endocrine-Sensitive Endpoints in the Great Pond Snail *Lymnaea stagnalis*

***Gaetan Yannick Tucoo**[1], Jun Han[2], David Goodlett[2], Elvis Genbo Xu[1] and Henrik Holbech[1], (1)University of Southern Denmark, Department of Biology, Denmark, (2)University of Victoria Genome BC Proteomics Center, University of Victoria, Canada*

Aligned with the 3Rs principles, the use of invertebrates as model organisms is one of the possible new approach methodologies (NAMs) investigated in ecotoxicological testing. The great pond snail Lymnaea stagnalis is a promising model organism for the risk assessment of endocrine-disrupting chemicals (EDCs). However, important gaps remain in the understanding of the endocrine system of mollusks and other invertebrate species. Elucidating the potential endocrine-disrupting mechanisms of compounds of interest requires a foundational understanding of the cascade of biological events, from the molecular to the organism level. The elaboration of adverse outcome pathways (AOPs) is key in this process, and omics approaches can help to link observed adverse effects, to molecular mechanisms. In this study, we want to investigate the presence and the role of vertebrate-like thyroid hormones (THs) and steroid hormones (SHs) in the great pond snail L. stagnalis. Egg and tissue samples from our snail colony in Denmark (wild type, Danish origin) were collected and sent to the UVic Genome BC Proteomics Center in Victoria, BC, Canada, for analysis. After reception, samples < 100 mg were directly homogenized by bead beating in a DTT/ascorbic acid/citric acid (5:10:10 mg/mL) buffer, and samples > 100 mg were ground into powder using liquid nitrogen in a mortar and pestle prior to homogenization. Hormones were extracted by liquid-liquid extraction with ethyl acetate (EA). After centrifugation, the EA phase was dried under a flow of nitrogen and samples were reconstituted in MeOH/H2O (40:60 v/v). The LC-MS/MS system consisted in a reversed-phase C18 column (2.1 x 50 mm, 1.8 µm particle size, Agilent Technologies), hyphenated with a triple-quadrupole system (Agilent 6495B). Our first results suggest that we are able to detect certain THs and SHs in egg or tissue samples. Although the role of such hormones in invertebrates has yet to be clearly understood, our findings are aligned with results already published about THs and SHs in invertebrate species. We also are, to our knowledge, the firsts to use a highly sensitive and selective detection method to detect simultaneously THs and SHs in wild-type L. stagnalis.

1.04.P-We012 Disruption of Thyroid and Sex Steroid Hormones by Trioctyl Trimellitate in Zebrafish: Integrating Mechanistic and Transcriptomic Analysis

***Yunchul Ihn**[1], Yujin Park[1], Jihye Park[2], Na-Youn Park[3], Younglim Kho[3], Keunsoo Kang[2] and Kyungho Choi[1], (1)Seoul National University, Korea, Republic of, (2)Dankook University, Korea, Republic of, (3)Eulji University, Korea, Republic of*

Tris(2-ethylhexyl) trimellitate (TOTM) is a widely used alternative plasticizer to replace bis(2-ethylhexyl) phthalate (DEHP), especially in medical environments. Although considered safer than DEHP, studies on TOTM's toxicity remain limited. This study investigated the effects of TOTM on thyroid hormones, lipid metabolism, and sex steroid hormones in both embryo-larval and adult male zebrafish. Fertilized zebrafish eggs were exposed to TOTM (0, <0.047, 0.42, and 5.00 mg/L) for seven days and were evaluated for changes in thyroid hormone levels, transcriptional activity of thyroid-regulating genes, and potential disruptions in lipid metabolism and related gene expressions. Transcriptomic analysis was also performed on 7-day post-fertilization (dpf) zebrafish larvae following exposure to 0 and 5.00 mg/L TOTM. Additionally, adult male zebrafish were exposed to TOTM (0, <0.047, and 0.38 mg/L) for 21 days, where alterations in thyroid and sex steroid hormone levels and corresponding transcriptional changes were assessed. In 7 dpf zebrafish larvae, exposure to TOTM significantly increased whole-body TT4 and TT3 levels, and down-regulated genes such as crh?, trh, mct8, and nkx2.1b. In the transcriptomics analysis, a

total of 1,380 differentially expressed genes (DEGs) were identified, with an adjusted p-value below 0.05; 402 DEGs were up-regulated, and 978 DEGs down-regulated. Gene ontology (GO) analysis showed that up-regulated DEGs were mainly associated with RNA splicing, while down-regulated DEGs were linked to disrupted cholesterol homeostasis and steroid metabolic process. In adult male zebrafish, exposure to TOTM resulted in a significant decreasing trend in TT3 levels accompanied by up-regulation of tg, tpo, nkx2.1b, and dio3a genes in the thyroid gland, as well as down-regulation of the dio2 gene in the liver. Additionally, a significant increase in E2 levels with a decrease in 11-KT levels was observed, accompanied by up-regulation of genes such as vtg1, vtg2, and cyp19a1.
While making a direct comparison with other studies may be challenging due to variations in exposure periods and conditions, the current observations suggest that this alternative plasticizer could alter hormonal balances at different life stages of zebrafish. Consequences in their normal development and reproduction warrant further investigations. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through Core Technology Development Project for Environmental Diseases Prevention and Management, funded by Korea Ministry of Environment (MOE) (RS-2022-KE002173)

1.04.P-We013 Association Between Exposure to Environmental Pollutants and Non-Alcoholic Fatty Liver Disease (NAFLD) and Development of Hepatotoxicity Biomarker Using Zebrafish
*Yunji Lee[1], Kijeong Yun[2] and **Kyunghee Ji**[2], (1)Yong In University, Korea, Republic of, (2)Yongin University, Korea, Republic of*
Non-alcoholic fatty liver disease (NAFLD), characterized by over 5% fat accumulation in the liver without excessive alcohol use or other liver conditions, is increasingly prevalent among adolescents. Traditionally diagnosed through invasive liver biopsies, efforts are underway to improve non-invasive methods using biomarkers and imaging tools. This study explored the association between urinary metabolites of bisphenol A (BPA) and di-(2-ethylhexyl) phthalate (DEHP) with NAFLD in adolescents using data from the 3rd Korean National Environmental Health Survey (KoNEHS) and evaluated potential biomarkers in zebrafish models. Data from 831 adolescents aged 12 17 years were analyzed, calculating urinary BPA and DEHP metabolites (MEHHP, MEOHP) and classifying NAFLD based on serum alanine aminotransferase (ALT) levels (?25 U/L for males, ?22 U/L for females). Zebrafish embryos were exposed to BPA and DEHP (0.03 300 ?g/L), and enzyme-linked immunosorbent assay (ELISA) and real-time PCR were used to assess liver enzymes and expression of ER stress and apoptosis genes. Results showed that NAFLD was more prevalent among overweight or obese males. Higher urinary BPA and MEHHP levels correlated with elevated ALT, suggesting an increased NAFLD risk from environmental exposure. In zebrafish, BPA and DEHP exposure reduced body length and increased ALT activity at 30 300 ?g/L. Significant upregulation of chop, baxa, and bcl2a genes indicated ER stress and apoptosis, potentially linking these chemicals to liver damage. This study highlights the hepatotoxic effects of BPA and DEHP, identifying chop, baxa, and bcl2a as potential biomarkers for detecting NAFLD induced by environmental pollutants. These findings underscore the need to monitor and regulate BPA and DEHP exposure to protect adolescent health. This work was supported by National Research Foundation of Korea (NRF) grant funded by the Ministry of Science and ICT (MSIT) of South Korea (RS-2023-00251751).

1.04.P-We014 An Integrative Omics Approach for the Development of Conceptual Adverse Outcome Pathways: A Case Study Map[ing Metabolic Syndrome in Tributyltin-Exposed Adipocytes
*Dayna Schultz[1], **Fotini Nikiforou**[1], Ilias Frydas[1], Nafsika Papaioannou[1], Thanasis Papageorgiou[1], Katerina Gabriel[1], Spyros Karakitsios[1] and Denis Sarigiannis[2], (1) Aristotle University of Thessaloniki, Greece, (2)National Hellenic Research Foundation, Greece*
Metabolic syndrome (MetS) is a condition distinguished by co-occurring symptoms that is increasingly attributed to exposure to endocrine-disrupting chemicals (EDCs). It is characterised by cardiometabolic irregularities and is associated with increased risk of cardiovascular disease (CVD), non-alcoholic fatty liver disease (NAFLD), and type 2 diabetes (T2D). Using an adverse outcome pathway (AOP) framework, this study leverages an integrated multi-omic approach using both univariate and multivariate techniques, as well as network and clustering analysis, to better visualise the intricate relationships between perturbed features (PFs), pathways, and disease associations. More specifically, Simpson-Golabi-Behmel syndrome (SGBS) pre-adipocytes were exposed to tributyltin (TBT), a known lipogenic substance, to assess metabolite and transcript dysregulation. Cells were grown to near confluence, incubated in differentiation medium for 4 days, and cultivated in maintenance medium for 6 days. The differentiation medium of TBT-exposed cells was additionally supplemented with 25nM TBT during the initial 4 days. On day 10, TBT-exposed cells and differentiated controls were compared. Samples for untargeted metabolomics were analyzed using Reversed Phase (RP) and Hydrophilic Interaction (HILIC) Liquid Chromatography in positive and negative ionization modes. Transcriptomic analysis was performed using Agilent microarrays

to determine differentially expressed genes (DEGs). All data analyses took place in R. Data preprocessing, batch correction, and statistical analyses were conducted using xcms, IPO, PMCMRplus, and xMSannotator packages for metabolomics, and limma for transcriptomics. Pathway analysis was performed using KEGG, WikiPathway, and RaMP-DB databases in clusterProfiler and MetaboAnalystR while disease associations utilised DisGeNet. Cluster analysis using the Jaccard Similarity index was performed to group diseases and pathways based on their PF fingerprints. Six conceptual AOPs (cAOPs) were developed that link disruptions in widespread pathway-level perturbances to adverse outcomes like xanthomatosis, bone remodeling disorders, cardiac outcomes, NAFLD, and insulin resistance. The resulting AOPs were also supported by recent literature findings. This method will be applied in future studies to explore environmental exposures and their contributions to various disorders, ultimately aiding in risk assessment and the development of targeted interventions.

1.04.P-We015 Toxicophenomic Assessment of the Combined Effect of Metsulfuron-methyl Exposure and Drought on Sinapis Arvensis

Valentine Guzniczak *and Signe Jensen, Copenhagen University, Denmark*

The integration of the effect of climate change is a pressing challenge for risk assessment (RA), as traditional methods are inadequate for evaluating multiple stressors. Fortunately, new data types emerge and, with them, the potential to tackle this challenge and improve RA. For example, toxicophenomics, defined as the application of phenotyping techniques in ecotoxicological studies, can yield data on hundreds of endpoints over time, allowing to dynamically capture the stress responses. This study aims to investigate the combined effects of metsulfuron-methyl exposure and drought on wild mustard (Sinapis Arvsensis) over time using toxicophenomic data. We hypothesise that toxicophenomics data will provide additional knowledge compared to traditional methods, making it a leverage point to develop the next generation of approaches in RA. The experiment was conducted on wild mustard (Sinapis arvensis). Plants were sprayed with increasing doses of the herbicide metsulfuron-methyl and were subjected to three different drought regimes. The plants were monitored in a fully automated high-throughput phenotyping platform for three weeks after spraying. The measurements consisted of daily non-destructive measurements and destructive measurements at the end of the experiment. The data will be analysed by fitting dose-response models and extracting parameters of interest, such as the benchmark dose. Multispectral imaging will yield reflectance data, which will be used to calculate vegetation indices, and fluorescence data, which, in combination with the molecular analyses of secondary metabolites, will allow us to identify bio-signatures and assess early response to drought stress. Other non-destructive measurements will include the number of yellow pixels per image, thermal imaging, and polyphenol content. Destructive measurements include dry weight, height, and leaf area. The benchmark doses will allow us to compare the impact of herbicide dose under different drought regimes across endpoints and over time, which is a major improvement compared to previous studies which compare one endpoint at one time point. This study will shed light on the potential of toxicophenomic data to effectively assess multiple stressors and will guide the development of RA towards more reliable predictions of environmental outcomes. The methods and analysis can be applied to other chemicals, stressors, endpoints and species, making it relevant to many fields within RA. This work was supported by the Novo Nordisk Foundation.

1.04.P-We016 Evaluating the Potential of Bioactive Metabolites in Red Seaweed Extracts: Addressing Key Challenges Through Integration and Innovation of Cell Assays

Ilias Semmouri*, Friedel Dewulf and Jana Asselman, Ghent University, Belgium*

Food security is one of the biggest challenges in the 21st century. As the focus of food requirements shifts towards enhancing human health and preventing disease. Seaweed has garnered significant attention as a natural source of bioactive compounds but also as a source of environmental contaminants when cultured in or harvested from the field. However, current research provides little insight into the effects of entire seaweed extracts which contain complex mixtures of bioactive ingredients with potential environmental pollutants, nor do we fully understand the molecular mechanisms through which they act in human cells. This knowledge gap limits our ability to assess the true potential of seaweed and consequences of increased environmental pollution. Therefore, we explored the use of novel approach methodologies to evaluate the impact of both purified compounds derived from red seaweed on human cell lines, while also examining whole seaweed extracts for a comprehensive analysis. The red pigment R-phycoerythrin (R-PE) and the carbohydrate floridoside were evaluated, while aquatic seaweed extracts (in PBS solution) from three red algal species, i.e. Porphyra umbilicalis, Acrochaetium secundatum and Gracilaria gracilis were explored. Cytotoxic, antioxidant, and metabolic properties, as early biomarkers of adversity, were evaluated towards two human cell lines: colon adenocarcinoma Caco-2 cells and the acute monocytic leukemia cell line THP-1. Cell viability, metabolic, cytokine and ROS measurements were performed on

THP-1 and Caco-2 after exposure to the different treatments. As such, the integration of these data will allow us to improve our understanding of the specific roles of the molecules of interest in the corresponding extracts, which will be crucial for AOP development. Through this research, we aim to advance both the aquaculture as food safety fields by establishing quantitative links between molecular markers and the chemical composition of seaweed.

1.04.P-We017 De Novo Transcriptome Assembly and Annotation of *Gammarus pulex*: A Valuable Resource For Ecotoxicogenomics

***Camilo Escobar Sierra**[1], Sameer Hassan[2], Fabian Weichert[3], Henrik Aronsson[2], Kathrin P. Lampert[1], Henner Hollert[3], Thomas Backhaus[4] and Pedro Inostroza[4], (1)University of Cologne, Germany, (2)University of Gothenburg, Sweden, (3)Goethe University Frankfurt, Germany, (4)University of Gothenburg, Sweden and RWTH-Aachen University, Germany*

This study presents high-quality de novo transcriptome assemblies for Gammarus pulex, a freshwater amphipod used in ecotoxicological research. These novel transcriptomes will allow the exploration of molecular responses (i.e., biomarkers, metabolic pathways, and molecular diversity) to chemical pollution. Transcriptomes were assembled from specimens collected in streams and small rivers featuring distinct loads of micropollutants, including pesticides, pharmaceuticals, and industrial chemicals in Sweden and Germany. We generated three assemblies: German (DE), Swedish (SWE), and a combined DE-SWE assembly. Quality validation removed a substantial number of low-confidence sequences, enhancing the fidelity of the final assemblies. Taxonomic analysis showed over 90% of assignments attributed to eukaryotic taxa. The DE-SWE assembly captured the highest gene and transcript diversity, supporting a broad representation of biological pathways. Annotation revealed extensive functional information, with the DE-SWE assembly containing 8.8% of sequences with unique annotations and displaying enriched metabolic diversity. Functional pathway enrichment analyses highlighted conserved biological processes, including organonitrogen compound metabolism and intracellular transport. We observed unique enriched pathways which were site-specific. Molecular function analyses revealed catalytic activity and protein binding as dominant roles across assemblies, with greater diversity in DE-SWE. This dataset provides a valuable resource for ecotoxicogenomic research, offering comprehensive gene models and pathways that enhance understanding of G. pulex responses to environmental stressors and inform aquatic pollution management. Funding by the Swedish Research Council FORMAS is gratefully acknowledged (project MixTOX, grant No. 2020-00976). Additional funding was provided by the FRAM Centre for Future Risk Assessment and Management Strategies at the University of Gothenburg.

1.04.P-We018 AQUADIVERS: Employing Metabarcoding to Assess the Local Impact of Metal Emissions on Freshwater Biodiversity

***Vanessa de Almeida Moreira**[1], Karel Viaene[2], Jana Asselman[3], Charlotte Nys[2] and Karel De Schamphelaere[1], (1)GhEnToxLab - Ghent University (UGent), Belgium, (2)ARCHE Consulting, Belgium, (3)Blue Growth Research Lab, Ghent University, Belgium*

Environmental monitoring of chemicals compares contaminant thresholds set by ecotoxicological testing with measured concentrations to avoid impacts on biodiversity. Ex-situ ecotoxicological assays typically use isolated pollutants on single-species individuals, which do not capture the complexity of natural communities, their interspecies interactions, or the combined effects of multiple pollutants. Moreover, traditional taxonomic approaches for biodiversity assessments come with limitations, including being impractical, not cost-effective, prone to misidentification, and insufficient consideration of whole-community impacts or key trophic and functional dynamics essential to ecosystem health. The AQUADIVERS project aims to address these gaps by assessing freshwater quality and biodiversity (focusing on eukaryotic organisms) at sites upstream and downstream of emission points of metal industry plants in Flanders, Belgium, while also examining additional impacts (e.g. on taxa richness) on freshwater ecosystems. This study employed a community-based approach, leveraging high-throughput environmental DNA (eDNA) metabarcoding techniques, which rely on the amplification and sequencing of genetic markers to identify multiple species within a sample. This approach moves beyond conventional monitoring methods and enable comprehensive biodiversity analysis. Alongside standard water quality measures, which included metal concentrations, organic carbon, and nutrients, this research investigated the eukaryotic microbial diversity within stone and glass periphyton (18S rRNA gene metabarcoding) at stations upstream and downstream of metal industry effluent discharge. The abundance of eukaryotic taxa, particularly diatoms (in line with regulatory guidelines) was used to calculate biodiversity indices for each site. Studying the relationship between taxa abundances, biodiversity indices and environmental stressors (e.g. metal concentrations) aided in identifying potential metal-sensitive and metal-resistant taxa and indicating if metal emissions were disrupting the local biodiversity. This highlights how metabarcoding, with its ability to detect diverse taxa and quantify their responses to

environmental pressures, can provide a powerful tool for biodiversity assessments, offering detailed insights into ecosystem health. This project is funded by Eurometaux and VLAIO (Flemish Agency for Innovation and Entrepreneurship).

1.04.P-We019 Aerial eDNA – A New Approach to Identify and Monitor Species in Farmland: A Pilot Study

Sabina Ramirez, Theo Kruger, Eric Linster, Michael Riffel, ***Martin Vallon*** *and Jan-Dieter Ludwigs, Rifcon, Germany*

All species leave DNA traces in the environment. Environmental DNA (eDNA) is released by any organism into the environment, via breathing, faeces, hair, urine, skin, gametes, etc. This eDNA can be extracted from environmetal samples such as soil, water or faeces without capturing potential target organisms in focus, even if it is not known whether the target organism is occurring in the sample area. More recently, studies have revealed that air also serves as a medium for transporting DNA. Approaches focussing on eDNA to monitor species are now widely recognized as a valuable tool for Biodiversity assessments. In our study conducted in a farmland landscape in southwestern Germany. We investigated the potential of aerial eDNA sampling for identifying species or specific taxonomic groups within the contexts of agrochemical registration procedures with a particular emphasis on vertebrates, because for the European environmental risk assessment of agrochemicals species of birds, mammals and other vertebrates utilizing cropped fields, need to be known and monitored. We explored the effectiveness of active and passive air sampling devices. Both type of air samplers were placed in two different sites for 24h or 2 weeks, respectively. After the sampling, DNA was extracted from the filters using the DNA blood and tissue extraction kit. Afterwards, two different genetic markers (12S and 16S) targeting vertebrates, were amplified via polymerase chain reaction PCR. Following PCR-based amplification, amplicons were sequenced using the real-time portable nanopore sequencing. The sequencing data was analysed using the National Center for Biotechnology Information (NCBI) public genetic reference for the identification of present species available in the data base.
Our initial results are promising, showcasing potential for widespread application of eDNA sampling and analysis for species detection, monitoring and finally complete biodiversity surveys, and the use of these non-invasively and time-saving method in the context of species, crop or farmland community based environmental agrochemical assessments.

1.04.P-We020 Metabolomics Reveal Polyethylene Terephthalate Microplastic-Induced Metabolic Disturbances Dependent on Different Shapes and Sizes

Kiyun Park*, Ji-Hoon Kim, Won-Seok Kim and Ihn-Sil Kwak, Chonnam National University, Korea, Republic of*

Microplastics (MP) are ubiquitously in aquatic environments. Their potential impacts and integration into the food web cause global concern. They are frequently found in marine organisms and environments with diverse shapes, sizes, and characteristics. In this study, we used the Mediterranean mussel Mytilus galloprovincialis as a marine benthic organism model to investigate the metabolic consequences of exposure to different polyethylene terephthalate MP sizes and shapes: round (27 32 ?m), small fibers (200 400 ?m), large fibers (3000 ?m), small fragments (20 ?m), medium fragments (45 75 ?m), and large fragments (>150 ?m). After exposure to high concentrations of MP for 14 days, round and small fiber-type MP were highly accumulated in mussels. Metabolomic analysis revealed that exposure to round and small fiber-type MP induced significant changes in 150 metabolites. Partial least squares-discriminate analysis (PLS-DA) showed that the round and small fiber MP treatment groups displayed similar cluster patterns that differed from those of the control group. In addition, only 22 annotated metabolites related to histidine, valine, leucine, and isoleucine degradation/biosynthesis and vitamin B6 and aminoacyl-tRNA biosynthesis were significantly affected by round or small fiber-type MP. Among the histidine metabolites, round and small fiber-type MP upregulated the levels of L-histidine, L-glutamate, carnosine, imidazole-4-acetaldehyde, 4-imidazolone-5-propanoate, and methylimidazole acetaldehyde and downregulated methylimidazole acetic acid and N-formimino-L-glutamate. These results suggest novel insights into the potential pathways through which MP of specific sizes and shapes affect metabolic processes in mussels.

1.04.P-We021 Transcriptomic Analysis of *Daphnia magna* Following Exposure to Biodegradable and Conventional Microplastics: Insights Into Molecular Toxicity Pathways

Nik Nurhidayu Nik Mut[1]*, Zhihan Cao*[2]*, Changhae Kim*[3] *and jinho jung*[3]*, (1)Korea University, Malaysia, (2)Korea University, China (Mainland), (3)Korea University, Korea, Republic of*

Traditional toxicity assessments often reveal minimal phenotypic responses in Daphnia magna exposed to biodegradable or conventional microplastics, suggesting that endpoints such as growth and reproduction may not fully capture the toxicity of these materials. To detect significant differences, studies often use unreasonably high microplastic concentrations, leading to conclusions that may not accurately reflect the actual impacts of microplastics on aquatic organisms. In contrast, transcriptomic analysis offers a highly sensitive approach to detecting gene expression changes caused by environmental pollutants, including microplastics. This study conducted a 21-day chronic exposure test on D. magna using polylactic acid (PLA) and polyethylene terephthalate (PET) microplastics. After the exposure period, RNA sequencing was performed to analyze transcriptomic changes. It is anticipated that distinct gene expression profiles will emerge across the control, biodegradable, and conventional microplastic exposure groups. These transcriptomic changes are expected to reveal both unique and overlapping molecular pathways affected by each type of microplastic. This study aims to provide valuable insights into the molecular mechanisms of microplastic toxicity and to identify potential biomarkers for exposure to biodegradable and conventional microplastics, offering a deeper understanding that cannot be achieved through phenotypic assessments alone. This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-RS202400335682)

1.04.P-We022 Size- and Shape-Dependent Toxicity of Microplastics on the Marine Rotifer *Brachionus koreanus*: In Vivo Toxicity and Multi-Omics Approach

Je-Won Yoo[1], Youn-Ha Lee[1], Jong-Seok Park[1], Tae-June Choi[1], Tae-Young Jeong[2], Chang-Bae Kim[1] and ***Young-Mi Lee***[1]*, (1)Sangmyung University, Korea, Republic of, (2)Hankuk University of Foreign Studies, Korea, Republic of*

The marine microplastic (MP, < 5mm) pollution has become a major environmental issue worldwide. As the small particulate pollutants similar in size to prey, MPs can be readily consumed by aquatic organisms, including small zooplanktons, leading to various toxic effects. Previous studies suggest that the physical properties of MPs such as size and shape are important to determine their toxicity, but underlying mechanisms of size- and shape-dependent toxicity of MPs are not well-understood. Thus, in this study, we investigated multigenerational chronic toxicity of MPs of different sizes and shapes (fragment-S, 0.5-µm; fragment-L, 5-µm; bead-S, 0.74 to 4.99-µm; bead-L, 3 to 16-µm) to the marine rotifer Brachionus koreanus. Subsequently, to determine underlying toxic mechanisms of MPs, transcriptomic and metabolomic modulation in B. koreanus were analyzed following acute MP exposure. The chronic toxicity test showed that fragment-S significantly reduced fecundity of rotifers, which was enhanced by following generations (F1 and F2). In contrast, other MPs didn t affect reproduction of rotifers. Transcriptomic analysis showed that 187 and 151 number of genes were significantly modulated after exposure to 5 mg/L of fragment-S and fragment-L, respectively, whereas only 4 and 2 genes were significantly affected at the same concentration of bead-S and bead-L, respectively. Metabolic analysis also showed that the most significant metabolomic changes were observed in the group exposed to fragment-S (5 mg/L; 304 metabolites), followed by fragment-L (5 mg/L; 178 metabolites), but not in groups exposed to spherical MPs (less than 11 metabolites at the same concentration). The gene ontology (GO) and pathway analysis revealed that the major toxic mechanism of MPs is disruption of metabolic processes, such as metabolism of carbohydrate, lipid, and protein, and secretion of digestive enzymes, which was more significantly modulated after exposure to fragment-S. In addition, stress response and cell signaling pathways were mostly affected by fragmented MPs, especially fragmented-S, implying different toxic mechanisms of MPs depending on their size and shape. Our findings suggest that MPS can negatively affect population of marine biota through disturbing their energy metabolism, which can be enhanced with smaller and rougher MPs. This finding gives us an insight into the risk assessment of MP in marine environments. This research was supported bythe Risk assessment to prepare standards for protecting marine ecosystem of the Korea Institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220383).

1.04.P-We023 An Integrated Multi-Omics Approach to Uncover the Shape-Dependent Toxicity Mechanisms of Microplastics in Juvenile Rockfish *Sebastes schlegeli*

Kwang-Min Choi*, Jee hyun Jung and Seong Hee Mun, Korea Institute of Ocean Science & Technology (KIOST), Korea, Republic of*

Microplastics (MPs) of various sizes and shapes are formed through the degradation of plastic debris in marine environments. While continuous exposure to MPs is a concern, the impact of MP morphology on aquatic organisms remains relatively unexplored. This study investigated the toxic effects of two common MP shapes, fragments and fibers, on juvenile black rockfish (Sebastes schlegeli). Fish were exposed to concentrations of 0.2, 2, 20, and 400 mg/L of each MP type. Although no significant mortality was observed, exposure to both MP types induced cytotoxicity, as evidenced by alterations in apoptosis, phagocytosis, and cell cycle progression. Notably, fiber-shaped MPs exhibited greater toxicity compared to fragments. Transcriptomic analysis revealed differential gene expression patterns between the two MP types. Exposure to fiber-shaped MPs resulted in a more pronounced downregulation of genes involved in immune response and cellular homeostasis. Metabolic analysis identified significant alterations in purine and arachidonic acid metabolism pathways. Our findings highlight the importance of considering MP morphology in assessing ecological risk. The observed shape-dependent toxicity of MPs can inform future pollution management strategies and environmental monitoring programs.

1.04.P-We024 Comparing In-Silico Predicted and Observed Transcriptomic Responses of *Gammarus pulex* to Micropollutants in Germany

Pedro Inostroza[1], *Camilo Escobar Sierra*[2], *Fabian Weichert*[3], *Patrik Svedberg*[4], *Henner Hollert*[3] *and Thomas Backhaus*[5], *(1)RWTH-Aachen University, Germany, (2)Universitat zu Koln, Germany, (3) Goethe University Frankfurt, Germany, (4)University of Gothenburg, Göteborg, Sweden, (5)Institute for Environmental Research, RWTH-Aachen University, Germany*

Chemical pollution is recognised as one of the major drivers influencing the ecological status of aquatic ecosystems. Micropollutants are organic chemicals occurring at trace environmental contractions, including pesticides, pharmaceuticals, personal care products, and industrial chemicals among other, which have raised concern due to their negative impact on aquatic organisms. Some of these chemicals have known mode and mechanism of action (e.g., neonicotinoid insecticides altering nicotinic acetylcholine receptors). Nevertheless, for many chemicals their mode of action is unknown. Aquatic benthic invertebrate fauna represents one of the Biological Quality Elements, which is used to determine the Ecological status of surface water bodies according to the EU Water Framework Directive. They are therefore extensively used as biological indicators to assess water quality. Nevertheless, a thorough understanding of the adverse biological consequences of micropollutant mixtures at the pathway level under real exposure conditions is still absent. In this study, we used in-silico predictions to assess the interaction of micropollutants with proteins and subsequently enrichment pathways analyses were conducted to identity pathways of interest. In addition, we used. RNA-based-sequencing (transcriptomic) approach on Gammarus pulex populations, shredder invertebrates, across a gradient of stations with increasing chemical pollution in the River Holtemme. Non-targeted gene assessment reveals alterations in gene expression, with an increasing number of differentially expressed genes (DEGs) downstream of chemical pollutant influences. Notably, a station downstream of a wastewater plant exhibits up to 6014 DEGs compared to the reference site. Our findings indicate a significant upregulation of invertebrate DEGs downstream of wastewater treatment plants. Furthermore, a pathways enrichment analysis identifies over-represented gene classes in categories such as nervous system development, carcinogenesis, and stress response across all stations under micropollutant stress. Thus, our results link observed biological responses to specific chemical groups, shedding light on the intricate interplay of micropollutants and their impact on freshwater macroinvertebrates in freshwater ecosystems.

1.04.P-We025 Temporal Trends in Transcriptomic Changes Induced by Suspended Particulate Matter Extracts in Zebrafish Embryos

Vanessa Runge[1], *Sarah Johann*[1], *Sebastian Eilebrecht*[2], *Bernd Gockener*[2], *Jan Koschorreck*[3] *and Henner Hollert*[1], *(1)Goethe University Frankfurt, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany, (3)Federal Environmental Agency Germany (UBA), Germany*

Over the years, organic contaminants have affected aquatic ecosystems such as rivers, often reaching concentrations that pose risks to exposed biota. In the context of assessing complex environmental samples, (higher throughput) screening methods are gaining importance as tools for research and potential regulatory application. The presented project aims to evaluate the integration of effect-based approaches, such as modified acute fish embryo toxicity test (FET) including transcriptomics, into environmental monitoring. As a proof of concept, the ecotoxicological potential in the river Rhine will be assessed by testing extracts of suspended particulate matter (SPM) samples from the Federal Environmental Specimen Bank (ESB) in the zebrafish embryo model, particularly investigating temporal and spatial trends. SPM samples from the Rhine at Weil and Koblenz from the years 2005 to 2021 were provided by the German ESB and extracted using the pressurized liquid extraction. In a range-finding FET with Danio rerio, lethal as well as a wide range of sublethal effects were observed in concentrations from 1.25 to 20 mgSEQ/mL. Embryotoxicity varied between both sites and throughout the time series with higher effects for Weil in the years 2005 and 2009 and for Koblenz in 2013 and 2017. For transcriptome analysis, embryos will be exposed to sublethal (10%-) effect concentrations. To identify potential chemical groups as drivers of toxicity, data will be correlated with existing chemical profiles of the SPM samples. Additionally, transcriptome results from the zebrafish will be compared to those from Abramis brama samples from the same years and locations to better understand the relevance of laboratory exposure experiments for real environmental scenarios and the relevance of screening methods for monitoring.

1.04.P-We026 Effects of Alternative Phthalates on Growth Hormone-Related Endocrine System, Neurobehavioral Development and Oxidative Stress in Zebrafish Larvae

Kyunghee Ji *and Kijeong Yun, Yongin University, Korea, Republic of*

Although there is growing concern about the presence of alternative phthalates in the environment, knowledge about their potential toxicity is quite limited. In this study, we evaluated the growth hormone (GH)/insulin-like growth factors (IGFs)-related endocrine system, neurobehavioral development, and oxidative stress induction of acetyl tributyl citrate (ATBC), acetyl triethyl citrate (ATEC), dibutyl adipate (DBA), and di-(2-ethylhexyl) adipate (DEHA) using zebrafish embryo/larvae. Zebrafish embryos were exposed to ATBC, ATEC, DBA, and DEHA (0, 0.03, 0.3, 3, 30, and 300 ?g/L) for 96 h, and changes in developmental parameters, behavior, hormones and gene transcriptions related to GH/IGFs axis, reactive oxygen species, and antioxidant enzymes were measured. ATBC exposure reduced body length and moving distance of larvae, while no significant effects on development and behavior were observed in larvae exposed to ATEC, DBA, and DEHA. Hypoactivity, decreased levels of GH, IGF-1, and acetylcholinesterase activity, and down-regulation of genes involved in central nervous system were observed in fish exposed to ATBC. The levels of superoxide dismutase, catalase, and glutathione peroxidase were significantly increased in fish exposed to ATBC. Pretreatment with N-acetylcysteine alleviated ATBC-induced GH-related endocrine disruption and neurobehavior toxicity. The results of this study revealed that behavior impairments and developmental delay induced by ATBC exposure are attributed to oxidative stress. This study was supported by the National Research Foundation of Korea (NRF; Project no. RS-2023-00251751).

1.04.P-We027 Investigation of Adverse Outcome Pathways Associated with Preeclampsia and Use of Zebrafish to Screen Environmental Pollutants

Inhye Lee[1]*, Kyungho Choi*[1] *and Kyunghee Ji*[2]*, (1)Seoul National University, Korea, Republic of, (2) Yongin University, Korea, Republic of*

Preeclampsia is a pregnancy disorder characterized by high blood pressure and proteinuria. Preeclampsia can lead to severe complications for both mothers and babies, including placental abruption and stillbirth. The heritability is estimated to be approximately 55%, and contributing factors include maternal nutritional deficiencies and exposure to environmental pollutants such as cadmium, bisphenol A, and phthalates, etc. Understanding the important causes of preeclampsia is essential to identify risks and screening chemicals associated with its development. Although zebrafish lack a placenta, they express genes such as vegfaa, sflt-1, eng, and hif1aa, which are orthologous to human genes involved in preeclampsia. Zebrafish shared some of their molecular mechanisms with humans, making them a useful model to study preeclampsia. In this study, adverse outcome pathways (AOPs) were investigated to identify molecular initiating events (MIEs) and key events (KEs) relevant to preeclampsia. Important angiogenic markers, including vascular endothelial growth factor (VEGF), soluble fms-like tyrosine kinase-1 (sFLT-1), soluble endoglin (sEng), and placental growth factor (PIGF), were evaluated along with pathways associated with exposure to environmental pollutants. An AOP tree was constructed to compare preeclampsia-related mechanisms between humans and zebrafish. The renin-angiotensin-aldosterone system (RAAS) pathway was selected for experimental validation. Zebrafish embryos were exposed to vatalanib, a VEGF receptor inhibitor, at concentrations of 0, 40, 200, and 1000 ?g/L for 96 h. VEGF protein levels were measured using enzyme-linked immunosorbent assay, and gene expression for vegfaa, sflt-1, eng, and hif1aa was analyzed using quantitative real-time polymerase chain reaction. Proteinuria was assessed using BCA protein assay kits. Vatalanib exposure altered VEGF levels and the expression of angiogenesis-related genes, indicating potential impacts on angiogenic pathways. Results indicate that zebrafish angiogenic biomarkers, including VEGF, vegfaa, sflt-1, hif1aa, and eng, are valuable for studying preeclampsia mechanisms. These findings suggest the potential of zebrafish as a predictive model for identifying chemicals linked to preeclampsia. Further studies are needed to investigate the effects of various environmental pollutants on the angiogenic pathway in zebrafish. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through Core Technology Development Project for Environmental Diseases Prevention and Management, funded by Korea Ministry of Environment (MOE) (RS-2022-KE002173)

1.04.P-We028 Transcriptomic Responses of Embryonic Flounder (*Paralichthys olivaceus*) to Hull In-Water Cleaning Wastewater Exposure

Seong Hee Mun*, Kwang-Min Choi and Jee hyun Jung, Korea Institute of Ocean Science & Technology (KIOST), Korea, Republic of*

Antifouling paints, which contain biocidal compounds, are applied to boat and ship hulls to prevent or minimize the attachment of fouling organisms. Despite the potential toxicity risk associated with these pollutants, there is a limited number of studies investigating and monitoring the toxic effects on embryonic fish using hull in-water cleaning (IWC) wastewater collected from ship. In this study, hull IWC wastewater from ship was collected from a ship in 2022 and toxic effect assessments were conducted on fertilized embryonic Olive flounder (Paralichtys olivaceus). After dividing the IWC wastewater into untreated wastewater and filtered wastewater, fertilized embryos were exposed to various dilution factors (10-, 100-, and 1000-fold dilutions). Chemical analysis of the IWC wastewater revealed high proportions of Cu, Fe, and Zn. There was no significant difference in the mortality of embryonic flounder exposed to untreated wastewater compared to filtered wastewater. However, malformations in morphogenesis, including pericardial edema, dorsal curvature, tail fin fold defects, and developmental delays, were observed in fertilized embryos following exposure to IWC from ship. To understand the molecular biology of malformation, eight genes related to (heart formation (nkx2.5, NK2 NK2 homeobox 5; SOX6, SRY-box containing gene 6; robo1, roundabout receptor1), bone malformation (bmp4, bone morphogenetic protein 4), fin malformation (plod2, procollagen-lysine 2-oxo-glutarate 5-dioxygenase 2, furin, furin, paired basic amino acid cleaving enzyme; wnt3a, Wnt family member 3a), and tumors (TP73, tumor protein p73) were evaluated using qRT-PCR. To clarify the potential toxic effects of IWC wastewater, we also conducted RNA-seq (high-throughput sequencing) on embryonic flounder exposed to hull IWC wastewater. In embryonic flounder exposed to IWC wastewater, genes related to nervous system development, cell development, muscle development, and animal organ development pathways were significantly differentially expressed. This study provided crucial evidence of the risks associated with IWC wastewater when exposed to marine organisms. Taken together, these results may inform strategies to improve hull-cleaning wastewater pollution management to better protect coastal ecosystems.

1.04.P-We029 Analyzing the Metabolic Effects of Nitrobenzene Exposure in Japanese Medaka (*Oryzias latipes*) with Consideration of Reproductive Cycle

***Jaehyeon Park** and Sang Don Kim, School of Environment and Energy Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of*

For impact investigation of chemical accidents in Korea, National Institute of Chemical Safety suggest the Criteria for calculating damage scale. Among them, in the case of biological resources, damage caused by chemical is recognized when death, disease, abnormal behavior, physical dysfunction, and external deformation occur. However, based on the current standards, the damage can be recognized only visually identifiable damaged fish, determining damage based on abnormal behavior or alteration of appearance is subjective and unclear. As a result, there is no standard for assessing the damage to fish that were near the accident site but did not die, even though they may have been affected by chemicals invisibly. Therefore, it is crucial to establish accurate standards for distinguishing fish damaged by chemicals. We chose nitrobenzene as an experimental chemical, because it is a highly toxic chemical to fish and showing a lot of usage in Korea. Therefore, this research investigates the impact of nitrobenzene on fish metabolism, particularly in Japanese medaka (Oryzias latipes), considering their reproductive cycle. We selected a sampling method to acquire samples from both the control and experimental groups as a singular entity, involving the concentration and measurement of extracorporeal metabolites released into the media over a designated time interval. We sampled four times a day in accordance to verify metabolic changes, which are characterized by daily ovulation. In this study, an investigation of the impact of both the reproductive cycle and nitrobenzene exposure on the extracorporeal metabolites of medaka was undertaken. distinctive identification of metabolites that exhibited a notable decrease post nitrobenzene exposure, as compared to their pre-exposure state, indicated an encompassing influence on the reproductive cycle. In further, enumeration and annotation of metabolites displaying significant changes in each analysis will be conducted. Subsequently, we will identify biomarkers to differentiate changes attributed to the reproductive cycle and those induced by nitrobenzene exposure. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Advanced Technology Development Project for Predicting and Preventing Chemical Accidents Project, funded by Korea Ministry of Environment (MOE) (2022003620001).

1.04.P-We030 Investigating the Effects of N-alkyl Dimethyl Benzyl Ammonium Chloride (ADBAC) on the Fathead Minnow (*Pimephales promelas*) Proteome, in a Two-Phase Approach and as Part of a Whole-Ecosystem Study

***Raina Mackenzie Kerr Hubley**[1], Theresa Warriner[1], Lauren Timlick[2], Vince Palace[3] and Denina B.D. Simmons[1], (1)Ontario Tech University, Canada, (2)International Institute of Sustainable Development-Experimental Lakes Area, Canada, (3)International Institute of Sustainable Development-Experimental Lakes Area & University of Manitoba, Canada*

N-alkyl dimethyl benzyl ammonium chloride (ADBAC) is a chemical disinfectant often integrated into household personal care products, surface cleaners, and cosmetics. Consumer ADBAC usage has significantly increased due to the ongoing COVID-19 pandemic. Individuals discharge these chemicals into wastewater, where the contaminants persist and become a threat to aquatic organisms. Although researchers have identified ADBACs in environmental water samples at ug/L concentrations, few studies have examined their toxicological effects on fish. When fish are exposed to contaminants, they may develop molecular changes within their tissues and biofluids. Scientists can utilize proteomics to determine the effects of contaminants on protein abundance, and they can examine potential protein biomarkers that are tied to adverse outcome pathways. We aimed to utilize a proteomic approach to determine the effects of an ADBAC mixture on the fathead minnow (Pimephales promelas). We exposed 330 fathead minnows to 4 concentrations of a benzalkonium chloride mixture (0.02ug/L, 0.2ug/L, 2ug/L, and 20ug/L) and solvent control (0ug/L) over a 28-day period. Following the ADBAC exposure, we anaesthetized the fish with 100 mg/L pH buffered tricaine methanesulfonate. Then, we collected mucus, plasma, and tissue samples. Next, proteins were sequenced with liquid chromatography-tandem mass spectrometry. Simultaneously, the International Institute of Sustainable Development Experimental Lakes Area (IISD-ELA) is conducting a multi-year, whole-lake ADBAC exposure. In this presentation, we will share the methodology from both phases of the study. Additionally, we will highlight the preliminary plasma and gill proteomics results from the laboratory exposure.

1.04.P-We031 Chronic Pollutant Exposure: Implications for Estuarine Fish Under Multi-Stressor Conditions

Juliane Schulte *and Andrej Fabrizius, University of Hamburg, Institute for Cell and Systems Biology of Animals, Molecular Animal Physiology, Germany*

Estuaries are subject to a range of environmental and anthropogenic stressors, particularly pollutants, which pose significant risks to aquatic life. Current research on the impacts of pollution and associated dose-response relationships in aquatic organisms tends to focus on single-treatment experiments in controlled laboratory settings with relatively short exposure durations. However, real-world estuarine environments often involve chronic exposure to complex mixtures of pollutants, exacerbated by additional stressors such as rising temperatures and hypoxia. These factors may interact in ways that are either synergistic or antagonistic, complicating the understanding of their cumulative effects. This study aims to investigate the impact of chronic exposure to micropollutants on two fish species within the Elbe estuary. Employing transcriptomic analyses, comet assays, and tissue anaylsis, samples were collected from five stations along the estuarine gradient across three seasons. The study builds upon a xenobiotic stress response observed in a previously conducted extensive transcriptomic data set. Given that molecular stress responses to pollution are known to intersect with pathways activated by hypoxia and elevated temperatures, the hypothesis is that chronic exposure to micropollutants may compromise the resilience of estuarine fish populations to climate change. This investigation aims to enhance understanding of how environmental pollutants impact aquatic organisms in the context of multi-stressor scenarios. This research is conducted in the research training group 2530 funded by the German Research Foundation.

1.04.P-We032 Optimization of Non-Lethal Fish Epidermal Mucus Collection Methods for Remote Fieldwork, Community-Based Monitoring, and Community Science

Keisha Ann Deoraj[1], Theresa Warriner[1], Michael Wilkie[2] and ***Denina B.D. Simmons****[1], (1)Ontario Tech University, Canada, (2)Wilfred Laurier University, Canada*

Fish epidermal mucus is one of the first lines of defence against chemical, physical and biological stressors. Acting as a natural, semi-permeable, chemical and biological barrier, fish epidermal mucus plays a critical role in the animal s immunological and protective function due to its mechanical and biochemical properties. As such, fish epidermal mucus is a repository of numerous innate and acquired components of immunity. Fish epidermal mucus is produced and sloughed off continuously, allowing for its non-invasive collection with relative ease compared to other methods (i.e., blood and tissue sampling). Mucus collection methods can be conducted with relative ease in a laboratory setting, but collection, handling, and preservation methods need to be developed and optimized for remote field sampling. The goal of this study was to optimize current fish epidermal mucus collection methods for remote field settings by testing if we could collect epidermal mucus on paper wipes (i.e., Kimwipes) and allowing them to air-dry, thereby eliminating the need for immediate laboratory interventions (i.e., reagent addition, centrifugal filtering, and cryopreservation). Simplified methods enable laypersons without a science background to easily collect samples, allowing for longer-term, community-based monitoring programs that prioritize humane, non-lethal, and minimally invasive methods, advancing field-based research scopes and opportunities beyond what was previously possible. In a laboratory setting, we collected epidermal mucus samples from sedated rainbow trout (Oncorhynchus mykiss) and lake sturgeon (Acipenser fulvescens) and stored samples in different conditions (i.e., aluminum foil sheets and plastic bags) and durations (i.e., 10, 20, and 30 days). We then measured proteins in epidermal mucus using liquid chromatography and non-targeted tandem high-resolution mass spectrometry paired with chemoinformatics and bioinformatics software. We present preliminary results from this study and discuss the next steps of our research.

1.04.P-We033 Exploring the Trophic Transfer Risks of Titanium Dioxide Nanoparticles in Aquatic Organisms

***Mario Araujo**[1], Isabel Benta-Oliveira[1], Elza Fonseca[1], Aldo Barreiro-Felpeto[1], Ines Soares[1], Laura Rodriguez-Lorenzo[2], Francisca Melo[1], Maria Ines Rivadeneira[1], Teresa Neuparth[1], Miguel Semedo[1], Maria Turkina[3], Miguel Oliveira[4], Begoña Espina[2] and Alexandre Campos[1], (1)CIIMAR, Portugal, (2)INL, Portugal, (3)Linkoping University, Sweden, (4)Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal*

Titanium dioxide nanoparticles (TiO? NPs) are widely used nanomaterials, commonly found in consumer products and cosmetics, such as sunscreens. Despite being regarded as biologically "safe" due to their inability to penetrate the skin, TiO? NPs can enter aquatic ecosystems through wastewater discharge or recreational activities like swimming. Consequently, titanium and TiO? NPs have been detected in aquatic environments. While partially excreted after ingestion, both titanium and TiO? NPs can accumulate in fish livers, where their presence has been associated with hepatocyte ultrastructural alterations, metabolic disturbances, inflammation, oxidative stress, and DNA damage. Since these effects depend on the route of exposure, this study investigates the impacts of 25 nm TiO? NPs across an aquatic trophic transfer chain comprising microalgae (Oxyrrhis marina), brine shrimp (Artemia salina), and zebrafish (Danio rerio). Preliminary findings indicate that O. marina , a highly phagocytic microalga, functions as a trophic vector for TiO? NPs. Further studies with A. salina revealed developmental and pigmentation alterations, as well as mobility impairments, upon consuming algae preloaded with TiO? NPs. Behavioural changes, nutritional composition, and metabolic biomarkers in A. salina are still being evaluated. The study extends to D. rerio exposed to TiO? NPs via A. salina , with comparisons being made between TiO? NPs ingested via contaminated water or via microalgae. Distinct mechanistic pathways, molecular targets, and biological roles seem to be associated with these two different exposure routes. Therefore, omic approaches (proteomics, lipidomics, microbiomics) and other methodologies are being applied to assess and link metabolic alterations, nutritional impacts, gut microbiota changes, and titanium accumulation in zebrafish. By examining these cascading effects, this research aims to enhance our understanding of TiO? NP behaviour in aquatic food webs, offering critical insights for environmental risk assessment and ecological management. This work was supported by the Portuguese Foundation for the Science and Technology (FCT) through the project NanoPlanet 2022.02340.PTDC, and through UIDB/04423/2020 and UIDP/04423/2020 contracts. M.J.A. and A.C. also acknowledge the FCT funding for the Scientific Employment Stimulus Program (2023.06491.CEECIND and CEECIND/03767/2018, respectively).

1.04.P-We034 Toxicokinetics of Perfluorinated Compounds (PFCs) in Frogs (*Rana tigrina cantor*) Via Skin Exposure and Effects of Hibernation

***Xiao-Jun Luo**, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, China (Mainland)*

We investigated the bioaccumulation and effects of hibernation on the toxicokinetics and maternal transfer of perfluorinated compounds (PFCs) in frogs via skin exposure. The assimilation efficiencies (AE) ranged from 9.4 84% and were negatively correlated with the carbon chain length of short perfluorocarboxylic acids (PFCAs) (< 9) but positively correlated with perfluorosulfonic acids (PFSAs). The AE pattern for long-chain PFCAs was found to be similar to that for PFCAs in hens. The egg was the main site for the deposition of PFSAs and long PFCAs, whereas the carcass was the main organ for short PFCAs. The maternal transfer of PFCs increases over time, reaching more than 80% of the total body burden for some compounds. No clear trend was observed between the egg-maternal ratio (EMR) and the carbon chain length of the PFSAs. For PFCAs, the EMR first sharply increased and then decreased with carbon chain length, reaching a maximum at an approximate carbon chain length of 10. Hibernation inhibited the development of eggs in frogs and resulted in bioamplification factors (BaMFs) of 1.79 and 2.70 for total PFSAs and PFACs, respectively. BaMFs for the liver (5.3 16.2) were larger than BaMFs for other tissues or organs, indicating hibernation significantly raised the concentrations of PFCs in the liver. The relative enrichment of PFCs in eggs decreased during hibernation. The bioamplification of PFCs in maternal tissues or organs is mainly caused by a decreased biotransformation rate of PFCs, whereas in eggs, it is mainly caused by weight loss. The results of the present study are significant for understanding the bioaccumulation and toxic effects of PFCs in oviparous animals with hibernation of physiological processes.

1.04.P-We035 Hepatic Transcriptome Alterations of *Xenopus Laevis* Following Multi Route Exposure to Graphene Oxide

***Florian Chapeau**[1], Thomas Moura[1], van xuan nguyen[1], Maialen Barret[1], Marion Vivant[1], Emmanuel*

Flahaut[2], Laury Gauthier[1], Eric Pinelli[1] and Florence Mouchet[1], (1)Centre de Recherche sur la Biodiversite et l'Environnement (CRBE), Universite de Toulouse, CNRS, IRD, Toulouse INP, Universite Toulouse 3 Paul Sabatier (UT3), France, (2)CIRIMAT UMR 5085, France
Graphene-based nanomaterials, such as graphene oxide (GO), exhibit unique properties that have driven their widespread use in industrial and medical applications. However, the potential release of GO into aquatic ecosystems throughout its life cycle raises the need for comprehensive ecotoxicological risk assessments to ensure its safe use. Amphibians, highly sensitive to environmental contaminants, have been studied for various toxic effects of GO, including genotoxicity, primarily at the larval stage through direct exposure. This study expands the scope by investigating the combined effects of direct and trophic GO exposure on post-metamorphic Xenopus laevis, focusing on hepatic transcriptomic analysis to explore GO's mechanisms of action on a critical organ involved in metabolism, erythropoiesis, and detoxification. To simulate realistic exposure scenarios, dipteran larvae were exposed to varying GO concentrations for 24 hours before being introduced as prey for juvenile Xenopus. The amphibians consumed GO-laden larvae while simultaneously being exposed to GO in the water column. mRNA was extracted from the whole liver of Xenopus after 24 and 96 hours and sequenced using high-throughput technologies to investigate transcriptomic profiles and identify GO-affected biological pathways. Differential gene expression analyses, coupled with gene ontology functional annotations, revealed transcriptomic disruptions induced by GO at concentrations as low as 0.1 mg/L, which are environmentally relevant. After 96 hours of exposure, the results suggested that GO primarily affects lipid and sugar metabolism as well as cell cycle regulation mechanisms. This was further confirmed by flow cytometry analysis of the cell cycle in erythrocytes, which showed an increase in mitotic cells, potentially indicating compensatory mechanisms in response to hypoxic conditions caused by GO. This study highlights multiple pathways of disruption in organisms exposed to GO under realistic conditions. The findings emphasize the need for long-term and multi-generational studies to fully assess the ecological impact of these nanomaterials and avoid underestimating their effects in aquatic ecosystems.

1.04.P-We036 Protein Panel to Assess Toxicity Mechanisms and Effects in the Zebrafish PAC2 Cell Line

***Mihai-Ovidiu Degeratu**, Giacomo Koch, Severin Ammann, Jessica Bertoli, Nikolai Huwa, Marion Revel, Rene Schonenberger, Kristin Schirmer, Colette vom Berg and Ksenia J Groh, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*
Fish cell-based assays provide valuable animal-free alternatives for predicting chemical toxicity to fish. While these in vitro assays are already well-established for the assessment of acute effects on cell viability, gaining a deeper understanding of molecular mechanisms of toxicity could enhance their predictive power in the context of chronic toxicity. Omics methods can deliver large-scale overviews of toxicant-induced molecular alterations. So far, transcriptomics has been applied most often, but protein-level studies could offer more substantiated insights into different cellular responses and their consequences, as proteins are more closely linked to phenotype. Using mass spectrometry-based targeted proteomics which allows measuring multiple proteins in one sample simultaneously, protein panels for toxicity assessment can be established, similarly to gene-based panels such as the S1500 list. Here, we present a tentative protein marker panel for monitoring toxicity effects and outcomes in cell lines of zebrafish (Danio rerio), chosen for the pilot studies because it is a well-studied fish model species with sequenced genome and substantial molecular resources available. To select candidate proteins for the panel, we performed a narrative review of studies reporting on genes and proteins associated with major mechanisms and effects of toxicity on molecular and cellular levels. For selected genes, 220 corresponding zebrafish proteins were identified in the UniProt database. While a large proportion of the pathways covered in the resulting list are related to cellular stress responses, as expected, also several other pathways, including lipid metabolism, longevity regulation and immune responses emerged as potentially important for toxicity responses. Candidate protein markers will be tested in the zebrafish PAC2 cell line exposed to a set of reference chemicals, including, e.g., 2,4-dinitrophenol (a protonophore disrupting cellular ATP synthesis), diethyl maleate (inducer of oxidative stress), nocodazole (inhibitor of microtubule polymerization), tunicamycin (inducer of endoplasmic reticulum stress via inhibition of protein glycosylation), and thapsigargin (inducer of endoplasmic reticulum stress via increase of cytosolic calcium ion levels). This work contributes to the establishment of a novel toxicity assessment method that relies on a simultaneous measurement of multiple protein markers to monitor toxicity mechanisms and effects in fish models. This research is funded by the Swiss National Science Foundation through National Research Programme 79 Advancing 3R Animals, research and society , project number 407940_206439, Expanding the fish invitrome towards a modular, socio-technical framework for animal-free prediction of chemical toxicity to fish.

1.04.P-We037 Time-Resolved Analysis of Trifloxystrobin-Induced Proteome Alterations in a Fish Cell Line

***Ksenia J Groh**, Mihai-Ovidiu Degeratu, Rene Schonenberger and Nikolai Huwa, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Trifloxystrobin is an organofluorine fungicide that has a broad application in agriculture. This substance disrupts cellular energy production cycle through effects on mitochondrial respiration, where it binds the ubiquinone binding site (Qo) of cytochrome b, leading to the obstruction of the flow of electrons between cytochrome b and cytochrome c1. While having lower toxicity in terrestrial animals, such as birds, trifloxystrobin shows high toxicity to aquatic organisms such as fish. In this study, we investigated the effects of trifloxystrobin exposure on the proteome of zebrafish (Danio rerio) PAC2 cells, aiming to identify the disrupted molecular pathways and evaluate the responses across the time continuum from acute (several hours) to chronic (several days, covering the doubling time period for this cell line). Cells exposed to trifloxystrobin at the concentration known to cause 50% reduction in cell population growth were harvested at 4, 24, 48 and 120 h post exposure and processed for global proteomics analysis using the S-trap and trypsin digestion. Peptides were analyzed by nanoLC-MS/MS in data-independent acquisition (DIA) mode, followed by directDIA library-free data processing workflow with Spectronaut (Biognosys) for peptide identification and protein group assignment, followed by post-processing analysis on the Perseus platform (MaxQuant). Proteomics analysis revealed the existence of several highly correlated clusters of proteins that tended to be either up or downregulated in response to trifloxystrobin exposure. In some clusters, stronger effects were observed in the beginning of exposure but disappeared with increasing exposure time. In other clusters, increasing exposure time led to stronger effects on protein expression. Differentially expressed proteins are now being investigated for their involvement in specific molecular pathways disrupted by trifloxystrobin exposure, as well as in relation to their suitability as biomarkers of long-term exposure to trifloxystrobin or similar compounds in the environment. We also aim to evaluate the similarity of omics responses observed in vitro with results of in vivo studies reported in the literature. This work provides a broad overview of proteome alterations induced by trifloxystrobin exposure in fish cells and could allow identification of protein biomarkers for follow up studies in other cell lines, fish embryos, or environmental samples such as fish tissues collected in the wild.

1.04.P-We038 Assessing the Effects of Emerging Contaminants on Gene Expression in *Stenella coeruleoalba* Biopsies and Human Cell Cultures

***Antonino Vincenzo Alessi**, Maria Cristina Fossi, Cristina Panti, Giacomo Limonta, Giulia Baini and Matteo Baini, University of Siena, National Biodiversity Future Center (NBFC), Italy*

In recent years, new classes of pollutants have received the attention of scientists and regulators. Many of these compounds, defined as contaminants of emerging concern (CECs), have not been well studied, making predictions of their toxicity on biota. CECs enter the environment from various anthropogenic sources and are distributed throughout environmental matrices. They have been detected in the marine environment at concentrations significantly higher than expected and their risk to human and environmental health may not be fully understood yet. CECs include a vast array of contaminants: such as pharmaceuticals and personal care products (PPCPs); plastic additives such as bisphenol A (BPA) and phthalate esters (PAEs) which are both commonly spread in marine organisms ranging from invertebrates up to top predators. There are currently few studies in literature regarding the impact of emerging contaminants towards organisms at highest level of the trophic chain, such as marine mammals, and also humans. Further studies are needed to better understand the toxicological risk that these contaminants may pose to the marine ecosystem and human health. We identified by literature research and in silico analysis a set of molecular endpoints involved in the homeostasis of the organism to better understand the effect that CECs may exert on mammals. By droplet digital PCR (ddPCR) we analyzed striped dolphin (Stenella coruloealba) skin biopsies and Homo sapiens cell cultures (fibroblasts, hepatocytes and CaCo-2), treated with mixtures of the most common and prevalent emerging contaminants, at realistic environmental concentrations (Ctrl, 1ug/l, 10 ug/l, 100 ug/l), based on previously conducted environmental samplings. Stenella coeruleoalba biopsies and Homo sapiens cell cultures were treated with the following mixtures: a mix of pharmaceuticals consisting of Carbamazepine, Valsartan and Ibuprofen; a mix of phthalates consisting of 9 of the most prevalent phthalates and a super mix consisting of a mix of pharmaceutical, phthalates and bisphenol A. To better understand the effects of emerging contaminants in top predators, this study evaluated the alterations in gene expression profiles for the same molecular endpoints across both species. Through the assessment of these endpoints, it was possible to identify which contaminants that warrant increased attention due to their relevant effects on gene expression in top predators at environmentally relevant concentrations.

1.04.P-We039 Transcriptomic Analysis of Diesel Particulate Matter-Induced Molecular Effects in H9C2 Cardiomyocytes

Kyoung Jin Nho*, Jae Hoon Shin and Jin Ee Baek, Institute of Occupation and Environment, COMWEL, Korea, Republic of*

Diesel particulate matter (DPM) exposure is linked to adverse cardiovascular and respiratory health effects, driven by oxidative stress, inflammation, and apoptosis. This study examines the molecular impacts of DPM on H9C2 cardiomyocytes through an integrative analysis combining RNA sequencing data from DPM-exposed cells, publicly available GEO datasets (GSE47495, GSE9694), and findings from recent literature. Transcriptomic profiling revealed significant upregulation of genes associated with oxidative stress (e.g., SOD1, CAT), inflammation (e.g., TNF-?, IL-6), and cell death pathways. These findings align with shared molecular responses observed in the GEO datasets and literature, highlighting conserved mechanisms underlying DPM-induced cytotoxicity. Pathway enrichment analysis further supports the activation of antioxidant defense and inflammatory signaling as key drivers of cardiotoxicity. This integrative approach underscores the systemic impact of DPM exposure and the need for targeted protective strategies to mitigate its harmful effects on cardiovascular health.

1.04.P-We040 Impact of Neuroactive Pharmaceuticals and Pesticides on Excitability of Neuronal SH-SY5Y Cells: Role in Identification of Biomarkers of Effect of Neuroactive Compounds

Irina Vulin*, Dina Tenji, Ivana Teodorovic and Sonja Kaisarevic, Laboratory for Ecophysiology and Ecotoxicology LECOTOX, Department of Biology and Ecology, University of Novi Sad, Serbia*

Rising levels of neuroactive compounds (NC) in the aquatic environment pose a novel risk to ecosystems. The promising strategy for environmental monitoring of NC would require development of bioanalytical tools including biomarkers of effect sensitive to NC exposure. Despite their key role in neuronal excitability, voltage gated channels are often overlooked in ecotoxicological studies, and their potential as biomarkers of effect of NC should be explored. This study investigated the effects of neuroactive pharmaceuticals and pesticides with different primary modes of action on the expression of genes encoding subunits of voltage-gated sodium (SCN4B and SCN1A) and calcium channels (CACNA2D1) in retinoic acid-differentiated SH-SY5Y cells. The cells were treated with 4 pharmaceuticals (sertraline, clozapine, carbamazepine, caffeine) and 4 pesticides (fipronil, imidacloprid, deltamethrin, diazinon) in the concentrations of 10 or 1 mg/L, 10 µg/L and 10 ng/L, followed by RT-PCR analysis. The results revealed significant downregulation (up to 3.8 times) of SCN1A by caffeine, clozapine and sertraline at multiple concentrations. The SCN4B expression was also significantly inhibited by sertraline and caffeine at 10 ng/L (6.3 times and 2.7 times, respectively). Similarly, SCN1A expression was significantly inhibited by all tested pesticides (up to 5 times, in 10 µg/L diazinon treatment) and SCN4B by fipronil, diazinon and deltamethrin, at specific concentrations. However, fipronil exposure at 10 µg/L induced overexpression of voltage-gated sodium channel subunits. The expression of CACNA2D1 was also affected, with significant inhibition (up to 2.7 times) by caffeine, fipronil and deltamethrin, and stimulation (up to 2.2 times) by clozapine and carbamazepine, at specific concentrations. These findings demonstrate that subunits of voltage-gated sodium and calcium channels are sensitive to NC, suggesting potential adverse effects on neuronal excitability regardless of their primary mode of action. The observed changes, especially in SCN1A expression, highlight their potential as promising novel biomarkers of effect of NC. The research was supported by Ministry of Science, Technological Development and Innovation of the Republic of Serbia (Grants No. 451-03-66/2024-03/200125 and 451-03-65/2024-03/200125) and Science Fund of the Republic of Serbia, Program for Excellent Projects of Young Researchers (PROMIS), Project BIANCO No. 6061817.

1.04.P-We041 In Vitro Transcriptomic Analyses and MicroFlow Assay for Natural Anthraquinone Dyes

Mikko Herrala*[1], Lauren Bradford[2], Andrew Williams[3], Nimisha Bhattarai[4], Jamie Scaglione[4], Leslie Recio[4], Matthew J. Meier[2], Francesco Marchetti[2] and Carole Yauk[5], (1)School of Pharmacy, University of Eastern Finland, Kuopio, Finland, (2)Health Canada, Canada, (3)Environmental Health Science and Research Bureau, Health Canada, Canada, (4)ScitoVation, United States, (5)Biology, University of Ottawa, Canada*

Colourants are important components in all commercial and industrial products, such as food, textiles, cosmetics, and packaging materials. Synthetic dyes derived from fossil sources are massively used in the textile industry. These dyes may cause health risks to workers, end-users and to the environment (especially through water contamination). There is increasing interest in developing safer and more sustainable dyes. Natural anthraquinone dyes extracted from bloodred webcap fungus (Cortinarius sanguineus), such as dermocybin, dermorubin and emodin, are potential alternatives to synthetic dyes. However, natural origin per se does not mean that these biocolourants are non-toxic or safe to use. It is known that emodin is mutagenic in Salmonella bacteria, while dermocybin and dermorubin are not mutagenic in this system. However, all of these anthraquinones increase reactive oxygen species production in human cell lines (Herrala et al., 2022, Yli-Öyrä et al., 2024). Therefore, we investigated the genotoxicity of these natural anthraquinone dyes using metabolically competent HepaRG cells to more closely mimic human liver biology. We used the MicroFlow assay to quantify micronucleus frequency (chromosome damage) and relative cell survival. To advance mechanistic understanding, transcriptomic profiles were produced using TempO-Seq (Templated Oligo assay with Sequencing readout) to analyze two biomarkers of DNA damage (TGx-DDI and GENOMARK). Ingenuity Pathway Analysis (IPA) was applied to identify upstream regulator of the altered genes and enriched canonical pathways. None of the dyes increased micronucleus formation and only emodin caused cytotoxicity. Interestingly, all three anthraquinone dyes resulted in extensive transcriptional perturbations, indicating some form of bioactivity, but they were non-genotoxic in biomarker analyses, in-line with the negative microflow results. No upstream regulators specifically explained changes in gene expression levels, but several canonical pathways were activated, mostly related to metabolism. In conclusion, dermocybin and dermorubin may provide suitable alternatives for synthetic dyes as they were not genotoxic in our models. Potent mutagenicity of emodin in bacteria did not translate to genotoxicity in human liver cells. However, transcriptomics revealed effects on gene expression levels that require further analysis to inform their implications to human health hazards. The research has been funded by the Research Council of Finland (grant #346744) and the UEF Water research programme, which is jointly funded by Saastamoinen Foundation, Jenny and Antti Wihuri Foundation, and Olvi Foundation.

1.05 Microbiota Under Stress: Impacts of Environmental Pollutants on Ecosystem and Host Health

1.05.T-01 Linking Pesticide Degradation with Microbial Community Shifts in Agricultural Soils

Marija Gadzimuradova[1], *Valentina Sechi*[2], *Peter van der Maas*[3] *and Nora B Sutton*[1], *(1)Wageningen University, Netherlands, (2)Wetsus, European Centre of Excellence for Sustainable Water Technology, Netherlands, (3)Van Hall Larenstein, University of Applied Sciences, Netherlands*

While essential for modern conventional agriculture, pesticides can cause damage to soil microbial ecosystems, compromising both soil health and resilience. Some of the negative effects of pesticide application include, but are not limited to, decline in microbial diversity, degradation of soil structure, decrease in water holding and nutrient cycling capacity. The aim of this study is to investigate how pesticide application influences soil microbial community dynamics. We also study the role of soil texture, organic matter content and initial microbial community in determining pesticide purification capacity of soils.

We hypothesize that (1) soils with higher organic matter will have elevated microbial activity, enhancing pesticide degradation; (2) pesticide application will reduce microbial diversity and abundance; and (3) by integrating pesticide degradation kinetics data and microbial community molecular data across different soils, we will be ale to identify specific microbial and fungal taxa shifts in response to pesticide breakdown. To test these hypotheses, we analyse three agricultural soils treated with a mixture of 11 pesticides, monitoring degradation kinetics alongside microbial shifts using RNA and DNA extractions and amplicon sequencing. Results are expected to highlight key microbial and fungal taxa involved in pesticide breakdown and reveal how initial soil characteristics modulate degradation efficiency. The findings of this study will provide valuable insights that can be utilized in bioremediation efforts, as they can inform targeted strategies to stimulate microbial and fungal communities and optimize amendment selection for sustainable agricultural soil management. Furthermore, deeper understanding of microbial community shifts in response to pesticide application may lead to development of novel microbiome-based soil health indicators. This research underscores the role of microbial communities in soil ecosystem functions, promoting more sustainable soil management and enhancing resilience to agricultural inputs for long-term productivity.

1.05.T-02 Investigating Microbiota and Geochemical Characteristics of Colorado Mining-Influenced Waters

Emma Jones-Fredrickson, *Carmen Maria Villarruel, Aaron Goodman, Zhaoxun Yang, Charles Depp, John Spear and James Ranville, Colorado School of Mines, United States*

Acid-mine drainage (AMD) is a global environmental challenge that threatens natural ecosystems and human water supplies. The extreme conditions created by low pH and high metal concentrations make AMD ideal for characterizing unique extremophilic microorganisms which play several roles from cycling nutrients to perpetuating acid generation. The core microbiome of mining-influenced waters is well understood, but additional investigation of the rare biosphere is needed. A better understanding of how microbial community compositions vary with water chemistry in AMD can improve methods in biomining, bioremediation, and mineral exploration and provide insights into ecosystem health. Our goal was to characterize the geochemistry and microbiology of 13 mining-impacted waters in the Colorado Mineral Belt and explore relationships between microbial community composition and water chemistry. Total and dissolved ion concentration, geochemical parameters (e.g. pH, DO, etc.), and 16S/18S rRNA genetic sequences were measured for each location. Due to high loads and Colorado s underlying geology, rare earth elements (REE s) were of particular interest. In our samples pH was a master variable controlling concentration and dissolution of several metals including total REE s. REE s were also correlated to dissolved oxygen, aluminum, manganese, copper, zinc, cadmium, chromium, and nickel. AMD microbial communities commonly include Leptospirillum, Ferroplasma, and Acidothiobacillus and we expect to find these genera in the core microbiome of all or most of our samples. We hypothesize that the rare biosphere will contain community members or compositions unique to the water chemistry of that sample and will specifically analyze possible relationships between the presence of different taxa, REE s, and other correlated variables mentioned previously. This investigation provides a simultaneous assessment of the geochemical and microbial composition of mining influenced waters over a large geographical range. Exploring relationships between microbial community compositions and water chemistry and geology in MIW s provide the potential opportunity to better understand novel extremophilic taxa. Relationships between the presence or abundance of specific genera and water chemistries will be presented with a particular focus on relationships with total REE s.

1.05.T-03 Assessing Microbial Community Functions as an Indicator of Marine Ecosystem Disturbance

Leila Chapron[1]*, Cyril Sweetlove*[2]*, Isabelle Calves*[1]*, Karine Lebarron*[1]*, Anthony Woo*[2]*, Emilie Villar*[3]*, Alban Ott*[2]*, Guillaume Cottin*[2] *and Anne-Leila Meistertzheim*[1]*, (1)Plastic At Sea, France, (2)L'Oreal, France, (3)Emilie Villar, France*

Microbial Ecotoxicology aims to study (i) the impact of chemical and/or biological pollution on microbial communities and their ecosystem functions, and (ii) their role in pollutant ecodynamics. Microbial communities are valuable indicators of ecosystem health and recovery due to their rapid responses to pollutants but only a limited number of studies provide information on their functional properties essential for maintaining key ecosystem resilience. Therefore, metagenomic approaches, combined with other analyses such as metabarcoding, could provide insights into functional diversity to address this issue. Here, we investigated the potential of metagenomic analysis alongside molecular fingerprinting to evaluate the functional resilience of microbial communities to an anthropic poison using 6 concentrations of 3,5 dichlorophenol after 1 hour, 7, 15, 20, and 42 days of exposition. Metagenomic, metabarcoding and microbial analyses revealed time- and dose-dependent effects of 3,5-dichlorophenol on marine microbial communities and functions. Exposure to increasing doses of 3,5-dichlorophenol showed no significant impact on microbial functions over 42 days at concentrations up to 210 ?g.L-1 (1X, known NOEC for standard tests on Daphnia). However, at 2100 ?g.L-1, microbial functions gradually shifted, with changes in bacterial communities and activation of metabolic pathways related to organic compound degradation, indicating pollutant biodegradation. At 21 mg.L-1 (10X), rapid shifts in microbial functions and communities suggested short-term lethality followed by activation of protective metabolic pathways. Although xenobiotic degradation pathways were triggered, the high dose exceeded biological capacity. These findings confirm the value of metagenomic analyses for assessing the impact of pollutant on microbial biodiversity functions.

1.05.T-04 Effects of Micropollutants and Their Degradation on Prokaryotic Communities at the Sediment–Water Interface

Gwenael Imfeld[1]*, Adrien Borrecca*[1] *and Stephane Vuilleumier*[2]*, (1)Institut Terre et Environnement de Strasbourg, Universite de Strasbourg, France, (2)Genetique Moleculaire, Genomique, Microbiologie, Universite de Strasbourg, France*

Pesticides and pharmaceuticals frequently enter aquatic ecosystems as complex mixtures, complicating our understanding of their persistence, interactions, and ecological impacts. This study investigates the dissipation and effects of metformin (a widely prescribed antidiabetic drug), metolachlor (an agricultural herbicide), and terbutryn (a herbicide used in construction materials) on prokaryotic communities at the sediment water interface. Micropollutants were introduced either individually or as a mixture (17.6 ?M per compound) using laboratory microcosms simulating the sediment water interface of aquatic systems. In a dedicated experiment, metformin degradation and its effect on prokaryotic communities were assessed under stable and variable oxygenation conditions in spiked laboratory microcosms. Metformin and metolachlor completely dissipated within 70 days, while terbutryn persisted, with no significant differences between single-compound and mixture exposures. Metformin showed a lag phase before undergoing rapid biotic degradation, yielding guanylurea and dimethylamine as transient transformation products, which may act as microbial carbon sources. The hypervariable V3?V4 region of the 16S rRNA gene was PCR amplified targeting both bacteria and archaea to evaluate the response of prokaryotic communities to micropollutant exposure. Prokaryotic community composition was strongly affected by the sediment and water matrix composition and incubation duration, with additional distinct effects induced by micropollutants. Recalcitrant compounds such as terbutryn and metolachlor in the mixture caused notable shifts in community structure. Interactions between oxygen conditions and metformin exposure were primarily additive, though some taxa exhibited synergistic or antagonistic responses, enabling the identification of potential microbial biomarkers of contamination. These findings underscore the intricate relationships between environmental conditions, micropollutant dynamics, and microbial ecology. The study highlights the need to account for non-additive interactions, microbial adaptations, and environmental factors, such as oxygen availability, when evaluating micropollutant degradation and ecological effects. By providing insights into micropollutant persistence and microbial community responses at the sediment-water interface, this research contributes to the understanding of ecosystem health and water quality management. This research and the fellowship of Adrien Borreca were funded by the CNRS 80|Prime program (2020-2023) and by the EU within the European Regional Development Fund (ERDF), support measure INTERREG VI in the Upper Rhine as part of the Reactive City A3-4 project (Towards a Reactive City without Biocides).

1.05.P-Tu027 Potential Adverse Effects of Plant Protection Products on Non-Target Organisms' Microbiome: Regulatory Challenges and Progress in the Environmental Risk Assessment

***Franco Ferilli**[1], Fernando Alvarez[2], Csaba Szentes[2] and Diana Di Gioia[3], (1)European Food Safety Authority, Parma, Italy, (2)European Food Safety Authority, Italy, (3)University of Bologna, Italy*

The potential adverse effects of plant protection products on non-target organisms microbiome has became an emerging concern due to the critical role microbiome has in regulating and? supporting host health and resilience. Effects on the microbiome are not explicitly addressed under current environmental risk assessment frameworks. Nevertheless, in a recent assessment, the European Food Safety Authority scrutinised the open peer-reviewed literature on the effects of active substances and plant protection products on microbiome in the context of the peer review of glyphosate, evaluating the reliability and relevance of the identified studies. Studies highlighted different impacts on the gut, skin, and soil microbiomes. The available studies followed on non-standardized methods, hampering comparability and repeatability, and lacked direct applicability to regulatory risk assessments. A critical challenge was identifying core microbiomes, i.e., essential microbial communities underpinning an organism s health, and determining how shifts in these communities signal stress or harm. Variability in core microbiome composition across regions, seasons, and environmental conditions further complicates assessments. Moreover, linking microbiome disruptions at the individual level to broader population and ecosystem-level outcomes remains a significant challenge. EFSA s work underscores the need for standardized testing protocols, microbiome databases for non-target organisms, and methodologies to link microbiome-level to population-relevant effects. This work highlights both the challenges and opportunities for advancing the environmental risk assessment for non-target organisms.

1.05.P-Tu039 Do Microplastics Change the Microbial Risk Profile of Wastewater?

***Olga Pantos**[1], Stefan Maday[2], Joanne Kingsbury[1], Louise Weaver[1], Hayden Masterton[1], Kim Handley[2] and Gavin Lear[2], (1)Institute of Environmental Science and Research, New Zealand, (2)University of Auckland, New Zealand*

Plastic pollution is pervasive and ubiquitous, and the harm it can cause is diverse. Impacts are dependent not only on polymer type or the associated chemicals (additives and non-intentionally added substance) but also size (nano- to macroplastics), morphotype, degree of aging and the organism and ecosystems with which they interact. Whilst there is an extensive body of knowledge of the physical and toxicological effects of plastics little is known of the effects on microbial function, or how two pollutants that pose a risk to human health - plastics and microbial pathogens interact, potentially altering the risk profile of both.

Wastewater treatment facilities act as a nexus for microbial pathogens and plastics. Depending on the level of treatment, plastic particles are removed from wastewater before discharge to the environment. Remaining particles are either released in treated effluent or enter the biosolids. As these plastics age they may leach and sorb pollutants and provide substrate for biofilm formation and optimal environment for conjugation, possibly impacting antimicrobial resistance (AMR) traits. To address the knowledge gap that exists for these plastic-microbe interactions we deployed five different artificially weathered plastic types and a glass control into the final maturation pond of a municipal wastewater treatment plant in ?tautahi-Christchurch, Aotearoa New Zealand. The plastic-associated biofilms (plastisphere) were sampled at 2, 6, 26, and 52 weeks, along with the ambient pond water, at three different depths (20, 40, and 60 cm from

the pond water surface). Plastisphere microbial diversity and functional potential were determined using metagenomic sequence analysis.
Bacterial 16S ribosomal RNA genes composition did not vary among plastic types and glass controls but varied among sampling times. Overall, there was no polymer-substrate specificity evident in the total composition of genes, but sampling time and depth were significant factors. The plastisphere housed diverse AMR gene families, potentially influenced by biofilm-mediated conjugation. The health risk of plastic-associated microbes in the effluent may therefore pose an increasing environmental, and human health risk and warrants further study. This study highlights that the removal of microplastics from wastewater (ideally preventi) is critical for the protection of the environment and humans from both chemical and microbial threats. This study was supported by the New Zealand Ministry of Business, Innovation and Employment, Endeavour Fund Research Programme C03X1802 (Impacts of microplastics on New Zealand s bioheritage systems, environment, and eco-services).

1.05.P-Tu045 Assessing the Effects of Pollutants in Stormwater Wetlands on Sedimentary Microbial Community Structure Using eDNA Metabarcoding
Anna Flynn[1]*, Sara M Long*[1]*, Vincent J. Pettigrove*[2]*, Kathryn Hassell*[1]*, Jeff Shimeta*[1] *and Mark Osborn*[1]*, (1)RMIT University, Australia, (2)Aquest Research Group, RMIT University, Australia*
Pollution poses a significant threat to freshwater ecosystems with metals and pesticides in particular representing long-term and widespread hazards. Constructed wetlands are an important tool for managing stormwater in urban landscapes, capturing and retaining contaminants in their sediments. Currently there is a lack of consideration for microbial taxa when determining the impacts of contamination on aquatic environments, and conversely an absence of microbial indices which could enhance current biomonitoring by increasing the scope and sensitivity of analyses. Environmental DNA is expanding the field of aquatic monitoring with the ability to assess biological profiles quickly and reliably, providing knowledge of how contamination affects ecosystems at a microbial level. By understanding what contaminants are in our waterways and how they affect all aspects of ecosystem functioning, we can better target mitigations to manage responses. In this study we collected sediment samples from the inlet and outlet of nine urban stormwater wetlands and one rural wetland, analysing them for chemical contaminants, and microbial community structure through 16S rRNA metabarcoding. Multivariate analyses were used to determine the interrelation between the chemical and biological data. We found significant variation in microbial communities between the rural wetland and all stormwater wetlands, between some of the stormwater wetlands, and between over half of the inlets to outlets. Cyanobacteria and Proteobacteria were mostly driving this variation, along with Planctomycetota and Bacteriodota. Seven families were also identified as having bioindicative potential for pollution in freshwater. We observed significant correlations between community structure and zinc and barium, with the latter not previously reported to be associated with microbial dynamics in freshwater. Our study further validates the use of eDNA metabarcoding to reliably evaluate sedimentary microbial profiles in freshwater, highlighting its value in the assessment and prediction of contamination in these environments. We identified pollutants of concern being seen commonly across urban environments in Melbourne and showed evidence that they are impacting the abundance and diversity of sedimentary microbial communities in stormwater wetlands. Through this we were able to identify potential microbial bioindicators which could be used in a biotic index as a measure of contamination in freshwaters.

1.05.P Microbiota Under Stress: Impacts of Environmental Pollutants on Ecosystem and Host Health

1.05.P-Tu027 Potential Adverse Effects of Plant protection products on Non-Target Organisms' Microbiome: Regulatory Challenges and Progress in the Environmental Risk Assessment
Franco Ferilli[1]*, Fernando Alvarez*[1]*, Csaba Szentes*[1] *and Diana Di Gioia*[2]*, (1)European Food Safety Authority, Italy, (2) University of Bologna, Italy*
The potential adverse effects of plant protection products on non-target organisms microbiome has became an emerging concern due to the critical role microbiome has in regulating and? supporting host health and resilience. Effects on the microbiome are not explicitly addressed under current environmental risk assessment frameworks. Nevertheless, in a recent assessment, the European Food Safety Authority scrutinised the open peer-reviewed literature on the effects of active substances and plant protection products on microbiome in the context of the peer review of glyphosate, evaluating the reliability and relevance of the identified studies. Studies highlighted different impacts on the gut, skin, and soil microbiomes. The available studies followed on non-standardized methods, hampering comparability and repeatability, and lacked direct applicability to regulatory risk assessments. A critical challenge was identifying core microbiomes, i.e., essential microbial communities underpinning an organism s health,

and determining how shifts in these communities signal stress or harm. Variability in core microbiome composition across regions, seasons, and environmental conditions further complicates assessments. Moreover, linking microbiome disruptions at the individual level to broader population and ecosystem-level outcomes remains a significant challenge. EFSA s work underscores the need for standardized testing protocols, microbiome databases for non-target organisms, and methodologies to link microbiome-level to population-relevant effects. This work highlights both the challenges and opportunities for advancing the environmental risk assessment for non-target organisms.

1.05.P-Tu028 Impact of Engineered Nanomaterials on Microbial Communities in the Aquatic Environment

***Milena Frelih**, Harald Bresch and Sonja Oberbeckmann, Federal Institute for Materials Research and Testing (BAM), Germany*

Engineered nanoparticles have garnered significant attention for their unique properties and potential applications across various industries. They were extensively examined for their toxicological effect in vitro and in vivo, but their effects on environmental and biological systems remain underexplored. A key area of concern is how nanoparticles interact with microbial communities in natural ecosystems, since these communities are vital for processes such as nutrient cycling, biodegradation, and maintaining ecosystem health and functioning. Currently, environmental risk assessments of nanoparticles majorly involve higher organisms (e.g. algae, zooplankton), but omit the effects on complex communities and ecosystems as a whole. This research aims to investigate the impact of nanomaterials on aquatic microbial communities using a combination of laboratory experiments and field-sampling along a gradient from low to highly anthropogenically impacted aquatic ecosystems around Berlin, Germany. To holistically assess changes in microbial composition and functional activity in response to nanomaterial exposure, we will apply molecular, microbiological, analytical as well as OMIC methods. We hypothesize that nanoparticles induce significant compositional changes in microbial community structures, potentially leading to alterations in stress responses and other functional effects. Nanomaterials have the potential to benefit the environment by contributing to energy and resource efficiency, remediation of contaminated sites, or water treatment. In order to represent truly sustainable products, though, a safe use for humans and ecosystems must be assured. Ultimately, this research will contribute to more accurate environmental risk assessments and help guide the responsible use of nanotechnology in various industries.

1.05.P-Tu029 Combining Tools for Early Warning in Water Quality Monitoring

***Marlea H.A.B. Wagelmans**[1], Marc van Bemmel[2] and Joep Appels[3], (1)Ministry of Infrastructure and Water Management (RWS), Netherlands, (2)Orvion bv, Netherlands, (3)OptiSenseData, Netherlands*

In the Netherlands, water quality in the river is measured and monitored with a view to public health and state of the river-bound ecosystems. The Water Framework Directive (WFD) states that all the water in the Netherlands must be a good habitat for the organisms that live there by the year 2027 and that it must be reasonably easy to make drinking water from it.

However, measuring water quality is still in its infancy when it comes to the speed of the measurement, the reliability with regard to the predictive value and the still limited chemical and biological insight into the water composition. In this poster an innovative combination of existing tools that will be further developed will be shown. The combination of BACTcontrol and UV/VIS chemical fingerprint in a flowthrough system that continuously monitors the water quality will activate an alarm when a deviation in microbiological and/or chemical parameters is detected. This alarm also triggers an additional sample to be taken for Next Generation Sequencing (NGS) on DNA and RNA in the surface water in order to determine the biodiversity of the sample. All data from these analyses are combined with data like temperature, river discharge, nutrients, oxygen levels. All of the results are visible on a dashboard. This enables water quality managers to act in a targeted and preventive manner in the event of water pollution.

1.05.P-Tu030 Better or Worse? Assessing the Effects of Warming on Interactions Between Emerging Contaminants and Freshwater Primary Producers

***Benjamin Thorpe**, The University of York, United Kingdom*

Freshwater is a finite resource for the human population and global economy that is increasing in demand. The services freshwater ecosystems supply for society is recognised through its value of $4?trillion annually. However, these ecosystems face significant threats from various anthropogenic stressors released from point and non-point pollution sources that often act in combination rather than individually. While research into the effects of emerging contaminants has gained momentum, the impact of rising water temperatures due to climate change, alongside more frequent heatwaves, remains insufficiently explored. This study presents an initial systematic literature review aimed at evaluating existing research on the combined stressors of warming and emerging contaminants. The review revealed the variability in synergistic or antagonistic effects depending on the biomarkers employed. Subsequently, key emerging contaminants (pharmaceuticals, pesticides, and heavy metals) were selected due to their risk assessed toxicity for further investigation through a laboratory study. Our experimental design involved assessing the interactions between these contaminants and freshwater primary producers, including phytoplankton, diatoms, and cyanobacteria, under varying temperature conditions in accordance with OECD 201 guidelines. Toxicity assessments were performed using effective concentration values derived from dose-response curves at three distinct temperatures: 15°C, 20°C, and 25°C. Initially nutrient enrichment will be studied first across the temperature rise on the primary producers to assess if it has an interactive effect before chemical exposure. In alignment with the literature's emphasis on the need for holistic approaches, a novel morphological analysis method was also employed to examine individual cellular responses. Preliminary results indicate that elevated temperatures significantly enhance the inhibitory effects of copper sulfate on the growth of the diatom Nitzschia palea. Additionally, higher temperatures exacerbated differences in chloroplast size between copper sulfate-exposed cells and controls, underscoring temperature's critical role in modulating contaminant toxicity at both population and cellular levels. The laboratory study is ongoing, and further analyses will contribute to a more comprehensive understanding of these interactions in freshwater ecosystems.

1.05.P-Tu031 Development of a Multispecies Test Method for Evaluating Phytoplankton Sensitivity to Chemical Exposure

Lalita Chomphen[1]*, Alejandra Bouzas-Monroy*[1]*, Amy Rose Ockenden*[2]*, Lorraine Maltby*[2] *and Alistair Boxall*[1]*, (1)University of York, United Kingdom, (2)The University of Sheffield, United Kingdom*

Phytoplankton are frequently used as model organisms in ecotoxicology studies due to their ecological importance, chemical sensitivity, and ease of cultivation in laboratory environments. They are essential for assessing the effects of pollutants on aquatic ecosystems. The toxicity of chemicals can vary greatly depending on the algal species. The OECD 201 guideline recommends just five species: two chlorophytes, Pseudokirchneriella subcapitata and Desmodesmus subspicatus; two cyanobacteria, Anabaena flos-aquae and Synechococcus leopoliensis; and a single diatom, Navicula pelliculosa. However, there is a lack of representation and ecotoxicological data for some groups, particularly diatoms. This study aimed to develop a multispecies test method for assessing phytoplankton sensitivity to chemical exposure by examining a range of species, including three chlorophytes, two cyanobacteria, and seven diatoms. In the method, test organisms are exposed to a toxicant for 3 d with an automated microplate reader employed to measure optical density. Calibration curves were generated to establish the relationship between cell numbers and optical density, facilitating the conversion of optical density readings to cell numbers allowing the calculation of average specific growth rates according to the OECD 201 guideline. Potassium dichromate was used as a reference substance to validate the testing procedures and four UV filters were used as study toxicants. Chlorophytes were found to be the most sensitive group to potassium dichromate (EC50=3.86-5.08 mg/L), while cyanobacteria and diatom species demonstrated EC50 values ranging from 12.21 mg/L to 102 mg/L. EC50 values were similar to values reported in the literature. For the UV filters, the diatom, Aulacoseira granulate (a species not in the OECD guideline) was the most sensitive species, with EC50 values being 0.027 mg/L, 0.006 mg/L, and 0.295 mg/L for homosalate, octocrylene, and benzophenone-3, respectively. Bemotrizinol was found to have no effects at its solubility limit. The results show that this growth-based method can be applied to various algal species and chemical agents, adhering to OECD guidelines for algal sensitivity testing, including standard and non-standard species. The findings contribute to understanding the ecological impacts of chemicals on phytoplankton, emphasizing the need for further research to elucidate the implications for aquatic ecosystem health.

1.05.P-Tu032 Optical Microrespirometry: A Comprehensive Tool for Profiling Toxic Responses in Plankton Communities

Paolo Taborelli *and Peter Roslev, Aalborg University, Denmark*

Optical microrespirometry is a potentially valuable tool in environmental toxicology for evaluating community level responses to environmental toxicants. Oxygen is a key molecule in the physiology of many macro- and microorganisms, and community level fluctuations in oxygen may indicate metabolic perturbations in response to chemical stressors. This study explored the potential of an optical microplate respiration system for assessing metabolic responses of microplankton communities to toxicant exposure. The microrespirometry system was based on multi-well glass microplates equipped with oxygen sensor spots for non-invasive monitoring of oxygen levels in real time. Mixed freshwater plankton communities were obtained from oligotrophic, mesotrophic and eutrophic lakes in North Jutland (Denmark). Toxicants included pesticides and biocides such as glyphosate, chlorhexidine and benzalkonium chloride in different concentrations. Multivariate statistics was used to analyse data generated during microrespirometry profiling. The results showed differences in aerobic metabolism of native plankton communities that corresponded to toxicant levels. In addition, functional groups of autotrophic and heterotrophic plankton organisms were activated by addition of low levels of inorganic or organic substrates and use of different light regimes (substrate induced respiration). It was subsequently possible to approximate the toxic responses of different functional groups in the plankton community. Changes in oxygen consumption of mixed communities often occurred in phases, and apparent community level EC50 values were calculated for both an initial respiration phase (hours) and a subsequent respiration phase (days). Microrespirometry based toxicity was evaluated further by measuring the efficacy of an advanced oxidation process in reducing apparent ecotoxicity. Water contaminated with biocides were treated with vacuum UV irradiation and responses in lake water was assessed before and after treatment. The results indicated that plankton microrespirometry could also be expanded to assess the environmental quality of water treated for reuse. Collectively, the study indicates that optical microrespirometry may be used as a sensitive and non-invasive proxy to assess community level inhibitory responses of lake plankton in real time. The methods enabled comprehensive profiling of plankton responses across toxicant concentrations, substrate conditions and trophic levels. This project has received funding from the European Union under the Horizon Europe Marie Sk?odowska-Curie Actions (MSCA) Doctoral Network program (Project IN2AQUAS; Grant agreement number 101119555).

1.05.P-Tu033 How Sensitive are Aquatic Fungi? A Case Study in the Light of Environmental Risk Assessment Using the Fungicide Trifloxystrobin as Model

***Lais Conceição Menezes da Silva**, Marcus Paterson-Roberts and Mirco Bundschuh, Institute for Environmental Sciences (iES Landau), University of Kaiserslautern-Landau (RPTU), Germany*

Aquatic hyphomycetes are anamorphic fungi usually found associated with decomposing organic substrates such as leaves and twigs. This association suggests these fungi are crucial for nutrient cycling, decomposing complex organic matter and enhancing the feeding and nutrition of higher trophic levels (i.e., detritivores). Despite their key role in ecosystem functions, ecotoxicological assessments for this group are limited, surprisingly, even for fungicides, a group of pesticides designed to control fungal (pest) species. By employing the fungicide trifloxystrobin as a model, this study aims to assess the value of testing non-target fungal species, here aquatic hyphomycetes, for environmental risk assessment. This was done by developing a species sensitivity distribution (SSD) from growth inhibition effect concentrations (ECx). We exposed eleven aquatic hyphomycete species, belonging to five different orders and grown on malt extract agar, to increasing concentrations of trifloxystrobin (up to 625 µg/L) in the darkness at 16 ºC for three weeks. Growth in terms of radial growth was measured weekly. EC values increased with exposure duration. Overall, EC10 values varied between 0.27 and 505 µg/L and EC25 between 1.53 and 504 µg/L. In the case of EC50 values, 6 of the 11 species tested had estimates above the tested concentration range (> 625 µg/L). Among the other five species, the EC50 values varied between 2.48 and 408 µg/L. There was no fungal order that stood out in its general sensitivity towards trifloxystrobin. Moreover, the hazardous concentrations for 5% of the species (H5), abstracted from the SSD curves with EC10 values, were estimated at 7d = 0.21 µg/L, 14d = 0.17 µg/L and 21d = 0.09 µg/L. Considering the lowest EC10 value and the maximum assessment factor (AF) for SSD curves, we calculated a Predicted No Effect Concentration (PNEC) of 0.05 µg/L for aquatic hyphomycetes, which is lower than the regulatory acceptable concentration (RAC) for trifloxystrobin in the European Union (0.11 µg/L), a scenario that would be enough to pose a risk to the most sensitive species. This reveals a gap between current regulations and the sensitivity of hyphomycetes to fungicides. To address this, further studies are needed, evaluating key substances as well as other endpoints. Such research could guide updates in environmental risk assessments, ensuring regulations fully encompass the diversity and ecological functions of freshwater habitats. CAPES-Humboldt Research Fellowship (grant nº. 88881.699331/2022-01)

1.05.P-Tu034 Spatiotemporal Dynamics of Riverine Benthic Microbial Communities and their Biodegradation Potential

***Joeselle Serrana**[1], Run Tian[2], Michael McLachlan[2], Francisco J. A. Nascimento[3], Elias Broman[3], Benoit Dessirier[4] and Malte Posselt[5], (1)Stockholm University Center for Circular and Sustainable Systems (SUCCeSS), Stockholm University, Sweden, (2)Department of Environmental Science (ACES), Stockholm University, Sweden, (3)Department of Ecology, Environment, and Plant Sciences (DEEP), Stockholm University, Sweden, (4)Baltic Sea Centre, Stockholm University, Sweden, (5)Department of Environmental Science (DEEP), Stockholm University, Sweden*

Pollution is a well-known cause of drastic ecosystem change, devastatingly affecting freshwater habitats. Despite recent progress in chemical and bioanalytical techniques, our understanding of the effects of chemical exposure on biological communities and ecosystems remains limited. The natural variability in species composition, ecological interactions, and complex mixtures of chemical pollutants impede the development of a standardizable and systematic approach to monitoring and assessing the impacts of freshwater pollution in impacted habitats. Most research focuses on how biological communities respond to pollutants, e.g., wastewater discharge, by examining shifts in community composition and diversity within specific groups. Benthic communities, particularly microorganisms, are naturally subjected to spatial and temporal variability. However, additional investigation is needed to evaluate how wastewater effluents affect the spatiotemporal dynamics of biodiversity and their associated functions. Exploring spatial variations and seasonal community dynamics in affected habitats can enhance our understanding of the link between the biodiversity of key organisms and their role in ecosystem processes (e.g., contaminant biodegradation). Using environmental DNA analysis, we assess the spatiotemporal dynamics of benthic community diversity and composition, i.e., prokaryotic, algae, fungi, protists, and metazoans, and their association with biodegradation potential from two wastewater-impacted rivers in Sweden. We also quantified ecological processes, e.g., stochastic and deterministic, regulating the seasonal assembly of the benthic communities. We aimed to understand the spatial and seasonal organization and dynamics of multitrophic community assembly and assess their link to the biodegradation capacities of the microbial communities in wastewater-impacted rivers.

1.05.P-Tu035 Does Exposure History Affect the Sensitivity of Sediment-Associated Microorganisms?

Hajar Bourassi[1]*, Freya Baeumlisberger*[2]*, Alexander Feckler*[1]*, Eric Bollinger*[1] *and Mirco Bundschuh*[1]*, (1)Institute for Environmental Sciences (iES Landau), University of Kaiserslautern-Landau (RPTU), Germany, (2)Faculty of Biotechnology, Mannheim University of Applied Sciences, Germany*

Inland waters are regarded as one of the most important production grounds of the greenhouse gas methane (CH4). The decomposition of organic matter depletes most of the oxygen in the sediment, resulting in anaerobic conditions, promoting microbial methanogenesis. As CH4 emissions from natural sources are increasing, examining the environmental factors that influence the increase, is of great relevance in the context of global change. A previous study has shown that the exposure of sediment-associated microorganisms to pharmaceuticals (i.e., an antibiotic mixture) stimulates the emissions of CH4, by affecting the methanogenesis in freshwater sediment. Here, we assess whether the exposure history of sediment-associated microorganisms in freshwaters modifies their sensitivity to increasing levels of pharmaceuticals reflected by differences in CH4 production. Differences in exposure history were assumed by sampling sediment-associated microorganisms at different sites, up- and downstream of wastewater treatment plants (WWTPs), which are point sources of pollution for a wide range of organic and inorganic chemicals. In detail, four streams in the upper Rhine valley were sampled at four sites in each stream: a pristine area, directly upstream of the WWTPs effluent, 50 m and 1 km downstream of the effluent. In the laboratory, sediment was exposed to an antibiotic mixture (i.e. amoxicillin, ciprofloxacin, erythromycin, sulfamethoxazole, and tetracycline) in a hermetically closed microcosm under anaerobic conditions. Two treatment levels, i.e. 5 and 5000 µg/L, in addition to the negative control are tested with 10 replicates per treatment. The systems are incubated at 20 ± 1° C in the dark, and CH4 and CO2 in the headspace are currently measured on a weekly basis, until production asymptotically approaches the maximum levels. Metabarcoding will shed light on changes in the microbial communities throughout the study. Data collection and analyses are still ongoing.

1.05.P-Tu036 Interactive Effects of Pollutants and Parasites on Cyanobacterial Metabolism

Erika Berenice Martinez-Ruiz[1]*, Jutta Fastner*[2]*, Stephanie Spahr*[1] *and Justyna Wolinska*[3]*, (1)Leibniz Institute of Freshwater Ecology and Inland Fisheries, Germany, (2)UBA, Germany, (3)Leibniz Institute of Freshwater Ecology and Inland Fisheries; Freie Universitat Berlin, Germany*

Water pollution from chemical substances, such as the herbicide metolachlor (MET), and solid waste, such as cigarette butts (CBs), poses significant risks to aquatic ecosystems. For instance, MET can disrupt the growth and general metabolism of non-target microorganisms. Similarly, CBs, one of the most common forms of global litter, contain various chemicals that leach into water, negatively affecting aquatic microorganisms. Despite their prevalence, little is known about the combined effects of these pollutants and biotic stressors, such as parasites, on phytoplankton. This study investigated the metabolic response of the toxigenic cyanobacterium Planktothrix agardhii exposed to both biotic (the chytrid parasite Rhizophydium megarrhizum) and abiotic stressors (CB leachate and MET). We measured key metabolic biomarkers, including microcystin levels, protein and lipid content, lipid peroxidation, and the enzymatic activity of superoxide dismutase (SOD) and glutathione-S-transferase (GST). MET exposure did not significantly alter protein or lipid content or enzyme activities in either infected or uninfected cultures. However, cyanobacteria exposed to both MET and chytrids exhibited reduced microcystin levels and lipoperoxidation, indicating an oxidative stress response countered by non-enzymatic mechanisms. In contrast, CB leachate reduced protein and lipid content and microcystin concentrations in the cyanobacteria only in the absence of the parasite, suggesting oxidative stress and metabolic disruption. Interestingly, simultaneous exposure to CB leachate and chytrids appeared to mitigate the negative effects. This study highlights the complex responses of cyanobacteria under combined abiotic and biotic stressors, revealing how anthropogenic pollutants shape aquatic microbial interactions and broader ecological processes. This work was supported by the DFG grant MA 9934/1-1 (EMR)

1.05.P-Tu037 Toxicity of 'Eco-friendly' Plasticizers on Plastic-Degrading Bacteria: Effects on microbial biofilm formation and Oxidative Stress Response

Dana Fahad M.S. Mohamed *and Jung-Hwan Kwon, Korea University, Korea, Republic of*

Plasticizers, widely used to enhance the flexibility and durability of polyvinyl chloride (PVC), have raised environmental and health concerns due to their potential toxicity. Traditional phthalates, like di(2-ethylhexyl) phthalate (DEHP), are notorious for their harmful effects, prompting the development of alternative plasticizers such as dioctyl terephthalate (DOTP) and acetyl tributyl citrate (ATBC), which are marketed as safer, eco-friendly options. However, the impact of these alternatives on microbial communities, especially those involved in plastic degradation, is not well understood. This study examines the effects of DOTP and ATBC on Rhodococcus ruber, a bacterium with plastic-degrading potential. Using live/dead staining and CellROX Green reagent, we assess bacterial viability and oxidative stress at various concentrations of DOTP (1%, 5%, and 10% v/v) and ATBC (1%, 5%, 10%, and 20% v/v), reflecting concentrations commonly found in plastic products (ranging from 1 20% v/v). Our findings reveal that both plasticizers cause significant harm to R. ruber, with increasing concentrations leading to higher mortality rates and oxidative stress. At 10% DOTP and 20% ATBC, no live cells were detected. These results highlight the need to better understand the environmental risks posed by alternative plasticizers and their potential impact on the plastisphere.

1.05.P-Tu038 Exploring the Biodegradation of Microplastics Using Gut Microbiota from Freshwater Insects

Dimitrija Savic-Zdravkovic[1]*, Tamara Janakiev*[2]*, Marija Petrovic*[2]*, Jelena Miljkovic*[2]*, Nikola Stankovic*[1]*, Ivica Dimkic*[3]*, Ana Vladan Samardžić*[1]*, Jelena Slavisa Stojanovic*[1] *and Djuradj Milosevic*[1]*, (1)University of Nis, Faculty of Sciences and Mathematics, Serbia, (2)University of Belgrade, Faculty of Biology, Serbia, (3)University of Begrade, Faculty of Biology, Serbia*

Microplastics in aquatic ecosystems pose significant risks to biodiversity and ecosystem health. Addressing this challenge requires sustainable and innovative strategies, such as leveraging microorganisms associated with aquatic organisms for bioremediation. This study investigates the gut microbiota of Chironomus riparius larvae as a potential source of bacterial strains capable of degrading microplastics. Bacterial strains isolated from the larval gut were tested for their ability to grow on minimal media supplemented with polyethylene (PE), polyvinyl chloride (PVC), and polyamide (PA) as the sole carbon sources. The ability to utilize microplastics was assessed by monitoring bacterial growth intensity. Notably, strains of Peribacillus simplex and P. frigoritolerans exhibited high growth on all three types of microplastics. Furthermore, Bacillus wiedmannii and B. thuringiensis/toyonensis demonstrated moderate degradation activity, indicating a potential role in breaking down recalcitrant polymers. Some additional strains, such as Paenibacillus xylanexedens, displayed limited plastic degradation. These findings highlight the potential of C. riparius gut microbiota as a reservoir of microplastic-degrading bacteria and underscore the importance of exploring natural microbial communities for sustainable bioremediation solutions. Future work will focus on scaling up these processes for broader environmental applications.

1.05.P-Tu039 Do Microplastics Change the Microbial Risk Profile of Wastewater?

Olga Pantos[1]*, Stefan Maday*[2]*, Joanne Kingsbury*[1]*, Louise Weaver*[1]*, Hayden Masterton*[1]*, Kim Handley*[2] *and Gavin Lear*[2]*, (1)Institute of Environmental Science and Research, New Zealand, (2)University of Auckland, New Zealand*

Plastic pollution is pervasive and ubiquitous, and the harm it can cause is diverse. Impacts are dependent not only on polymer type or the associated chemicals (additives and non-intentionally added substance) but also size (nano- to macroplastics), morphotype, degree of aging and the organism and ecosystems with which they interact. Whilst there is an extensive body of knowledge of the physical and toxicological effects of plastics little is known of the effects on microbial function, or how two pollutants that pose a risk to human health - plastics and microbial pathogens interact, potentially altering the risk profile of both.

Wastewater treatment facilities act as a nexus for microbial pathogens and plastics. Depending on the level of treatment, plastic particles are removed from wastewater before discharge to the environment. Remaining particles are either released in treated effluent or enter the biosolids. As these plastics age they may leach and sorb pollutants and provide substrate for biofilm formation and optimal environment for

conjugation, possibly impacting antimicrobial resistance (AMR) traits. To address the knowledge gap that exists for these plastic-microbe interactions we deployed five different artificially weathered plastic types and a glass control into the final maturation pond of a municipal wastewater treatment plant in ?tautahi-Christchurch, Aotearoa New Zealand. The plastic-associated biofilms (plastisphere) were sampled at 2, 6, 26, and 52 weeks, along with the ambient pond water, at three different depths (20, 40, and 60 cm from the pond water surface). Plastisphere microbial diversity and functional potential were determined using metagenomic sequence analysis.
Bacterial 16S ribosomal RNA genes composition did not vary among plastic types and glass controls but varied among sampling times. Overall, there was no polymer-substrate specificity evident in the total composition of genes, but sampling time and depth were significant factors. The plastisphere housed diverse AMR gene families, potentially influenced by biofilm-mediated conjugation. The health risk of plastic-associated microbes in the effluent may therefore pose an increasing environmental, and human health risk and warrants further study. This study highlights that the removal of microplastics from wastewater (ideally preventi) is critical for the protection of the environment and humans from both chemical and microbial threats. This study was supported by the New Zealand Ministry of Business, Innovation and Employment, Endeavour Fund Research Programme C03X1802 (Impacts of microplastics on New Zealand s bioheritage systems, environment, and eco-services).

1.05.P-Tu040 Microbial Degradation Potential of Hydrocarbon Contaminants in the Baltic Sea
Joeselle Serrana[1], *Benoit Dessirier*[2], *Francisco J. A. Nascimento*[3], *Elias Broman*[4] *and Malte Posselt*[5], *(1)Stockholm University Center for Circular and Sustainable Systems (SUCCeSS), Stockholm University, Sweden, (2)Baltic Sea Center, Stockholm University, Sweden, (3)Department of Ecology, Environment, and Plant Sciences (DEEP), Styockholm University, Sweden, (4)Department of Ecology, Environment, and Plant Sciences (DEEP), Stockholm University, Sweden, (5)Department of Environmental Science (ACES), Stockholm University, Sweden*
The Baltic Sea is loaded with petroleum-based substances, e.g., hydrocarbons and plastic waste, from various sources. Microbial communities drive organic matter degradation and can naturally degrade environmental pollutants. The information on the degradation potential of contaminant-exposed microbial communities can be used to estimate persistence or to predict the fate or accumulation of petroleum-based pollutants in the environment. This would be useful in managing and mitigating the crisis in crude oil and plastic pollution in the Baltic region. However, there is still limited information on the degradation potential of microbial communities in the Baltic Sea, alongside the lack of environmental monitoring information on these contaminants. This prompts the need for a comprehensive profile of the region's microbial degradation capacity. In this study, we compiled metagenomic datasets, profiled the microbial community structure, and identified hydrocarbon degradation genes from benthic sediment and water column samples collected from the Baltic Sea. We report the taxonomic and functional information on the potential of Baltic Sea microbes to degrade various types of hydrocarbon contaminants. Notably, metagenome-assembled genome taxonomy revealed that known hydrocarbon-degrading taxa (e.g., UBA9160 and Acidimicrobiales) were present in both benthic and pelagic environments of the Baltic. Aerobic degradation was also the most prominent and abundant degradation pathway in all environmental samples. The microbial taxa associated with hydrocarbon degradation showed variations in their substrate preferences between environmental samples and across the Baltic Sea basin. Long-chain alkanes and dibenzothiophene are the preferred substrates of hydrocarbon degraders. Our report aims to deepen our understanding of microbial degradation of contaminants that would be useful for improving mitigation strategies for crude oil spills and plastic pollution in the Baltic Sea while addressing critical environmental concerns.

1.05.P-Tu041 Sea urchin Microbiota/Immune Cell Model for Assessing the Mutual Immune Response to Nanoparticles
Annalisa Pinsino[1], ***Andi Alijagic***[2], *Mauro Biondo*[1], *Magnus Engwall*[2], *Roberta Russo*[3], *silvia scalese*[4], *Viviana Scuderi*[4], *Simona Taverna*[1] *and Martina Ussia*[4], *(1)Institute of Translational Pharmacology (IFT), National Research Council (CNR), Italy, (2)Man-Technology-Environment Research Center (MTM), orebro University, Sweden, (3)Institute for Biomedical Research and Innovation (IRIB), National Research Council, Italy, (4)Institute for Microelectronics and Microsystems (IMM), National Research Council (CNR), Italy*
Each nanomaterial exhibits novel, cutting-edge features whose benefits depend on their safety and biocompatibility. The innate immune system acts as the first player involved in the recognition/interaction of nanomaterials, representing the main hub for explaining the safety of each new nanomaterial. Still, it is not the only system involved. The co-evolution of the microbiota with the innate immune system built an interdependence regulating immune homeostasis that is poorly studied, mainly because of the practical

and ethical difficulties of studies in mammalian models. Herein, we propose a new investigative strategy for the assessment of potential toxicity/safety concerns regarding Iron-Oxide Nanoparticles (Fe-oxide NPs) in the Fe2O3 structure, known to be used in several biomedical and environmental applications, by investigating the simultaneous interaction of particles, immune cells, and the microbiota associated with the blood of the sea urchin in a natural co-culture system, where cell-cell signaling remains preserved. Sea urchins share with human beings many gene families and biological pathways involved in innate immune defense but also a complex microbial community with a high taxonomic composition, including bacteria colonizing the human gut. The simultaneous interaction of particles, immune cells, and the associated microbiota is addressed in vitro-ex vivo by applying a wide-ranging approach, including Raman spectroscopy, 16S Next-Generation Sequencing, Cell Painting, and NanoString nCounter. Our findings highlight a shift in the composition of microbial groups associated with the molecular reprogramming of the sea urchin immune cells exposed to Fe-oxide NPs and an increase in extracellular vesicles released in the culture medium upon insult. A tolerogenic multi-level immune cell-microbiota response is designed to restore homeostasis and maintain the system in physiological balance by immune cell/microbiota conditioning (mutual immune response). Based on the evidence of the similarities between sea urchins and humans, the sea urchin microbiota/immune cell model becomes an excellent interactive proxy-to-human system for probing the immunological safety of NPs in environmentally relevant conditions and limiting animal use. This work has been financed by the European Union (Next-generation EU), PNRR, M.4-C2-1.1 through the MUR-PNRR PRIN 2022 project SURPRISE (GA P2022LASKT) and the MUR-PNRR project SAMOTHRACE (GA ECS00000022).

1.05.P-Tu042 Impact of Mining-Derived Metal Contamination on Fish Parasites at Tar Creek Superfund Site, Oklahoma

*Matteo Minghetti[1], Jason B. Belden[2], **Aryanna rene Carr**[2], Matthew Bolek[3] and Stacey Herriage[2], (1)Integrative Biology, Oklahoma State University, Stillwater, United States, (2)Oklahoma State University, Stillwater, United States, (3)Oklahoma State University, United States*

The Tri-State Tar Creek Mining District, once a lead and zinc mining hub, now suffers from severe contamination, with metals like lead, cadmium, and zinc leaking into the soil and water. This study examines how metal pollution influences fish parasitic loads and the relationship between fish and their parasites in these stressed environments. Parasites are more sensitive to metals than fish, but specific adaptive mechanism are poorly understood. Moreover, little is known about how metal exposure affects parasite diversity and health. This research enhances our understanding of metal pollution's impact on parasite populations, communities, and fish-host interactions. Field sampling took place at four sites across the Grand Lake area in Oklahoma: two reference sites (Grand Lake Honey Creek & Sycamore Creek) and two polluted sites (Tar Creek E40 and Miami, OK). Water analysis showed a clear gradient of metal contamination, with zinc levels ranging from 1.1 µg/L at reference sites to 7,000 µg/L at polluted sites. Cadmium ranged from 0.10 µg/L at reference sites to over 12 µg/L at polluted locations, and lead levels were 1.8 µg/L at reference sites and 2.5 µg/L at polluted sites. Fish were euthanized, dissected for parasites, and species richness and parasitic load was recorded. The most common parasite, the metacercariae stage of the trematode Posthodiplostomum sp., was isolated for metal analysis. A pool of fifty to seventy-five metacercariae was dried and acidified for inductively couple plasma mass spectrometry analysis (ICP-MS). Preliminary results suggest fish persist even in highly contaminated sites, but parasite species richness is notably lower at polluted sites (Miami/E40: $2.2 \pm 1.1/1.0 \pm 0.7$) compared to reference sites (GLHC/SYC: $2.4 \pm 0.9/2.4 \pm 0.547$). Parasitic load differed significantly, with fish from polluted sites hosting distinct parasite communities and an average of 109 parasites per fish, compared to 252 parasites per fish in fish from cleaner sites.

The study aims to determine if water contamination levels correlate with parasite metal bioaccumulation and diversity changes. It explores how parasitic load differs between clean and polluted sites, whether parasites accumulate metals differently from fish, and if fish and parasites co-evolve to tolerate metal exposure. By examining these relationships with water chemistry, the research addresses fundamental questions of cross-species adaptation to metal pollution.

1.05.P-Tu043 Ecotoxicological Assessment of a copper-based Nanopesticide toward *Xenopus leavis* and its Gut Microbiota

***Thomas Moura**[1], Florian Chapeau[1], van xuan nguyen[1], Marion Vivant[1], Camille Larue[1], Maialen Barret[1], Laurence Chevalier[2], Laury Gauthier[1], Eric Pinelli[1] and Florence Mouchet[1], (1)Centre de Recherche sur la Biodiversite et l'Environnement (CRBE), Universite de Toulouse, CNRS, IRD, Toulouse INP, Universite Toulouse 3 Paul Sabatier (UT3), France, (2)Groupe de Physique des Materiaux, GPM-UMR6634, CNRS, Universite de Rouen, France*

Copper nanoparticles are widely used for their antibacterial and antifungal properties, especially in nanopesticides for agricultural applications. Their release from soil to aquatic environments might threaten non-target organisms. Amphibians have already been heavily impacted by anthropogenic activities and their associated gut microbiota are likely to be sensitive to products such as copper nanoparticles. Ecotoxicological data and studies on commercial formulations that specifically focused on aquatic systems are still scarce. The aim of this study was to determine the impact of a copper (Cu(OH)?)-based nanopesticide, Kocide 3000® (K3), in comparison to Kocide 2000® (K2), a non-nanosized equivalent, at environmentally relevant concentrations (0.005 , 0.010 , 0.025 and 0.050?mg?Cu L?1). For this purpose, X. laevis tadpoles were exposed for 12 days, after which several endpoints were measured, and 16S rDNA gene sequencing was performed to characterize the bacterial composition in the gut. Copper salt (CuSO?·5H?O) was also tested to provide a benchmark for assessing copper-related toxicity alongside the complex commercial formulations. Both Kocide® products were found to inhibit the growth of exposed organisms with a significant effect at 0.050 mg Cu/L. Analyses showed that all contaminants, regardless of the concentration, induced erythrocyte cell cycle disturbances. The results obtained with the micronucleus assay demonstrated the genotoxicity of the nanopesticide K3. Regarding the intestinal microbiota response, no effect on alpha diversity was observed at the tested doses. However, bacterial communities were shown to be significantly altered. The effect of the two commercial products differs from that of copper alone, inducing a differential modification of the bacterial community structure, visible in the abundance of phyla. Only the nanopesticide K3 induced significant changes compared to the negative control at all tested concentrations. This study highlights the effects of copper nanopesticides on aquatic organisms and their associated microbiota, contributing to the understanding of microbial responses to environmental stressors. It also emphasizes the need for further research into the mechanisms underlying the genotoxic and microbiota-related impacts of copper nanopesticides, as well as their broader ecological consequences following agricultural use.

1.05.P-Tu044 Effects of Graphene Oxide on *Xenopus Laevis* After Multi Pathway Exposure: Focus on Host Associated Microbiomes

Florian Chapeau[1]*, Thomas Moura*[1]*, van xuan nguyen*[1]*, Maialen Barret*[1]*, Marion Vivant*[1]*, Emmanuel Flahaut*[2]*, Laury Gauthier*[1]*, Eric Pinelli*[1] *and Florence Mouchet*[1]*, (1)Centre de Recherche sur la Biodiversite et l'Environnement (CRBE), Universite de Toulouse, CNRS, IRD, Toulouse INP, Universite Toulouse 3 Paul Sabatier (UT3), France, (2)CIRIMAT UMR 5085, France*

Graphene-based nanomaterials, such as graphene oxide (GO), possess unique properties that have spurred their application in industrial and medical fields. However, GO is likely to be released into aquatic ecosystems during its life cycle, necessitating a thorough evaluation of its ecotoxicological risks to ensure its safe use. Amphibians are particularly sensitive to environmental contaminants, and previous studies have demonstrated various toxic effects of GO, including genotoxicity, primarily in larval stages through direct exposure. This study extends the scope by investigating the combined effects of direct and trophic GO exposure on post-metamorphic Xenopus laevis, with a focus on its impact on microbiomes critical for host homeostasis, nutrient absorption, and immunity. To simulate realistic exposure scenarios, dipteran larvae were exposed to different concentrations of GO for 24 hours before being introduced as prey to juvenile Xenopus. These amphibians ingested the GO-laden larvae while also being exposed to GO in the water column. Genomic DNA was extracted from the entire intestine and a skin fragment of Xenopus after 24 and 96 hours to analyze bacterial community composition. The microbiota of the dipteran larvae was also characterized. The results revealed GO-induced shifts in the abundance of key intestinal phyla, such as Firmicutes and Bacteroidetes, which are often associated with dysbiosis. On the skin, significant alterations in microbiome composition were observed, including changes in Proteobacteria, a phylum crucial for resistance to pathogens like Batrachochytrium dendrobatidis. Additionally, the microbiota of dipteran larvae, representing the lower trophic level, was affected by GO exposure. This study highlights the potential ecological consequences of GO contamination at environmentally relevant concentrations, demonstrating its disruptive effects on microbiomes under realistic exposure conditions. The findings underscore the importance of integrating microbiome analyses into ecotoxicological studies to account for indirect effects that may have significant ecological implications.

1.05.P-Tu045 Assessing the Effects of Pollutants in Stormwater Wetlands on Sedimentary Microbial Community Structure Using eDNA Metabarcoding

Anna Flynn[1]*, Sara M Long*[1]*, Vincent J. Pettigrove*[2]*, Kathryn Hassell*[1]*, Jeff Shimeta*[1] *and Mark Osborn*[1]*, (1)RMIT University, Australia, (2)Aquest Research Group, RMIT University, Australia*

Pollution poses a significant threat to freshwater ecosystems with metals and pesticides in particular representing long-term and widespread hazards. Constructed wetlands are an important tool for managing stormwater in urban landscapes, capturing and retaining contaminants in their sediments. Currently there is a lack of consideration for microbial taxa when determining the impacts of contamination on aquatic environments, and conversely an absence of microbial indices which could enhance current biomonitoring by increasing the scope and sensitivity of analyses. Environmental DNA is expanding the field of aquatic monitoring with the ability to assess biological profiles quickly and reliably, providing knowledge of how contamination affects ecosystems at a microbial level. By understanding what contaminants are in our waterways and how they affect all aspects of ecosystem functioning, we can better target mitigations to manage responses. In this study we collected sediment samples from the inlet and outlet of nine urban stormwater wetlands and one rural wetland, analysing them for chemical contaminants, and microbial community structure through 16S rRNA metabarcoding. Multivariate analyses were used to determine the interrelation between the chemical and biological data. We found significant variation in microbial communities between the rural wetland and all stormwater wetlands, between some of the stormwater wetlands, and between over half of the inlets to outlets. Cyanobacteria and Proteobacteria were mostly driving this variation, along with Planctomycetota and Bacteriodota. Seven families were also identified as having bioindicative potential for pollution in freshwater. We observed significant correlations between community structure and zinc and barium, with the latter not previously reported to be associated with microbial dynamics in freshwater. Our study further validates the use of eDNA metabarcoding to reliably evaluate sedimentary microbial profiles in freshwater, highlighting its value in the assessment and prediction of contamination in these environments. We identified pollutants of concern being seen commonly across urban environments in Melbourne and showed evidence that they are impacting the abundance and diversity of sedimentary microbial communities in stormwater wetlands. Through this we were able to identify potential microbial bioindicators which could be used in a biotic index as a measure of contamination in freshwaters.

1.05.P-Tu046 Soil Microbial Ecotoxicology – Protecting Ecosystem Key Players and Preserving Ecosystem Services

***Lara Jochum*[1]*, Naomi Young*[2] *and WIlliam Orsi*[3]*, (1)Ramboll Deutschland, Germany, (2)Ramboll UK Ltd., United Kingdom, (3)Ludwig-Maximilians-University of Munich, Department of Earth and Environmental Sciences Palaeontology & Geobiology, Germany*

This presentation will explore current requirements under various existing EU regulations to assess ecotoxicological impact on microbial communities. It will delve into the regulations and compare with the latest scientific studies and research to identify whether microbial communities are sufficiently protected from hazards of chemicals emitted to the environment. Any gaps that are identified will be discussed with regard to the effects that chemical pollutants may have on soil microbial communities. We will explore subsequent ripple effects that extend from microbial communities to other organisms within the ecosystem and ultimately on the functionality of the ecosystem itself. Microbial communities are the basis of most ecosystems on Earth, ranging from deep-sea vents over planktonic communities to various soil ecosystems. Colonization by microorganisms and their metabolic impact make these ecosystems available to other organisms and in many cases are a driving force behind the diverse ecosystems that are found around the world. As a result, disturbance to those sometimes very sensitive microbial communities, can have far reaching effects, impacting biodiversity, ecosystem function and finally ecosystem services. It is known that microorganisms can react radically to a changed chemical environment by using different nutrients or changing their metabolism based on availability of different electron acceptors/donors. While this is well known for lab cultures and has been extensively studied in the lab for numerous microbial communities, the far-reaching impacts this might have on a global scale are poorly understood. Chemical pollution may for example, lead to toxicity effects, changing the composition of microbial communities or impact nutrient availability. With molecular tools becoming increasingly available over the past two decades, we now have the tools to study microbial ecotoxicology in the field using a combination of various incubation methods combined with molecular and sequencing approaches. In this presentation I will provide an outlook on how experimental methods may be used to understand the impact of chemical pollution on microbial communities in selected environments. Comparing this with the initial review of the current regulatory status, we will understand which gaps will need to be addressed from a regulatory perspective to protect microbial communities in the environment and preserve their critical function within ecosystems.

1.05.P-Tu047 High-Throughput Screening of Organic Contaminants Affecting Host-Associated and Environmental Microbiomes

***Göksu Celik*[1]*, Claire Lamb*[2]*, Alexander Loy*[2] *and Thilo Hofmann*[1]*, (1)University of Vienna, Centre for Microbiology and Environmental Systems Science, Division of Environmental Geosciences, Austria, (2)University of Vienna, Centre for Microbiology and Environmental Systems Science, Division of Microbial Ecology, Austria*

Tire chemicals and per- and polyfluoroalkyl substances (PFAS) are among the most concerning environmental pollutants due to their persistence, widespread distribution, and harmful effects. While traditional (eco)toxicological studies often focus on in vitro and in vivo models, they typically involve a limited selection of organisms, tissues or cells, with little attention is given to microbial communities. However, microbiomes are crucial for maintaining human health and ecological balance, playing vital roles in immune function, nutrient cycling and pathogen resistance in both human and environmental systems. Exposure to xenobiotics, such as persistent or toxic pollutants, can disrupt microbiome composition and is a potential driver of shifts in microbial diversity and function. To address this, we conducted a comprehensive screening of the effects of tire chemicals and PFAS on both host-associated (human gut and lung) and free-living (soil) microbiomes. To systematically investigate chemical contaminant-microbiome interactions across diverse systems, we evaluated the growth of about 60 representative bacterial, archaeal, and fungal strains sourced from human gut, lung, and soil habitats, following exposure to 30 chemicals (tire additives and PFAS) and their mixtures. Our overarching goal is to provide the first comprehensive, cross-system understanding of the impact of emerging pollutants on human and environmental health by elucidating how microbial growth is affected by exposure to tire chemicals and PFAS across diverse habitats. Authors acknowledge funding from the Austrian Science Fund, Cluster of Excellence CoE7, Grant-DOI 10.55776/COE7.

1.06.A Data-Driven Toxicology: Practical Applications and Insights into Using Existing and Emerging Data in Support of Human and Environmental Health

1.06.A.T-01 FAIR Toxicology Data Approaches Being Developed in PARC

*Iseult Lynch[1] and **Indrani Mahapatra**[2], (1)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom, (2)University of Birmingham, United Kingdom*

Risk Assessment, whether for humans or the environment, requires access to high quality data regarding both exposure and hazard of chemicals, which presents a significant challenge currently as each sub-domain (exposure, toxicology, human and environmental (bio)mitoring) has its own methodological approaches and conventions in how to collect, capture, store and share data, and these are not necessarily compatible (interoperable in technical terms). A major effort within PARC is devoted to developing and optimising the working practices, and technical solutions, to enable integration of disparate data for enhanced chemical risk assessment and responsive regulation. Toxicology data spans a huge range of approaches (in vitro, in vivo, in silico), end-points (apical / regulatory, mechanistic), timescales (acute, chronic, repeat dose, post-exposure monitoring, surveillance), data types (omics, image, summary etc.) and organisational frameworks (e.g., adverse outcome pathways). Here we present the PARC Toxicology cluster activities, including landscape mapping existing approaches (inventory of FAIR Enabling Resources for Toxicology), the PARC metadata at investigation, study and assay (ISA-Tab) levels and metadata capture templates and code-book, and the development of new metadata capture templates for end-points not yet covered in the OECD Harmonized Templates. Within the PARC Toxicology cluster activities to make toxicology data FAIR (Findable, Accessible, Interoperable and Re-usable) are grouped under 4 key areas - regulatory toxicity, omics, images and AOP. While each have unique challenges and objectives, there are a lot of commonalities across the approaches and tools available to support FAIRification of these data, such that the clustering will ensure cross-talk and sharing of best practices across areas. A toxicology-wide landscape mapping has been performed to capture the full spectrum of FAIR Enabling and FAIR Supporting resources, which has been published as the PARC Toxicology FAIR Implementation profile, and will be presented along wiht a FAIR Convergene Matrix showing commonalities with other projects / efforts working on toxicology, including the ASPIS project cluster, and gaps where no FAIR Enabling Resources exist, as a mens to prioritrise our FAIR-Tooling developement efforts. This is a living document that will be continuous updated as new tools or approaches emerge, or as tools or approaches become obsolete in this fast-moving field. Funded via the Horizon-Europe Partnership for Assessment of the Risks of Chemicals (PARC, Grant Agreement No. 101057014), with co-funding for UK contribution via Innovate UK (project ID 1003384).

1.06.A.T-02 Precision Environmental Health: A Data-Driven Approach That Identifies Hazards of Complex Chemical Mixtures in the Environment

***Xiaojing Li**, Jiarui Zhou, Luisa Orsini and John K. Colbourne, School of Bioscience, Centre for Environmental Health and Justice (CERJ), University of Birmingham, United Kingdom*

The assessment and regulation of chemical toxicity to protect human health and the environment is done one chemical at a time and seldom at environmentally relevant concentrations. However, chemicals are found in the environment as mixtures, and their toxicity is largely unknown. Understanding the hazard posed by chemicals within the mixture is critical to enforce protective measures.
Here, we demonstrate the application of a data-driven, hypothesis-free approach to the sentinel and

ecotoxicology model species Daphnia to reveal the biomolecular response induced by real-world mixtures. We exposed a Daphnia strain to the river waters of the Chaobai River and measured gene expression profiles. Using a multi-block correlation analysis, we establish correlations between chemical mixtures identified in 30 water samples with gene expression patterns induced by these chemical mixtures. We identified 80 metabolic pathways putatively activated by mixtures of inorganic ions, heavy metals, polycyclic aromatic hydrocarbons, industrial chemicals, and a set of biocides, pesticides and pharmacologically active substances. Our data-driven approach discovered both known bioactivity signatures with previously described modes of action and new pathways linked to undiscovered potential hazards. This study demonstrates the feasibility of reducing the complexity of real-world mixture toxicity to characterise the biomolecular effects of defined chemical components based on gene expression monitoring of the sentinel species Daphnia. This work was supported by the Royal Society International Collaboration Award (grant No IC160121), the European Union s Horizon 2020 research and innovation programme (grant No. 965406), the National Natural Science Foundation of China (grant No. U20A20133), and the Natural Environmental Research Council Innovation People (grant No. NE/Y005120/1).

1.06.A.T-03 Ecotoxicity Prediction of Plastic Additives and Their Alternatives Using ToxCast/Tox21 Data-Based Machine Learning Models Within a Cross-Species Adverse Outcome Pathway Framework

***Donghyeon Kim**, Siyeol Ahn and Jinhee Choi, University of Seoul, Korea, Republic of*

Plastic pollution is a critical global issue, with micro- and nano-sized particles from degrading plastics leaching additive chemicals into the environment, contributing significantly to toxicity. While hazards of legacy plastic additives like DEHP are known, ecotoxicity data for many alternatives remain limited. Large repositories of in vitro high-throughput screening data, such as the US EPA's ToxCast, offer valuable resources, but their application has largely been limited to human risk assessment rather than ecotoxicological contexts. The adverse outcome pathway (AOP) framework offers a promising approach to bridging this gap by linking molecular toxicity endpoints to apical effects in both humans and ecological species. This study aimed to identify cross-species AOPs relevant to plastic additives and develop machine learning models for predicting the ecotoxicity of alternative plasticizers. The in vitro response of plastic additives in human cells was examined, and conserved mechanisms were identified using SeqAPASS. These mechanisms were compared to in vivo ecotoxicity data from the ECOTOX database to determine their relevance to apical toxicity in ecological species. Based on this analysis, potential cross-species AOPs were identified. Machine learning models were then trained using molecular fingerprints and datasets integrating ToxCast bioassays with ECOTOX data. Model performance was assessed through five-fold cross-validation and in-loop validation. Mechanisms related to androgenicity leading to developmental and reproductive toxicity were conserved across humans and fish. For chemicals tested in both in vitro ToxCast/Tox21 assays and in vivo studies, bioactive concentrations (AC50) for androgen receptor binding and transcription were significantly correlated with the lowest effect levels (LELs) observed in ecological species. These findings informed the development of cross-species AOPs. Machine learning models trained on in vitro and in vivo datasets achieved high performance, with AUC-ROC values ranging from 0.68 to 0.92. This study demonstrated the utility of integrating ToxCast/Tox21 bioassays and AOP frameworks to develop ecotoxicity prediction models for data-poor plastic additives chemicals, addressing key data gaps in ecological risk assessment. A case study for screening alternative plastic additives is ongoing. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through 'Core Technology Development Project for Environmental Diseases Prevention and Management', funded by Korea Ministry of Environment (MOE) (2021003310005).

1.06.A.T-04 Revolutionizing Chemical Testing: 70% of Chemicals May Not Require Fish In Vivo Studies

***Richa Malik**[1], Bruno Campos[2], Claudia Rivetti[3], Luigi Margiotta-Casaluci[4] and Christer Hogstrand[4], (1)King s College London, United Kingdom, (2)Unilever, Bedford, United Kingdom, (3)Unilever, Sharnbrook, United Kingdom, (4)King's College London, United Kingdom*

Environmental risk assessment is required for regulatory approval and marketing of chemicals. It traditionally includes aquatic ecotoxicity studies of species from three trophic levels: algae, crustaceans and fish. The large number of resources, costs, and animals used for toxicity tests, lack of societal acceptance, and phasing out of animal testing for regulatory purposes have resulted in the increasing uptake of the 3Rs (Reduce, Replace, and Refine) principles in safety science. These drivers alongside the push for an enhanced understanding of toxicity, increased the attention towards the use of new approach methodologies (NAMs). One such method is identifying chemicals for which fish are the most sensitive aquatic taxa and understanding the biological mechanisms resulting in toxicity. The ECOTOXicology

Knowledgebase (ECOTOX) with aquatic toxicity data for 10,157 chemicals is a valuable platform for cross-species analysis of toxicity data. We performed a large-scale analysis of the ECOTOX data for comparative sensitivity assessment of different aquatic species to chemicals. We hypothesised that this would help identify group chemicals for which risk assessment based on algae and invertebrate data would be protective of fish, too. We developed a Python pipeline to extract, refine, harmonise, and analyse the median lethal concentrations (expressed as LC50s) and No Observed Effect Concentrations (NOECs) for all available laboratory-based aquatic toxicity studies. Our study shows that most chemicals in the ECOTOX database have comparable median NOECs and LC50 values across different aquatic trophic levels, and fish display higher sensitivity than other species for only a small percentage of chemicals. Understanding the pathways underlying the apparent higher sensitivity of fish to these chemicals may provide a strong rationale for predicting species sensitivity to untested chemicals. It would also bypass the need for chemical testing in fish where a more sensitive lower trophic level is available as an alternative (algae/invertebrate).

1.06.P-Th002 The Impact of Chemicals Found in the Urban Environment on the Genetic Variation in Mice

***Daniel Guignard**, Tiffany Scholier and Marissa B Kosnik, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Biodiversity has been declining at an alarming rate in recent years due to human activities. Among the pressures exerted in the environment, chemical pollution has been ranked as the third largest driver of biodiversity loss, just below land/sea use change and direct exploitation of natural resources. While chemical risk assessments traditionally focus on species sensitivity to chemical exposure, the impact of chemical pollution on genetic diversity remains underexplored due to challenges such as limited data availability and high costs of sequencing many individuals from wild populations across many species. Nonetheless, the preservation of genetic diversity of wild populations is gathering high interest from the international community and was included in the first global policy agreement at the UN Biodiversity Conference (COP15) in 2022. To better understand how human activities, particularly how chemical pollution can impact the genetic profiles of populations, new computational methods are urgently needed. To address the current knowledge gap of this growing field of research, our approach capitalizes on publicly available data of wild single nucleotide polymorphism (SNPs) from 814 wild mice sampled across 268 locations. We used a landscape genomics approach to characterize the relationship between genetic variation and urban land use data as a proxy for chemical pollution. As a result, we identified 296 genes associated to the urban environment based on significant intragenic SNPs. These genes were mapped to a new, integrated dataset connecting chemicals, toxicity pathways, and phenotypic outcomes based upon public databases (Comparative Toxicogenomics Database, Reactome, Monarch Initiative). Through this, we identified chemicals with strong associations to urban environments, including combustion pollutants, consumer product derivatives, industrial chemicals, and pharmaceuticals. This approach identified genetic variants in genes potentially adapted to the selective pressures exerted by urban chemical exposure. Our framework provides a novel method for prioritizing chemicals based on their potential impacts on the genetics of wild populations, therefore addressing the key challenge of limited data availability. By integrating and repurposing disconnected datasets, this strategy supports conservation goals and offers a scalable tool for chemical risk assessment across species and environments.

1.06.P-Th009 Towards Reliable Chemical Toxicity Predictions with Quantified Uncertainty

***Kerstin von Borries**[1], Katie V Beckwith[2], Jonathan M Goodman[2], Weihsueh A Chiu[3], Olivier Jolliet[1] and Peter Fantke[4], (1)Technical University of Denmark, Denmark, (2)University of Cambridge, United Kingdom, (3)Texas A&M University, United States, (4)substitue ApS, Goethe University, Denmark*

Chemical impact assessments are limited by insufficient data on chemical fate, exposure and effects. Machine learning (ML)-based in silico prediction tools offer high prediction performance and broader applicability than conventional quantitative structure-activity/property relationships. However, their widespread uptake has been hindered by inconsistent applicability across chemicals and lack of transparency regarding model reliability, which undermines confidence in their predictions and complicates integrating predicted and measured data sources. This work demonstrates how uncertainty-aware ML can address some of these challenges by (1) developing models that quantify data- and model-related uncertainty, and (2) using these models to predict reproductive/developmental and general non-cancer human toxicity points of departure (PODs) for >130,000 marketed chemicals. Our results show that the uncertainty-aware ML methods provide well-calibrated uncertainty estimates that are closely aligned with observed prediction errors, assigning more unfamiliar chemicals higher prediction uncertainty. Applying the models to diverse marketed chemicals identifies hotspots of high toxicity, including dioxins and PFAS, and areas of high uncertainty, such as alkaloids, metals and organometallic compounds. Our results address critical data gaps by providing human toxicity PODs with 95% confidence intervals for a large set of marketed chemicals. Furthermore, they demonstrate how uncertainty-aware ML highlights unreliable chemical classes that should be systematically targeted in future data generation and model development to improve prediction reliability, addressing key drivers of uncertainty such as lack of representation or limited descriptor applicability. Widespread adoption of uncertainty-aware ML will be crucial to enhance the transparency and reliability of ML predictions, paving the way for broader acceptance and application of in silico approaches in chemical assessments. This work was financially supported by the Safe and Efficient Chemistry by Design (SafeChem) project funded by the Swedish Foundation for Strategic Environmental Research (grant no. DIA 2018/11).

1.06.P-Th011 Generalized Multivariable Linear Regression-PBPK Modelling for Nanoparticle Biodistribution Prediction Using Physicochemical Properties
***Jimeng Wu**, Peter Wick and Bernd Nowack, EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland*
Physiologically based pharmacokinetic (PBPK) models are essential for predicting nanoparticle (NP) biodistribution, supporting drug delivery and toxicity research. However, traditional PBPK models are often limited to specific NP types, typically requiring animal studies for accurate parameterization, which restricts broader applicability. This study aims to develop a generalized PBPK model that integrates physicochemical properties for early screening of NP delivery efficiency, reducing reliance on animal testing. We developed a generalized PBPK model based on in vivo mouse studies, assisted by multivariable linear regression (MLR) modeling to predict the biodistribution of NPs based on their physicochemical properties. Integrating biodistribution data from five non-dissolvable NPs (Au, FeO, TiO?, Graphene oxide, and SiO?), we investigated how NP properties (core material, coating, zeta potential, shape, hydrodynamic size, and dose) affect NP distribution across four key organs (kidney, liver, spleen, lung). The model demonstrated strong predictive performance for kinetic indicators, achieving an adjusted R^2 of up to 0.95. Predictor frequency analysis indicated that zeta potential and coating had the biggest influence on biodistribution, with NP size also significantly impacting organ-specific interactions. The model accurately predicted delivery efficiency but encountered limitations in estimating the full set of PBPK model parameters, likely due to dataset constraints. For example, some FeO and GO studies with identical NP properties exhibited substantial variance in PBPK model parameter distributions, highlighting the need for more diverse NP property data to enhance predictive accuracy. In conclusion, this generalized MLR-PBPK model provides a practical and interpretable approach for NP evaluation, supporting early screening and reducing the need for animal studies. Expanding the dataset and exploring non-linear models could improve predictions, particularly for full concentration-time profiles. This model represents a promising tool for predictive toxicology and optimized NP design, with potential applicability across species, contributing to safer and more effective NP applications.

1.06.B Data-Driven Toxicology: Practical Applications and Insights into Using Existing and Emerging Data in Support of Human and Environmental Health

1.06.B.T-01 Searching for the Evolutionary Origins of Chemical Toxicity
***John K. Colbourne**, University of Birmingham, United Kingdom*
Regulatory toxicology faces the fundamental challenge of setting chemical exposure safety limits for many species, including humans, based on experimental data obtained from only a few standard test species. This pragmatic approach to testing representative species of the animal kingdom cannot achieve the desired protection of human health and the environment without an evolutionary and ecological interpretation of why the toxicity experimentally observed in a suite of species (the source of toxicological information) is predictive of the response of other distantly related organisms. PrecisionTox provides evidence on the feasibility of understanding the health impact of chemicals on all animals, including ecological keystone species and humans, based on the evolutionary conservation of pathways to toxicity. The project creates and assembles transcriptomics and metabolomics data into putative biomolecular key toxicity events shared among model species (Danio rerio embryos, Xenopus laevis embryos, Daphnia magna, Caenorhabditis elegans and Drosophila melanogaster) and human cells. A customised data analysis and visualisation tool allows users to explore the comparative toxicology results from a pilot study to reveal the extent to which specific mechanistic responses in species distributed among long branches of animal phylogeny are interpretable in light of human biology. Overall, the concept of toxicity by descent, which posits that there is an evolutionarily shared response to chemicals across animals, can already be gleaned from a relatively small number of tested substances. PrecisionTox builds a case for One Health Toxicology, allowing for a concerted effort to protect people and the environment from the

harmful effects of chemical pollution. This project has received funding from the European Union s Horizon 2020 research and innovation programme under Grant Agreement No. 965406.

1.06.B.T-02 A Harmonized ECOTOX Dataset to Train a Random Forest Model for Predicting Ecotoxicity Effects in Honeybees

***Junxuan Shi*[1]**, *Olivier Jolliet*[1] *and Peter Fantke*[2], *(1)Quantitative Sustainability Assessment, Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (2)substitute ApS, Denmark*

Available data for chemical ecotoxicity in honeybee are primarily ED50 acute data. However, ED10 chronic exposure levels correspond more to real-world levels and aligned with state-of-the-art life cycle impact assessment methods, but mostly lacking. We address this gap by developing a random forest model trained by a large, comprehensive ecotoxicity-chemical property dataset with 5328 records covering 540 chemicals. The ecotoxicity data were sourced from the ECOTOX database and primarily harmonized through category and unit standardization to achieve data consistency and uniformity. We performed weighted linear regressions on the harmonized dataset to extrapolate endpoints, establishing an integrated ED10-equivalent chronic and acute dataset across different life stages (adult and larva) and exposure types (oral and dermal). These datasets were enriched with chemical properties, e.g., mode of action, molecular descriptors, chemical categories, from multiple sources. The enriched dataset was split into training and test sets using two splitting schemes: totally random , where the dataset was randomly split, and random by chemical , where the chemicals present in the training and test dataset were kept distinct. Both splitting schemes were tested on the model training and prediction, applying cross-validation to avoid overfitting. The totally random -based model showed a performance with root mean square error (RMSE) of 0.78, while a decreasing performance with an RMSE of 1.34 was observed when using the random by chemical -based model. However, we observed improved performance when constraining the dataset by fixing the life stage and effect type, resulting in RMSE between 0.87 and 0.93. This suggests that the random forest model was hindered by the ecotoxicity variability introduced by data attributes. By fixing these attributes, the model achieved a satisfactory performance even with limited data of 309 records. Eventually, we applied the random forest model to predict the ecotoxicity data of selected pesticides. These data were input into an impact assessment model to characterize the impact of the applied pesticide on honeybee. This study provides an integrated ecotoxicity-chemical property dataset suitable for various model training and data analysis. We also trained a random forest model to predict ecotoxicity data for honeybee and evaluated the impact of unknown chemicals on honeybee using the predicted ecotoxicity data. This project is funded by Bayer AG Crop Science Division.

1.06.B.T-03 Modeling the Bigger Picture: Hierarchical Approaches for Integrating Diverse Toxicological Data in Mechanistic Models

***Florian Schunck*[1]**, *Wibke Busch*[2] *and Andreas Focks*[3], *(1)Osnabruck University, Germany, (2)Helmholtz Center for Environmental Research, Leipzig, Germany, (3)Institute of Mathematics, Osnabrück University, Germany*

Molecular measurements from high-throughput methods are becoming increasingly available and extend the existing wealth of diverse toxicological data. Jointly integrating such data into mechanistic models can advance chemical risk assessment by increasing the level of biological understanding. However, there is still a lack of understanding and methods for integrating qualitatively and quantitatively different datasets from different experiments into mechanistic models. Two major challenges remain: 1. Datasets are often incomplete due to experimental limitations (data sparsity). 2. Datasets from multiple sources are noisy due to experimental and biological variation (data variability). To fully utilize such data for advancing the understanding of the underlying processes of toxic effects of chemicals and improving predictions of untested substances, the issues of data sparsity and data variability must be addressed. In the presented work, these issues are addressed by applying Bayesian hierarchical modeling to a diverse dataset. As a mechanistic model, we use a molecular TKTD model fitted on time-resolved internal concentration, nrf2 expression, and survival data after exposure to diclofenac, diuron, and naproxen from 42 experiments with zebrafish embryos. To study the potential of hierarchical modeling, we estimate the true external concentration as a function of the nominal external concentration multiplied by an experiment-specific deviation factor. Early results show that, on average, the modeled external concentrations deviate by a factor of 2.1 (94% HDI = [1.9, 2.3]) with a log standard deviation of 0.81 from the nominal concentrations. Using the hierarchical approach, all 42 experiments included in the entire dataset could be used. In contrast, when estimating the model parameters without a hierarchical approach, 11 experiments where exposure concentrations clearly deviated from the nominal concentrations had to be excluded to achieve a reasonable fit. The approach shows how hierarchical modeling approaches can be instrumental in revisiting existing experimental data and integrating them into mechanistic models together with newly incoming molecular data to understand chemical effects in organisms and approach predictive risk assessment.

1.06.B.T-04 A Data Analysis Pipeline for High-Content Bioimage Phenotyping in Toxicology: Development and Applications

Miha Tome[1]*, Barbara Jozef*[2]*, Sven Mosimann*[3]*, Kristin Schirmer*[3] *and Anze Zupanic*[1]*, (1)Department of Biotechnology and Systems Biology, National Institute of Biology, Slovenia, (2)Department Environmental Toxicology, Eawag, Switzerland, (3)(1) Department Environmental Toxicology, Eawag, Dubendorf; (2) Institute of Biogeochemistry and Pollutant Dynamics, ETHZ, Zurich, Switzerland*

Our research on fish demonstrated a strong link between in vitro cellular response, such as reduced proliferation, and in vivo impaired growth following chemical exposure. Chemicals that didn t impair growth in fish similarly fail to reduce cell count in vitro. This raises a question: how do chemicals with diverse structures and mechanisms of action result in the same outcome reduced cell population and thus, impaired fish growth?

Investigating these questions, we used the RTgill-W1 cell line from rainbow trout, known for its predictive power in linking in vitro cell numbers with in vivo organism size. We employed established methods, such as chemical exposure experiments and transcriptomics, and innovative methods such as translatomics and high-content bioimage phenotyping.

Here, we present a novel computational pipeline for the analysis of high-content bioimages for ecotoxicological purposes. The pipeline includes extracting information from segmented images, quality control with trained classifiers, pooling of the data at the individual cell level, removal of batch effects and outliers, and feature selection and correlation filtering. Exploration of each step allowed us to establish an optimal decision tree for noise reduction and refining the data for interpretation. Among other, we showed that standardization of the data is needed for accurate analysis of the images, while removal of the artefacts seemed less important. We also introduced a new method for selecting the most relevant features based on dose-response considerations; and showed that the maximum-mean discrepancy can be used as a measure of image perturbation, which is slightly more sensitive than traditional cell-count based concentration-response curve fitting. We found that the 2D UMAP data projection was the most helpful for biological interpretation of the results, as it shows a separation of the cell populations both with increasing chemical concentration as well as with days after exposure. Features related to the lysosome and nuclei intensity were among the most perturbed, pointing to impaired autophagy and cell cycle disruption.

Tailored to our specific experimental setup and biological question, this pipeline enabled the management and analysis of large bioimaging datasets, producing clearer dose-response signals for interpreting cellular mechanisms. The presented study serves as a blueprint for constructing similar workflows for a wide range of high-content image-based assays.

1.06.P-Th001 Benchmarking Environmental Risk for Plant Protection Products: A Case for Insecticides and Acaricides

Paul Nnamdi Ozoh *and Ralf Bernhard Schaefer, Research Center One Health Ruhr, Ecotoxicology and Faculty of Biology, University Duisburg-Essen, Germany*

Agricultural pesticides, while vital for crop protection, are increasingly recognised as critical contributors to biodiversity loss despite stringent regulatory frameworks in the European Union (EU). Current environmental risk assessments (ERA) for plant protection products (PPPs) often fail to provide comparable risk outcomes across substances, taxonomic groups, and environmental compartments. This study addresses this gap by developing a benchmarking framework to rank PPPs based on their relative environmental risks, focusing on insecticides and acaricides approved in the EU. We compiled a comprehensive database using prospective ERA data from regulatory sources to achieve this. Key parameters included toxicity, persistence, bioaccumulation, mobility, and exposure scenarios. The risk quotient (RQ) for aquatic organisms served as the primary benchmark, enabling comparisons across organism groups, representative uses, time scales, tiers, and exposure scenarios.

Preliminary results highlight significant variability in RQs, with several substances approved only for specific uses or with risk mitigation measures. Notably, substances with high persistence and bioaccumulative potential posed elevated risks. These findings underline the importance of tier-specific analyses and the need for consistent, comparative methodologies.

Our study underscores the potential of benchmarking to enhance the transparency and efficiency of ERAs, enabling more informed regulatory decisions. This framework can advance biodiversity protection and inform future regulatory practices by identifying high-risk substances and prioritising mitigation strategies. This investigation is supported by the European Partnership for the Assessment of Risks from Chemicals (PARC) under grant agreement No. 101057014. This publication reflects only the author's

view, and the European Commission is not responsible for any use that may be made of the information it contains.

1.06.P-Th010 Prediction of In Vitro Neurotoxicity Through Machine Learning

Christoph Schuer[1]*, Lilian Gasser*[2]*, Antoine Escoyez*[2]*, Kristin Schirmer*[1]*, Guillaume Obozinski*[2] *and Marco Baity-Jesi*[1]*, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Swiss Data Science Center (SDSC), Switzerland*

Neurotoxicants, i.e., chemicals that specifically affect structural or functional aspects of the nervous system, pose a challenge to environmental hazard assessment. Neurotoxicity can follow different modes of actions by targeting specific receptors, molecules, or cells within an organism. Hence, many in vitro assays have been developed to assess the effects of chemicals on different mechanistic targets or cellular structures. However, even with their marked advantages, high throughput in vitro methods cannot fulfill the growing needs for fast and cost-effective neurotoxicity testing of chemicals. Here, in silico methods, such as machine learning models, can integrate a range of in vitro endpoints to allow for rapid and, after model implementation, low-cost prediction of neurotoxic potential across a broad range of assay endpoints. We selected neurotoxicity-related data for in vitro effect assays from the latest version of invitroDB database and processed them through the pytcpl pipeline by Arturi et al. (under revision). The resulting dataset of 50 endpoints was split into training and test data and used to develop binary classification models (logistic regression, support vector machines, random forest, and extreme gradient boosting (XGBoost). The Friedman s tests for all endpoints showed that, based on average precision, ROC, and MCC, the models perform similarly, and no model is superior. For 42 of 50 endpoints all models performed better than random and for more than half of the endpoints all models achieved an average precision above 0.6. Class imbalance, e.g., overrepresentation of inactive compounds, and differences in the range of chemical properties between training and test set influenced performance as well as the threshold used to label a chemical as active in a respective endpoint. The latter was further investigated at different levels (response levels of 0.1, 0.5, 0.9 in an endpoints) and, for some endpoints, lowering the threshold towards the more conservative level of 0.1 improved the performance. Overall, the application of machine learning models to predict neurotoxicity based on in vitro data shows promise to enable rapid prediction of the neurotoxic potential of chemicals. This, in turn, strengthens the case for the use of machine learning to integrate data sources from different alternatives to animal testing with chemical features to cover a broad spectrum of modes of action.

1.06.P Data-Driven Toxicology: Practical Applications and Insights into Using Existing and Emerging Data in Support of Human and Environmental Health

1.06.P-Th001 Benchmarking Environmental Risk for Plant Protection Products: A Case for Insecticides and Acaricides

Paul Nnamdi Ozoh *and Ralf Bernhard Schaefer, Research Center One Health Ruhr, Ecotoxicology and Faculty of Biology, University Duisburg-Essen, Germany*

Agricultural pesticides, while vital for crop protection, are increasingly recognised as critical contributors to biodiversity loss despite stringent regulatory frameworks in the European Union (EU). Current environmental risk assessments (ERA) for plant protection products (PPPs) often fail to provide comparable risk outcomes across substances, taxonomic groups, and environmental compartments. This study addresses this gap by developing a benchmarking framework to rank PPPs based on their relative environmental risks, focusing on insecticides and acaricides approved in the EU. We compiled a comprehensive database using prospective ERA data from regulatory sources to achieve this. Key parameters included toxicity, persistence, bioaccumulation, mobility, and exposure scenarios. The risk quotient (RQ) for aquatic organisms served as the primary benchmark, enabling comparisons across organism groups, representative uses, time scales, tiers, and exposure scenarios.
Preliminary results highlight significant variability in RQs, with several substances approved only for specific uses or with risk mitigation measures. Notably, substances with high persistence and bioaccumulative potential posed elevated risks. These findings underline the importance of tier-specific analyses and the need for consistent, comparative methodologies.
Our study underscores the potential of benchmarking to enhance the transparency and efficiency of ERAs, enabling more informed regulatory decisions. This framework can advance biodiversity protection and inform future regulatory practices by identifying high-risk substances and prioritising mitigation strategies. This investigation is supported by the European Partnership for the Assessment of Risks from Chemicals (PARC) under grant agreement No. 101057014. This publication reflects only the author's view, and the European Commission is not responsible for any use that may be made of the information it contains.

1.06.P-Th002 The Impact of Chemicals Found in the Urban Environment on the Genetic Variation in Mice

***Daniel Guignard**, Tiffany Scholier and Marissa B Kosnik, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Biodiversity has been declining at an alarming rate in recent years due to human activities. Among the pressures exerted in the environment, chemical pollution has been ranked as the third largest driver of biodiversity loss, just below land/sea use change and direct exploitation of natural resources. While chemical risk assessments traditionally focus on species sensitivity to chemical exposure, the impact of chemical pollution on genetic diversity remains underexplored due to challenges such as limited data availability and high costs of sequencing many individuals from wild populations across many species. Nonetheless, the preservation of genetic diversity of wild populations is gathering high interest from the international community and was included in the first global policy agreement at the UN Biodiversity Conference (COP15) in 2022. To better understand how human activities, particularly how chemical pollution can impact the genetic profiles of populations, new computational methods are urgently needed. To address the current knowledge gap of this growing field of research, our approach capitalizes on publicly available data of wild single nucleotide polymorphism (SNPs) from 814 wild mice sampled across 268 locations. We used a landscape genomics approach to characterize the relationship between genetic variation and urban land use data as a proxy for chemical pollution. As a result, we identified 296 genes associated to the urban environment based on significant intragenic SNPs. These genes were mapped to a new, integrated dataset connecting chemicals, toxicity pathways, and phenotypic outcomes based upon public databases (Comparative Toxicogenomics Database, Reactome, Monarch Initiative). Through this, we identified chemicals with strong associations to urban environments, including combustion pollutants, consumer product derivatives, industrial chemicals, and pharmaceuticals. This approach identified genetic variants in genes potentially adapted to the selective pressures exerted by urban chemical exposure. Our framework provides a novel method for prioritizing chemicals based on their potential impacts on the genetics of wild populations, therefore addressing the key challenge of limited data availability. By integrating and repurposing disconnected datasets, this strategy supports conservation goals and offers a scalable tool for chemical risk assessment across species and environments.

1.06.P-Th003 Data-Driven Insights into Plastic Additives-Induced Toxicities Using Stressor-centric Adverse Outcome Pathway (AOP) Networks

***Nikhil Chivukula**[1], Ajaya Kumar Sahoo[1], Shreyes Rajan Madgaonkar[1], Kundhanathan Ramesh[2], Shambanagouda Rudragouda Marigoudar[3], Krishna Venkatarama Sharma[3] and Areejit Samal[1], (1)The Institute of Mathematical Sciences (IMSc); Homi Bhabha National Institute (HBNI), India, (2)The Institute of Mathematical Sciences (IMSc), India, (3)National Centre for Coastal Research, Ministry of Earth Sciences, Government of India, India*

Plastics are pervasive pollutants in atmospheric, terrestrial, and aquatic ecosystems due to their widespread use and environmental persistence. Plastic additives, intentionally incorporated to enhance plastic properties, leach into the environment upon plastic degradation, posing significant ecological and human health risks. Limited knowledge of these chemicals across the plastic life cycle hampers effective regulation and product safety assessments. To address this challenge, a data-centric approach was employed to investigate the toxicological impacts of plastic additives through the Adverse Outcome Pathway (AOP) framework. The study also focused on classification of additives by their presence in priority use sectors, exploration of associated toxicity pathways, and identification of prevalent adverse health outcomes linked to plastic additives. A dataset of 6470 additives from chemicals documented in plastics was curated and classified into ten priority use sectors, including food packaging, personal care products, and agriculture. Toxicogenomics and biological endpoint data from five exposome-relevant resources were integrated to identify associations between 1287 additives and 322 complete, high-quality AOPs documented in AOP-Wiki. These associations informed the construction of a stressor-centric AOP network, categorizing additives by use sectors and organizing AOPs under 27 disease categories according to the documented adverse outcomes. Individual plastic additive AOP networks were visualized and made publicly accessible at https://cb.imsc.res.in/saopadditives/. The utility of the constructed plastic additives AOP network was demonstrated by identifying highly relevant AOPs for three priority additives: benzo[a]pyrene (B[a]P), bisphenol A (BPA), and bis(2-ethylhexyl) phthalate (DEHP). Published experimental evidence was used to explore the human- and ecotoxicology-relevant toxicity pathways associated with these additives. Additionally, this study revealed that many of these additives, which are produced in high volumes globally, can potentially accumulate in human tissues as xenobiotics, and lead to severe adverse effects on various organ systems. Overall, this study provides the first stressor AOP network for plastic additives, revealing toxicity pathways and prevalent adverse outcomes. It also assists in their risk assessment and regulatory decision-making, thereby contributing towards a toxic-free circular economy for plastics.

1.06.P-Th004 Development of an Adverse Outcome Pathway Leading to Neurodevelopmental Disorders and its Application to Screening Chemicals in Consumer Products
***Siyeol Ahn**, Donghyeon Kim, Keon Kang, Hyunwoo Kim, Kimoon Na and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of*
The environmental causes of neurodevelopmental disorders (NDDs) are still poorly understood. There is growing evidence that exposure to various chemicals in consumer products, including endocrine disrupting chemicals, potentially affect development and behavior. In this context, a putative AOP network associated with NDD was identified to provide insight into the NDD potential of chemicals in consumer products using an Integrated Testing Strategy (ITS). First, human genes related to the synaptic function mechanism of NDD were selected using the SFARI Gene database. Next, the putative AOP network was developed using the database mining approach using the Comparative Toxicogenomics Database and AOP Wiki. Leveraging this AOP network, chemicals in consumer products were screened by assigning ToxCast assays to specific key events (KEs). Further experiments were performed on KEs that were not assigned to the ToxCast assay, such as BDNF level, NMDA receptor binding, and learning (measured as development and behavior). For these assays, human embryonic stem cells, human neural stem cells, Caenorhabditis elegans wildtype and mutants (nlg-1(lf) and nrx-1(lf)) were exposed to chemicals and molecular docking were performed. Among the chemicals in consumer products, BPA and DEHP showed high bioactivity for ToxCast assay related to AOP network such as calcium influx, decreased synaptogenesis, and decreased neuronal network function. Next, BPA has been predicted to have the highest binding affinity for NMDA receptor binding, a Molecular Initiating Event. When exposed to BPA and DEHP, C. elegans (wild type, nlg-1, nrx-1) showed significant changes in locomotive behavior and BDNF levels in human stem cells were also altered. BPA has the highest NDD-leading potential, as BPA reacted with most KEs. ITS was applied to ToxCast database, in silico prediction, in vitro, stem cells, and C. elegans disease models. This study suggests that environmentally concerning chemicals can be screened for their effects on disease potential using our ITS. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE)(RS-2023-00215309).

1.06.P-Th005 Leveraging Zebrafish Embryo Phenotypic Observations to Advance Data-Driven Analyses in Toxicology
***Nils Klüver**, Paul Michaelis, Silke Aulhorn, Hannes Bohring, Jan Bumberger, Kristina Haase, Tobias Kuhnert, Eberhard Kuester, Janet Kruger, Till Luckenbach, Riccardo Massei, Lukas Nerlich, Sven Petruschke, Thomas Schnicke, Anton Schnurpel, Stefan Scholz, Nicole Schweiger, Daniel Sielaff and Wibke Busch, Helmholtz Center for Environmental Research, Germany*
Zebrafish have emerged as a central model organism in toxicological research. Zebrafish embryos are exempt from certain animal testing regulations which facilitates their use in toxicological testing. Next to the zebrafish embryo acute toxicity test (ZFET) according to the OECD TG 236, fish embryos are used in mechanistic investigations, chemical screenings, in ecotoxicology, and drug development. However, inconsistencies in the applied test protocols and the monitored endpoints in addition to a lack of standardized data formats, impede comprehensive meta-analyses and cross-study comparisons. To address these challenges, we developed the Integrated Effect Database for Toxicological Observations (INTOB), a comprehensive data management tool that standardizes collection of metadata and phenotypic observations using a controlled vocabulary. By incorporating data from more than 600 experiments into the database and subsequent comprehensive data analyses, we demonstrate its utility in improving the comparability and interoperability of toxicity data. Our results show that the ZFET can detect toxicity spanning seven orders of magnitude at the scale of effect concentrations. We also highlight the potential of read-across analyses based on morphological fingerprints and their connection to chemical modes of action, provide information on control variability of the ZFET, and highlight the importance of time for mechanistic understanding in chemical exposure-effect assessments. With our data analysis workflow and INTOB database we demonstrate how professional data management marks a significant advancement by offering a comprehensive framework for the systematic use of zebrafish embryo toxicity data, thus paving the way for more reliable, data-driven chemical risk assessment.

1.06.P-Th006 Derivation of Hazardous Concentrations of Soil Pollutants for The TRIAD Approach
***Haemi Kim**[1], Dokyung Kim[2], Yubeen Song[1], Sun-Hwa Nam[2], Lia Kim[1], Seunghun Hyun[3], Sunhee Hong[4], Seung-Woo Jeong[5] and Youn-Joo An[2], (1)Department of Environmental Health Science, Konkuk*

University, Korea, Republic of, (2)Department of Environmental Health Science / Human and Eco Care Center (HECC), Konkuk University, Korea, Republic of, (3)Department of Environmental Science and Ecological Engineering, Korea University, Korea, Republic of, (4)Department of Plant Resources and Landscape, Hankyong National University, Korea, Republic of, (5)Department of Environmental Engineering, Kunsan National University, Korea, Republic of
The TRIAD approach, published by ISO in 2017 for site-specific soil ecological risk assessment, integrates chemical-, ecotoxicological-, and ecological-lines of evidence (LoEs) to calculate integrated risk (IR). To determine and refine the chemical-LoE, hazardous concentrations based on species sensitivity distribution (SSD) require toxicity data on pollutants. Some countries (e.g., USA, Australia, Netherlands, UK, and Cananda) has their own ecological protection standards, meanwhile, other countries may not have their own standards for pollutants. Thus, this study aimed to collect soil toxicity data of soil pollutants and to estimate hazardous concentrations based on SSD for TRIAD. Twenty pollutants were prioritized and categorized, and their toxicity data were sourced and classified from the USEPA ECOTOX database. Hazardous concentrations were then estimated based on SSD analysis. This study is significant as it redefines ecological protection standards for soil pollutants using diverse data sources, making the results applicable to international guidelines, irrespective of specific national standards. Our data provide a foundation for site-specific ecological risk assessments, contributing to the development and enhancement of the TRIAD guideline. This work was supported by Korea Environment Industry & Technology Institute (KEITI) funded by Korea Ministry of Environment No.2022002450002(RS-2022-KE002074).

1.06.P-Th007 Network-Based Investigation of Petroleum Hydrocarbons-Induced Ecotoxicological Effects and Their Risk Assessment
***Shreyes Rajan Madgaonkar**[1], Ajaya Kumar Sahoo[1], Nikhil Chivukula[1], Panneerselvam Karthikeyan[2], Kundhanathan Ramesh[3], Shambanagouda Rudragouda Marigoudar[2], Krishna Venkatarama Sharma[2] and Areejit Samal[1], (1)The Institute of Mathematical Sciences (IMSc); Homi Bhabha National Institute (HBNI), India, (2)National Centre for Coastal Research, Ministry of Earth Sciences, Government of India, India, (3)The Institute of Mathematical Sciences (IMSc), India*
Petroleum hydrocarbons (PHs), primarily made of carbon and hydrogen, are significant environmental pollutants derived from crude oil and its products. They are introduced into ecosystems through anthropogenic activities such as transportation, offshore drilling, and oil spills, causing long-term ecological harm. While environmental risks of PHs are often assessed using total petroleum hydrocarbon (TPH) levels, the risks posed by individual PHs and their toxicity mechanisms remain underexplored. This study addresses this challenge by leveraging network-based approaches to evaluate the ecological effects of PH exposure. A curated dataset of 320 PHs was developed from literature, and toxicological endpoint data were systematically integrated. Stressor-centric adverse outcome pathway (AOP) networks linked 75 PHs to 177 ecotoxicologically relevant AOPs in AOP-Wiki, while stressor-species networks were constructed using toxicity concentration and bioconcentration data from ECOTOX for 80 and 28 PHs, respectively. Species sensitivity distributions (SSDs) were generated to calculate hazard concentrations (HC05) for aquatic species and predicted no-effect concentrations (PNECs) and risk quotients were derived for US EPA priority polycyclic aromatic hydrocarbons (PAHs) based on environmental data from Indian coastal and river waters. Notably, these analyses revealed that many aquatic species, particularly crustaceans, are highly sensitive to PH exposure, emphasizing the need for targeted protective measures in ecosystems where such pollutants are prevalent. This study advances the understanding of PH-induced toxicity through network-based approaches, uncovering PH-specific toxicity pathways and ecological risks. Additionally, derived threshold concentrations and AOP data can guide environmental quality standards. Findings have practical applications for events like oil spills, enabling the formulation of more effective mitigation strategies. By using network-based frameworks to analyze ecotoxicological data, this study highlights how PHs affect ecological species, with potentially broader implications for human and animal health within the One Health context. Ultimately, this study highlights the importance of regulating PHs in the environment and safeguarding ecosystem health.

1.06.P-Th008 Enhancing Interpretability of High-Throughput Toxicological Data Using Self-Organising Maps
***Jessica Reinmueller**[1], Sebastian Buchinger[1], Andreas Schuettler[1] and Joerg Hackermueller[2], (1)German Federal Institute of Hydrology (BfG), Germany, (2)Centre for Environmental Research, Germany*
The availability of toxicity data for the huge number of chemicals found in the environment is limited, which results in substantial challenges during monitoring and assessment of environmental contamination. High-throughput initiatives like the Tox21 program of the US-Environmental Protection Agency (EPA) aim to fill this gap by supplying in vitro effect data for thousands of chemicals and hundreds of different endpoints. Yet, even such datasets can be scarce and heterogeneous due to, for instance, varying test

substances and concentration ranges, which often limits the predictive power of models based on this data. In order to address these challenges, the hypothesis that self-organising maps (SOMs) can be employed to enhance the interpretability of such effect data and to fill data gaps was formulated. Therefore, data from the ToxCast database (version 4.1, US-EPA) were manually curated and aggregated. Concentration-response curves of reference substances were modelled using nonlinear Bayesian regression. Subsequently, effect data of test substances were normalised based on these reference curves of the respective assay followed by modelling the concentration-response curves of test substances using nonlinear least-squares regression. The respective best-fitting models were used for the extrapolation of effect data within a defined concentration range. Finally, using the SOM algorithm, assays were organised into a two-dimensional map based on the similarity of the extrapolated effect curves of the tested substances, thereby reducing data dimension and filling data gaps. The SOM performance was enhanced by tuning hyperparameters based on summed squares of topological error and explained variance. Bootstrap resampling with the tuned parameters was performed to analyse robustness. The trained SOM can be used, for instance, in the assessment of environmental monitoring data of chemical contamination for screening and prioritisation of chemicals and their effects. To do so, effect profiles for specific chemicals or mixtures using the map's structure were generated exemplarily as a concise visual representation of in vitro effects. In summary, a framework is proposed to complement gap-filling approaches in an effect-based way rather than based on chemical structure as in read-across approaches, while also increasing the robustness and interpretability of effect data, thereby aiding in prioritising chemicals and effects in environmental monitoring.

1.06.P-Th009 Towards Reliable Chemical Toxicity Predictions with Quantified Uncertainty
Kerstin von Borries[1]*, Katie V Beckwith*[2]*, Jonathan M Goodman*[2]*, Weihsueh A Chiu*[3]*, Olivier Jolliet*[1] *and Peter Fantke*[4]*, (1)Technical University of Denmark, Denmark, (2)University of Cambridge, United Kingdom, (3)Texas A&M University, United States, (4)substitue ApS, Goethe University, Denmark*
Chemical impact assessments are limited by insufficient data on chemical fate, exposure and effects. Machine learning (ML)-based in silico prediction tools offer high prediction performance and broader applicability than conventional quantitative structure-activity/property relationships. However, their widespread uptake has been hindered by inconsistent applicability across chemicals and lack of transparency regarding model reliability, which undermines confidence in their predictions and complicates integrating predicted and measured data sources. This work demonstrates how uncertainty-aware ML can address some of these challenges by (1) developing models that quantify data- and model-related uncertainty, and (2) using these models to predict reproductive/developmental and general non-cancer human toxicity points of departure (PODs) for >130,000 marketed chemicals. Our results show that the uncertainty-aware ML methods provide well-calibrated uncertainty estimates that are closely aligned with observed prediction errors, assigning more unfamiliar chemicals higher prediction uncertainty. Applying the models to diverse marketed chemicals identifies hotspots of high toxicity, including dioxins and PFAS, and areas of high uncertainty, such as alkaloids, metals and organometallic compounds. Our results address critical data gaps by providing human toxicity PODs with 95% confidence intervals for a large set of marketed chemicals. Furthermore, they demonstrate how uncertainty-aware ML highlights unreliable chemical classes that should be systematically targeted in future data generation and model development to improve prediction reliability, addressing key drivers of uncertainty such as lack of representation or limited descriptor applicability. Widespread adoption of uncertainty-aware ML will be crucial to enhance the transparency and reliability of ML predictions, paving the way for broader acceptance and application of in silico approaches in chemical assessments. This work was financially supported by the Safe and Efficient Chemistry by Design (SafeChem) project funded by the Swedish Foundation for Strategic Environmental Research (grant no. DIA 2018/11).

1.06.P-Th010 Prediction of In Vitro Neurotoxicity Through Machine Learning
Christoph Schuer[1]*, Lilian Gasser*[2]*, Antoine Escoyez*[2]*, Kristin Schirmer*[1]*, Guillaume Obozinski*[2] *and Marco Baity-Jesi*[1]*, (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Swiss Data Science Center (SDSC), Switzerland*
Neurotoxicants, i.e., chemicals that specifically affect structural or functional aspects of the nervous system, pose a challenge to environmental hazard assessment. Neurotoxicity can follow different modes of actions by targeting specific receptors, molecules, or cells within an organism. Hence, many in vitro assays have been developed to assess the effects of chemicals on different mechanistic targets or cellular structures. However, even with their marked advantages, high throughput in vitro methods cannot fulfill the growing needs for fast and cost-effective neurotoxicity testing of chemicals. Here, in silico methods, such as machine learning models, can integrate a range of in vitro endpoints to allow for rapid and, after model implementation, low-cost prediction of neurotoxic potential across a broad range of assay

endpoints. We selected neurotoxicity-related data for in vitro effect assays from the latest version of invitroDB database and processed them through the pytcpl pipeline by Arturi et al. (under revision). The resulting dataset of 50 endpoints was split into training and test data and used to develop binary classification models (logistic regression, support vector machines, random forest, and extreme gradient boosting (XGBoost). The Friedman s tests for all endpoints showed that, based on average precision, ROC, and MCC, the models perform similarly, and no model is superior. For 42 of 50 endpoints all models performed better than random and for more than half of the endpoints all models achieved an average precision above 0.6. Class imbalance, e.g., overrepresentation of inactive compounds, and differences in the range of chemical properties between training and test set influenced performance as well as the threshold used to label a chemical as active in a respective endpoint. The latter was further investigated at different levels (response levels of 0.1, 0.5, 0.9 in an endpoints) and, for some endpoints, lowering the threshold towards the more conservative level of 0.1 improved the performance. Overall, the application of machine learning models to predict neurotoxicity based on in vitro data shows promise to enable rapid prediction of the neurotoxic potential of chemicals. This, in turn, strengthens the case for the use of machine learning to integrate data sources from different alternatives to animal testing with chemical features to cover a broad spectrum of modes of action.

1.06.P-Th011 Generalized Multivariable Linear Regression-PBPK Modelling for Nanoparticle Biodistribution Prediction Using Physicochemical Properties

***Jimeng Wu**, Peter Wick and Bernd Nowack, EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland*

Physiologically based pharmacokinetic (PBPK) models are essential for predicting nanoparticle (NP) biodistribution, supporting drug delivery and toxicity research. However, traditional PBPK models are often limited to specific NP types, typically requiring animal studies for accurate parameterization, which restricts broader applicability. This study aims to develop a generalized PBPK model that integrates physicochemical properties for early screening of NP delivery efficiency, reducing reliance on animal testing. We developed a generalized PBPK model based on in vivo mouse studies, assisted by multivariable linear regression (MLR) modeling to predict the biodistribution of NPs based on their physicochemical properties. Integrating biodistribution data from five non-dissolvable NPs (Au, FeO, TiO?, Graphene oxide, and SiO?), we investigated how NP properties (core material, coating, zeta potential, shape, hydrodynamic size, and dose) affect NP distribution across four key organs (kidney, liver, spleen, lung). The model demonstrated strong predictive performance for kinetic indicators, achieving an adjusted R^2 of up to 0.95. Predictor frequency analysis indicated that zeta potential and coating had the biggest influence on biodistribution, with NP size also significantly impacting organ-specific interactions. The model accurately predicted delivery efficiency but encountered limitations in estimating the full set of PBPK model parameters, likely due to dataset constraints. For example, some FeO and GO studies with identical NP properties exhibited substantial variance in PBPK model parameter distributions, highlighting the need for more diverse NP property data to enhance predictive accuracy. In conclusion, this generalized MLR-PBPK model provides a practical and interpretable approach for NP evaluation, supporting early screening and reducing the need for animal studies. Expanding the dataset and exploring non-linear models could improve predictions, particularly for full concentration-time profiles. This model represents a promising tool for predictive toxicology and optimized NP design, with potential applicability across species, contributing to safer and more effective NP applications.

1.06.P-Th012 Evaluation of Human Exposure to Phthalates and Correlation with Contamination in the Indoor Environment

***Glaucia Olivatto** and Joyce Cristale, UNICAMP, Brazil*

The technological advances in the last century have led to the large scale production of a huge number of synthetic organic compounds, used in various types of applications. As a result, high concentrations of toxic substances are now present in the environment, which can have harmful effects on human health and ecosystems. One group of compounds that has raised great concern is the phthalates, which, despite the imposition of restrictions and regulations in some countries, still reach an annual global consumption of 6 million tons. These products are mainly employed as plasticizers, which are used in the production of food packaging, toys, cosmetics, medical devices, and construction materials, among others. Phthalates are not covalently bound to polymers and can easily migrate into the environment or fluid system, being commonly reported in environmental samples,food and inside environments. Knowing that a large part of post-pandemic society has adopted hybrid working hours, which means that they stay in their homes for longer periods each week, the presence of these compounds in indoor air and dust samples has been indicated as an important route of human exposure to phthalates, through involuntary ingestion, inhalation, and/or dermal absorption. Human exposure to these products has been proven to be related to various diseases and health implications. Thus, the aim of this study was to reuse existing data in the scientific literature on the occurrence of phthalate products inside homes, considering air and dust samples, as well as their correlation with biological samples from residents of the habitations. For this, we analyzed empirical data and used equationsto estimate the daily uptake per individual and the health risk associated with these pollutants. Our results indicate that the phthalate metabolites identified through biomonitoring correlate with the phthalates identified in the internal environment of the homes, with higher molecular weight phthalates being more frequent in dust samples and lower molecular weight phthalates being more frequent in air samples. The risk assessment shows that children are the most vulnerable to daily intake through involuntary ingestion of dust, and the estimated values are worrying and exceed the tolerable limits set by international authorities. For further information and risk assessments of human exposure in this context, more studies covering the African continent and South America are still needed. We thank the Fundação Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) and the Universidade Estadual de Campinas (UNICAMP) for supporting our research.

1.06.P-Th013 Improving the Reliability of Chemical Property Predictions: A Thermodynamic Perspective

Ali Akbar Eftekhari *and Olivier Jolliet, Technical University of Denmark, Denmark*

Accurate prediction of physical and chemical properties is crucial for assessing the dispersion and fate of chemicals in a multimedia environment. These properties are often estimate by Quantitative Structure-Activity or Structure-Property Relationships (QSAR/QSPR), which are trained on large sets of experimental data with molecular structure as independent variables. These models are often trained to directly calculate the desired physicochemical properties. In this case, the consistency of the estimated values relies on the consistency of the training data and the potential of the models to capture the thermodynamic relationships between the predicted properties. An alternative is to first obtain experimental values or estimate the critical properties of the pure chemicals with a QSPR method (e.g. Joback and its extensions) and then use an appropriate mechanistic or semiempirical model, e.g. an equation of state to estimate the properties. This method ensures the consistency of the estimated properties but does not guarantee their accuracy. Here, we utilize both workflows to estimate the physicochemical properties of a large database of compounds for which some of the physicochemical properties and critical properties are measured. For the QSAR/QSPR method, we use EPI Suite and OPERA for estimating pure chemical (vapor/sublimation pressure, boiling/melting point) and multiphase binary/ternary properties (water solubility, Henry s law constant, and octanol-water partition coefficient). We repeat the calculations with semi-empirical thermodynamic relations, cubic equations of state and predictive activity coefficient model UNIFAC in combination with the experimental and estimated critical properties. We finally compare the estimations with available experimental data and flag the experimental values that are inconsistent with the rest of the data, and rank the models based on the closest prediction to the experimental data for each compound. Finally, we utilize the highest ranked model to predict the physicochemical properties of ~10,000 compounds that are included in the next release of USEtox 3. By systematically evaluating the thermodynamic consistency of QSAR/QSPR predictions and training data, we aim to improve the accuracy and reliability of chemical fate and transport models, ultimately leading to more informed environmental risk assessments.

1.06.P-Th014 Critical Review of the Environmental Exposure and Ecotoxicity Potential of Decabromodiphenylethane (DBDPE) in Aquatic and Terrestrial Biota Using a Chemical Activity-Based Risk Assessment

Kate Fremlin, Nicole Berg and ***Frank Gobas****, Simon Fraser University, Canada*

Screening assessments of decabromodiphenylethane (DBDPE) concluded that DBDPE was persistent but non-toxic at concentrations below its measured aqueous solubility of 0.72 μg/L. However, the assessments were inconclusive on the bioaccumulation potential of DBDPE and whether the current concentrations detected in the environment have potential to bioaccumulate to levels of concern. To address this knowledge gap, we performed a risk assessment and reviewed 66 studies that reported concentrations of DBDPE measured in a range of plants and animals and 58 studies that reported toxic effect concentrations of DBDPE determined in toxicity tests. The objectives of the risk assessment were 1) to critically evaluate all the studies that measured concentrations of DBDPE in biota with a set of comprehensive criteria and guidelines for conducting field studies that monitor chemical concentrations in the environment; and 2) to use a weight of evidence analysis to facilitate the comparison between the environmental exposure concentrations and the toxic effect concentrations. To perform the risk assessment, we used a chemical activity analysis of the available exposure and toxicity data for DBDPE. Approximately 70% of the studies that reported concentrations of DBDPE measured in biota were considered of acceptable quality whereas 30% of the studies were considered of unacceptable quality so concentrations from these studies were excluded from further analyses. The chemical activity analysis showed that to date all toxicological effects endpoints of DBDPE in toxicity tests occurred at concentrations that are equal to chemical activities of DBDPE that are well above the maximum chemical activity of DBDPE. Essentially, DBDPE concentrations used in toxicological tests were above the sorptive capacity of the medium involved in the toxicity tests and are not thermodynamically feasible to occur in the environment. Conversely, the chemical activity analysis showed that concentrations of DBDPE measured in biota from various locations around the world were below the maximum chemical activity of DBDPE so are considered thermodynamically feasible. Moreover, the chemical activities of DBDPE in biota from around the world are several orders of magnitude lower than the chemical activities of DBDPE that are associated with toxicological effects of DBDPE. Thus, to date DBDPE has not accumulated in biota to levels of toxicological concern or which present a risk for adverse effects.

1.06.P-Th015 In-silico Models for the Toxicity Prediction of Disinfection By-Products (DBPs) Resulting from Disinfection Processes in Drinking Water Treatment Plants (DWTPs)

***Blanca Pozuelo Rollon**, Cristina Sanchez Ferri, Javier Alcodori and Arantxa Ballesteros Riaza, ITENE - Instituto Tecnologico del Embalaje, Transporte y Log stica, Spain*

According to the European Environmental Agency (EEA), most of the EU s freshwater use comes from rivers and ground water. Besides, the European Water Report of 2018, showed that around 60% of European surface waters are not in good ecological status and 62% are not in good chemical status. With this information, it can be appreciated a risk of humans being exposed to different pollutants. In terms of contamination of drinking water there are some challenges that drinking water treatment plants (DWTPs), last barrier before human exposure, must face, such as the hazardous disinfection processes, which lead to the formation of different products known as Disinfection By-Products (DBPs), which come from the natural organic matter present in water. Although many DBPs have already been identified, most remain unregulated. It is considered that the understanding of their formation mechanisms as well as the study of their toxicity need to be evaluated. For this, in-silico models which aim to predict these characteristics are being developed. Firstly, a specific model to predict the final DBPs for four pollutants is being implemented. In addition, two Quantitative Structure Activity Relationship (QSAR) models to predict carcinogenicity and genotoxicity are being developed. With these models, it would be possible to estimate carcinogenicity and genotoxicity for predicted DBPs and filter the most representative ones to further evaluate the actual toxicity using in vitro assays to deepen understanding of their effects. Particularly valuable will be assays utilizing cell lines that represent major human exposure routes. To ensure the reliability of the QSAR models, two main methods have been used: statistical validation to quantify how closely they align with actual data and similarity tests to ensure predicted molecules remain within the applicability domain. This validation shows low accuracy for both classification model (genotoxicity) and regression one (carcinogenicity) showed low accuracy for prediction. To improve the performance, we are working on retraining both models to further exploration of the parameter space.
This integrated approach, combining predictive modelling with in vitro tailored to OECD guidelines, exemplifies a New Approach Methodology (NAM) for chemical risk assessment. It provides a more detailed understanding of the carcinogenic and genotoxic effects of chemicals through integrative analysis of new sources and types of data. Abstract written thanks to funding from the European Union, within the Horizon Europe programme under grant agreement 101082015.

1.06.P-Th016 Aquatic Toxicity of Palladium: A Grouping and Read-Across Approach for Some Palladium Substances and Why Others Need Separate Assessments

***Tina Liesirova** and Jelle Mertens, European Precious Metals Federation, Belgium*

Palladium (Pd) is crucial in catalytic converters, significantly reducing greenhouse gas emissions. However, its use has increased Pd concentrations in freshwater, where its solubility enhances mobility and bioavailability, potentially harming aquatic organisms. Despite this, the ecotoxicity database for Pd is limited. This study summarizes acute and chronic ecotoxicity data for algae, invertebrates, and fish, developing a grouping and read-across approach to derive threshold concentrations. Additionally, it identifies substances requiring individual assessment due to unique properties. The findings aim to support hazard and risk assessments in an EU regulatory context. A literature review and quality assessment were conducted to identify reliable data, supplemented by industry-owned test data. Ecotoxicity thresholds were derived as lethal/ effective concentration 50 (L/EC50), causing death/ sublethal effects in 50% of organisms for acute studies, and as no observed effect concentration (NOEC) or effective concentration 10 (EC10) for chronic studies. Using aquatic speciation, toxicity data, and chemical structure, a grouping approach was proposed for hazard assessment. Reliable acute data are available for algae, invertebrates, and fish, while chronic data exist only for algae and invertebrates. Algae emerged as the most sensitive trophic level in both study types, with a sensitivity gradient of algae > invertebrates > fish. Acute thresholds for algae align with predictions from the quantitative ion-activity relationship (QICAR) model. Toxic thresholds for all species remain significantly above natural Pd levels (<0.001 µg Pd/L). Most simple inorganic Pd substances respeciate to palladium(II) hydroxide upon dissolution, with negligible effects from counterions. These substances were grouped for read-across assessment. However, compounds like palladium di(4-oxopent-2-en-2-oate), palladium(II) acetate, and palladium dinitrate showed unique speciation or toxicity profiles. For example, palladium di(4-oxopent-2-en-2-oate) exhibited an atypical sensitivity gradient (fish > algae > invertebrates), while palladium dinitrate showed lower toxicity across all trophic levels. These substances require individual assessments. This study validates the read-across approach for simple Pd substances, highlighting algae as the most sensitive trophic level. However, it emphasizes that certain Pd compounds, due to their distinct properties, must be assessed individually.

1.06.P-Th017 Applying In Vitro High-Throughput and High-Content Screening Assays for Toxicity Analysis of Environmental Water Samples: Emphasis on Liver and Endocrine Disrupting Effects

Kaini Wang[1], Ssu-Ning Chen[1], Olivia Lautan[1], Chia-Chi Hsu[1], ***Shu-Ju Chuang**[2]* *and Rong-Jane Chen[1], (1)NCKU, Taiwan (Greater China), (2)NCKU*

Rapid global population growth and increasing human activities have driven industrial development, leading to excessive pollutant emissions into aquatic environments. This has severely contaminated vital water resources, particularly lakes, rivers, and oceans, threatening marine life and potentially affecting human health through the food chain. Therefore, monitoring water quality is critical to ensuring public safety. Conventional chemical analysis typically focuses on individual substances and may underestimate the toxicity of environmental water, as it cannot detect the biological effects of mixtures of pollutants. In contrast, integrating biological analysis methods provides a faster and more sensitive approach that detects both individual compounds and complex pollutants, allowing for a more comprehensive understanding of environmental water quality. This study collected river water and industrial wastewater samples from various sites in Taoyuan City, Taiwan, to analyze chemical pollution levels. Cell-based high-throughput and high-content screening assays were employed to evaluate the toxicity. The results from chemical analyses and toxicity tests were combined using the Toxicological Priority Index (ToxPi) to rank the toxicity of water samples. The results showed that most river water samples, tested at four dilution concentrations, did not exhibit significant cytotoxicity. However, androgen receptor activity showed seasonal variations, and estradiol production in the steroidogenesis pathway was affected, indicating potential endocrine-disrupting activity with seasonal fluctuations. In addition, no significant effects were observed on mitochondrial function or in the micronucleus test, suggesting normal liver cell function and no genotoxicity. We suggest that the indication of endocrine-disrupting toxicity in the water samples points to the presence of potential endocrine disruptors, making it an important direction for future water sample toxicity assessments. By integrating alternative testing and computational toxicology, this study provides a more comprehensive understanding of the hazards posed by water quality, helping to ensure environmental and public health.

1.06.P-Th018 Impact of Indoor VOC Exposure on Atopic Dermatitis and Rhinitis: Insights from the Korean National Health and Nutrition Survey

***Eun-Hee Lee**, Tae-Hyeong Kim and Ji-Eun Oh, Far East University, Korea, Republic of*
Eun-Hee Lee1, Tae-Hyeong Kim1, Ji-Eun Oh2

This study aimed to explore the association between indoor volatile organic compounds (VOCs) and the prevalence of atopic dermatitis and rhinitis. Using data from the 8th Korean National Health and Nutrition Examination Survey (KNHANES) conducted from July 2020 to August 2021, we analyzed 1,540 adults aged 19 and older who completed a survey regarding the diagnosis of atopic dermatitis. Exposure to VOCs, such as benzene (N-Acetyl-S-(phenyl)-L-cysteine), toluene (N-Acetyl-S-(benzyl)-L-cysteine), ethylbenzene, styrene, xylene, acrolein, 1-bromopropane, and 1,3-butadiene, was assessed using urinary biomarkers analyzed through LC-MS/MS. Statistical analysis revealed that participants with atopic dermatitis and rhinitis had significantly higher geometric mean (GM) concentrations of benzene. Specifically, the GM (SD) concentration of benzene was higher in individuals with atopic dermatitis (5.642 (1.124)) compared to those without (4.858 (1.033)), and in those with rhinitis (5.042 (1.067)) compared to those without (4.864 (1.037)). Additionally, the odds ratio for atopic dermatitis associated with benzene exposure was elevated (OR = 2.156, 95% CI: 1.526-3.048), while the association with rhinitis was weaker and not statistically significant (OR = 1.182, 95% CI: 0.953-1.466). The variability in VOC exposure was also influenced by household ventilation; households with proper ventilation had lower benzene concentrations (GM = 4.865 (1.033)) compared to households without ventilation (GM = 7.716 (1.310)). These findings suggest that specific VOCs, including benzene, may exacerbate atopic conditions, highlighting the importance of improved indoor air quality and ventilation in mitigating exposure risks.

1.06.P-Th019 Digital Product Passports for Improved Consumer Transparency and Health Impact Awareness

***Asif Pasha Mohammed**, AIMEN Research Center, Spain*

The growing demand for transparency in product sustainability and safety has sparked the development of Digital Product Passports (DPPs), offering significant potential for improving consumer awareness of health risks and environmental impacts throughout a product s lifecycle. DPPs decentralized and comprehensive product information, providing detailed data on chemical compositions, material sourcing, and health risks, including the identification of hazardous substances. These passports are poised to support informed, health-conscious, and sustainable consumer choices, but the effective implementation of such systems remains a challenge. This work aims to address two key goals: (i) identify the primary challenges in creating accessible, standardized, and informative DPPs, and propose practical solutions to overcome these hurdles, and (ii) explore how DPPs can enhance consumer transparency and raise awareness of health impacts. A multi-faceted approach is presented, focusing on several strategies to ensure DPPs are both accessible and informative: Standardized Formats: Establishing consistent data formats for critical health and safety information, making it easier for consumers to evaluate product safety and environmental impacts. Leveraging data standards like the FAIR (Findable, Accessible, Interoperable, Reusable) principles will ensure DPPs are universally compatible and understandable. Improved Consumer Accessibility: Utilizing mobile technology such as QR codes or NFC chips enables consumers to access DPPs instantly via their smartphones. This approach increases product data accessibility in real-time, empowering consumers with essential health and sustainability information at the point of use. Health Impact Information Integration: By incorporating health-related data from internationally recognized toxicity databases (e.g., REACH in the EU), DPPs can provide consumers with up-to-date information about chemical risks, allergens, and other harmful substances. This ensures that product labels are not only comprehensive but also reliable, helping consumers make health-conscious decisions. Through the adoption of standardized data formats, enhanced accessibility and integration of health impact information, DPPs can provide health impact awareness by helping consumers understand exposure risks associated with certain materials and guiding safer use of them.

1.07.A Advancing the Environmental Safety Assessment of Chemicals through New Approach Methodologies (NAMs): From Early Development to Practical Applications

1.07.A.T-01 A High-Throughput Alternative Approach for Acute Fish Toxicity

***Jo Nyffeler**[1], Felix Harris[1], Clinton Willis[1], Gabrielle Byrd[1], Brett Blackwell[1], Beate Escher[2], Alex J. Kasparek[1], John Nichols[1], Jonathan Haselman[1], Grace Patlewicz[1], Daniel L. Villeneuve[1] and Joshua Austell Harrill[1], (1) Office of Research and Development, US Environmental Protection Agency, United States, (2) Helmholtz Centre for Environmental Research UFZ, Germany*

At present there are only two New Approach Methods (NAMs) recognized for acute fish toxicity. OECD TG429 uses the rainbow trout gill cell line RTgill-W1 in combination with plate-reader based viability endpoints to predict acute fish toxicity. The method works for a wide range of chemicals, but is limited in throughput due to the large well-format (24-well) and the requirement for analytical verification of the exposure concentration. We aimed to develop a high-throughput alternative in 384-well format, using TG429 as a starting point. In addition to the plate-reader based viability assay, two additional assays were implemented: (1) an image-based cell viability assay (using Hoechst and propidium iodide); and (2) high-throughput phenotypic profiling (with Cell Painting) to detect sub-cytotoxic effects. We then tested 225 chemicals, each at eight concentrations and in four independent experiments. We derived effective concentrations (typically EC50) for the viability assays and phenotype altering concentrations (PAC) for the Cell Painting assay. These potency values were compared with published results from RTgill-W1. To compare with in vivo data from rainbow trout and fathead minnow, the nominal potency values were converted to predicted exposure concentration with a new in vitro disposition model. Of the 225 tested chemicals, 151 (67%) were active in the Cell Painting assay, some of which were also active in one or both of the cell viability assays. A total of 46 chemicals have been tested in RTgill-W1 in previous studies. For all but two chemicals, the PAC was lower than the EC50 estimates of previous studies, indicating that the PAC can serve as a lower bound to the EC50 for cell viability. In vivo lethal concentrations (LC) were collected for 93 chemicals. For 59 chemicals the adjusted in vitro effect concentration could be compared to the in vivo LC50. A root-mean-squared error of 1.27 (in log10 µM) was obtained; for 73% of chemicals the in vitro potency was protective (i.e., comparable or lower than the in vivo potency). This result is equivalent to nominal results obtained from TG429, with TG429 reaching a root-mean-squared error of

1.14 when in vitro disposition is measured experimentally. To conclude, TG429 gives slightly more accurate results, but our approach enables the high-throughput testing of chemicals, which can assist in prioritization of chemicals in environmental safety testing. This abstract does not reflect USEPA policy.

1.07.A.T-02 Critical Membrane Concentration and Baseline Toxicity of Organic Pollutants in a High-Throughput Rainbow Trout Cell Assay Used for Environmental Hazard Assessment

Julia Huchthausen[1]*, Jenny Braasch*[1]*, Paloma de Oro-Carretero*[2]*, Maria Konig*[1] *and Beate Escher*[3]*,*
(1)Helmholtz Centre for Environmental Research, Germany, (2)Complutense University of Madrid, Spain, (3)Helmholtz Centre for Environmental Research; Environmental Toxicology, Eberhard Karls University Tubingen, Germany

The traditional fish acute toxicity test commonly used in environmental risk assessment requires a large number of fish and uses mortality as the primary endpoint, which raises ethical concerns and poses logistical challenges. To address these issues, we developed a high-throughput, image-based in vitro assay using a cell line from the rainbow trout, RTgill-W1. This assay aligns with New Approach Methodologies (NAMs) and the aim of modernizing hazard assessment by providing a reliable, efficient, and animal-free method for evaluating the toxicity of environmental pollutants. The RTgill-W1 assay was optimized for a 384-well format, enabling automated, high-throughput testing with the use of live-dead staining via Hoechst 33342 and propidium iodide, which allows accurate assessment of cell viability in response to toxic exposures. It was applied to evaluate the cytotoxicity of 42 neutral and ionizable organic chemicals, spanning five orders of magnitude in hydrophobicity. Freely dissolved effect concentrations of the tested chemicals were measured using solid-phase microextraction to determine the critical membrane concentration, and a mass balance model was applied to predict the nominal baseline toxicity. As baseline toxicity represents the minimum toxicity elicited by chemicals through the disruption of cellular membrane function, quantitative structure?activity relationships (QSARs) for baseline toxicity can serve as an anchor for effect assessment. These models can provide valuable insights into potential cytotoxic mechanisms, guide appropriate dosing, and identify issues related to experimental performance or assay quality. The majority of the tested chemicals were found to be baseline toxicants and 17 chemicals showed higher toxicity than predicted baseline toxicity. The RTgill-W1 image-based assay is robust, simple, and suited for high-throughput screening. Its reliance on live-dead staining rather than metabolic activity determination minimizes assay artifacts and ensures reproducibility, providing an ethical, reliable, and effective alternative to conventional fish toxicity tests. This assay not only improves sustainability in environmental toxicology, but also contributes to a better understanding of chemical hazards in the aquatic environment. It provides a scalable solution that aligns with regulatory goals for modern, animal-free toxicity testing and improved environmental risk assessment.

1.07.A.T-03 Grouping and Assessment of Chemicals for Hazard and Risk Assessment By High Content Analysis Using The Zebrafish Embryo as an Alternative Model

Stefan Scholz[1]*, Camila Zanini*[1]*, Ann-Kathrin Koblitz*[1]*, Tiberius Moller*[1]*, Muhammad Arslan Aslam*[1]*, Chidiebere Ajugwo*[1]*, Emmanuel Chukwu*[1]*, Julia Noth*[1]*, John K. Colbourne*[2] *and Riccardo Massei*[1]*,*
(1)Helmholtz Centre for Environmental Research, Dpt. Ecotoxicology, Germany, (2)University of Birmingham, Chair of Environmental Genomics, United Kingdom

For ethical reasons and to keep pace with the development of new compounds, there is a growing demand for using new approach methods (NAMs) in hazard and risk assessment. The zebrafish embryo (Danio rerio) (ZFE) has been extensively used as an alternative model for hazard characterization and to explore the mechanistic basis of chemical toxicity. Its primary advantage lies in its ability to represent the complexity of an entire organism while offering diverse endpoints that are able to capture various modes of action of chemicals.Traditionally, ZFE-based assessments rely on microscopic observations, which are prone to observer bias and have limited capacity for deriving concentration-response analyses for specific endpoints. Within the EU project PrecisionTox, we utilized the ZFE model alongside other alternative organismal models to characterize 200 chemicals spanning diverse modes of action and use categories. Our approach involved and automated, unbiased phenotype assessments, cardiovascular and behavioral effects. Morphological phenotypes were evaluated using automated positioning and imaging of embryos. Videos were captured to analyze heart rate and cardiovascular effects. Behavioral endpoints such as spontaneous tail contractions, photomotor responses, and locomotor responses were systematically assessed using video analysis. From over 50 endpoints, concentration-response curves and corresponding EC50 values were derived. To estimate the specificity of observed effects, we compared the observed effect concentrations with the predicted ZFE baseline toxicity. For pharmaceuticals and pesticides with known specific modes of action, high sensitivity ratios (predicted baseline toxicity LC50 / observed EC50) confirmed that our approach could detect specific effects. In a case study involving acrylamides and imidazoles, we compared chemical structure-based grouping with observed effect patterns. While significant overlap was observed between the two, deviations highlighted the value of combining both approaches for read-across scenarios in risk assessment. By analyzing the effect patterns of all 200 test compounds and comparing them with known modes of action, we are further evaluating the diagnostic potential of our automated assessment methodology. This work received funding by the European Union s Horizon 2020 research and innovation program project Toward Precision Toxicology: New Approach Methodologies for Chemical Safety (PrecisionTox) , grant agreement no. 965406. We gratefully acknowledge access to the platform CITEPro (Chemicals in the Environment Profiler) funded by the Helmholtz Association for ZFE experiments and pKa determination.

1.07.A.T-04 Sensitivity of Fishes to Polycyclic Aromatic Hydrocarbons

Justin Dubiel[1]*, Cameron Hunter Collins*[2]*, Brayden Oblak*[1]*, Remi Labeille*[3]*, Andreas N.M. Eriksson*[1]*, Zhe Xia*[4]*, Lauren Eagon*[2]*, Vann Lynne Boyte*[5]*, Frauke Seemann*[3]*, Danielle Philibert*[6]*, Benjamin Patrick de Jourdan*[7]*, Gregg Tomy*[4]*, Jonathon Doering*[2] *and Steve Wiseman*[1]*, (1)University of Lethbridge, Canada, (2)Louisiana State University, United States, (3)Texas A&M University, United States, (4)University of Manitoba, Canada, (5)Louisiana State Uiversity, United States, (6)Huntsman Marine Science Centre, St. Andrews, NB, Canada, (7)Huntsman Marine Science Centre, Canada*

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental chemicals that induce toxicity in fish by activating the aryl hydrocarbon receptor (AhR). Fishes are known to differ dramatically in sensitivity to AhR activation by the prototypical AhR agonist TCDD and PAHs. Predictive models linking AhR activation by TCDD to early life-stage mortality have been developed to aid in risk assessment, however this model is not applicable to PAHs. This research aims to 1) develop a predictive model linking AhR activation and early life-stage mortality for PAHs and 2) explore molecular mechanisms underlying differences in species sensitivity. This research utilized a standardized in vitro reporter gene assay to develop species sensitivity distributions based on half maximal effect concentrations (EC50s) for transactivation of the AhR by benz[a]anthracene and 8-methylbenz[a]anthracene in 18 species of fish. To determine whether differences in sensitivity to AhR activation correspond with differences in sensitivity to early life-stage mortality embryos of fathead minnow (Pimephales promelas), zebrafish (Danio rerio), and brook trout (Salvelinus fontinalis) were exposed to PAHs by microinjecting a standardized volume of chemical solution directly into the yolk sac of embryos. Lastly, in silico docking studies and primary sequence analyses were performed to determine binding potential energies and investigate the role of receptor subdomains in differences in species sensitivity. Interspecies variation in sensitivity to AhR activation by PAHs exceeded 500-fold and there is a strong and significant relationship between sensitivity to AhR activation (EC50) and sensitivity to early life-stage mortality (LD50; $p = 0.007$, $R2 = 0.86$). Predicted LD50s made using this approach averaged an accuracy of 3.3-fold relative to measured LD50s. While no significant correlation exists between binding potential energies and AhR activation ($p = 0.11$, $R2 = 0.36$), there was a significant correlation between the size of the glutamine-rich and acidic-rich subdomains of the transactivation domain of the AhR ($p= 0.0005$, $R2 = 0.65$). Due to the abundance of PAHs in the environment, differences in sensitivity across species, and practical limitations of performing traditional toxicity tests across numerous species, developing in vitro and in silico tools to assess these toxicities more efficiently could be essential for more objective ecological risk assessment of these chemicals.

1.07.A.T-05 In Silico Prioritization of Flame Retardants: Integrating Molecular Docking and Dynamics Simulations to Assess Endocrine Disruptor Potential

Kimoon Na[1]*, Minjun Jung*[2]*, Jaeseong Jeong*[1]*, Rakwoo Chang*[2] *and Jinhee Choi*[1]*, (1)School of Environmental Engineering, University of Seoul, Korea, Republic of, (2)School of Applied Chemistry, University of Seoul, Korea, Republic of*

Numerous flame retardants (FRs) have been reclassified due to their recognized hazards, including potential endocrine-disrupting properties. This study systematically screened potential endocrine-disrupting chemicals (EDCs) among commonly used FRs in the EU through an advanced in silico-based workflow integrating molecular docking and molecular dynamics (MD) simulations. Molecular docking was conducted to evaluate the binding affinities of FRs to Androgen Receptor (AR) and Estrogen Receptor alpha (ER?), prioritizing compounds with strong interactions for further analysis. Detailed 100 ns MD simulations assessed the dynamic behavior, binding stability, and interaction resilience of the selected FR-receptor complexes. Key parameters, including Gibbs free energy (?G), root-mean-square deviation (RMSD), and hydrogen bond persistence, were normalized and compared to reference compounds to evaluate EDC potential. Among the FRs analyzed, N,N'-ethylenebis(3,4,5,6-tetrabromophthalimide) exhibited strong binding affinity and dynamic EDC-like behavior with both receptors, suggesting significant endocrine-disrupting potential. Four FRs, including 6H-dibenz[c,e][1,2]oxaphosphorin 6-oxide and N,N'-ethylenebis(3,4,5,6-tetrabromophthalimide, were identified with strong receptor interactions and notable regulatory data gaps. Additionally, Phenol, isopropylated, phosphate (3:1) showed unstable interactions with ER? despite being listed in EU EDC assessments, while high-production compounds such as Cyanuric acid remain absent from regulatory lists, emphasizing the need for further evaluation. By integrating molecular docking and robust MD simulations, this study provided comprehensive insights into FR-receptor interaction dynamics and structure-activity relationships. The findings highlight the potential of in silico methods to support regulatory frameworks by identifying high-risk FRs and addressing existing regulatory gaps, facilitating enhanced chemical safety assessments. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE)(RS-2023-00215309)

1.07.B Advancing the Environmental Safety Assessment of Chemicals through New Approach Methodologies (NAMs): From Early Development to Practical Applications

1.07.B.T-01 Assessing a Primary Hepatocyte Monolayer Culture System for Studying Pharmaceutical Clearance in Fish

***Chrisna Matthee**, Andrew Ross Brown, Anke Lange, Maciej Trznadel and Charles Tyler, University of Exeter, United Kingdom*

The presence of active pharmaceutical ingredients (APIs) and their metabolites in aquatic ecosystems presents potential risks to non-target organisms such as fish. Fish are extensively used in the environmental risk assessment (ERA) of human pharmaceuticals, yet our understanding of their drug metabolism and transport capabilities is limited. While in vivo tests are currently being used to help fill this knowledge gap, they present major ethical concerns and uncertainties in terms of organism-specific pharmacokinetics. In vitro cell-based models can provide valuable information to help support prioritisation strategies for in vivo studies, and, in addition, help validate existing in silico models. To this end, we assessed the use of a rainbow trout (Oncorhynchus mykiss) primary hepatocyte monolayer culture system for predicting hepatic clearance for five diverse APIs, and for building further understanding on how these APIs affect drug metabolism and transport systems in fish. Briefly, this involved the isolation of primary hepatocytes from the livers of rainbow trout, culturing the liver cells as monolayers under physiologically relevant conditions and then exposing them to different concentrations of the selected APIs for up to 24h. Samples of culture medium and cells were subsequently collected to analyse parent API depletion (via LC-MS/MS), metabolic enzyme activity (ethoxyresorufin-O-deethylase, EROD) and the relative expression of metabolism- and transport-related target genes. The monolayers were able to clear all tested APIs (0.1 and 1 µM nominal exposure concentrations) to varying extents (26-100%). Generally, clearance rates were consistent across replicate cultures for each of the studied APIs, and, in most cases, extrapolated in vivo clearance rates were comparable to those observed in humans. EROD activity was detectable and inducible in the hepatocyte monolayers, with three APIs (at 100 µM) causing significant EROD induction after 8h. Two of the APIs tested (at 0.1-1 µM) caused significant upregulation of key genes involved in API metabolism and transport after only 2h. Taken together, our findings show that rainbow trout primary hepatocyte monolayers provide a relevant and replicable in vitro model for predicting the clearance of diverse APIs and for understanding the effects of API exposure on metabolism and transport systems in fish, hence providing valuable data for validating in silico models and informing in vivo studies. This work was funded by Servier Laboratories as part of PREMIER (Prioritisation and Risk Evaluation of Medicines in the EnviRonment). PREMIER has received funding from the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement No 875508. This Joint Undertaking receives support from the European Union s Horizon 2020 research and innovation programme and the European Federation of Pharmaceutical Industries and Associations.

1.07.B.T-02 Refining the Environmental Risk Analysis of Pharmaceuticals to Fish By Considering Fish (Versus Human) Blood Plasma Binding in the Fish Plasma Model

***Andrew Ross Brown**[1], Maciej Trznadel[1], Alison Nimrod Perkins[2], Mike Lee[3], Tea LM Pihlaja[4], Tiina Sikanen[4], Mirco Weil[5], Anja Coors[6] and Charles Tyler[1], (1)University of Exeter, United Kingdom, (2)Eli Lilly, United States, (3)ELi Lilly, United States, (4)University of Helsinki, Finland, (5)ECT Oekotoxikologie, Floersheim am Main, Germany, (6)ECT Oekotoxikologie, Germany*

In the project PREMIER (Prioritization and Risk Evaluation of Medicines in the Environment) a fish decision tree has been developed to minimise in vivo fish testing for legacy human pharmaceuticals. Part of this decision tree relies on the Fish Plasma Model (FPM), which uses the lipophilicity (LogD) of an active pharmaceutical ingredient (API) to predict its concentration in the blood plasma of exposed fish from the measured API concentration in the surrounding water. If the predicted environmental concentration (PEC) is below the therapeutic water concentration (TWC) (Eq.1), the fish plasma concentration will be below the human therapeutic concentration (HtPC) and fish are unlikely to experience pharmacological effects. A key assumption in the FPM is that the unbound fraction of API (i.e. not bound to plasma proteins) in blood plasma, which is available for pharmacological action, is the same in fish as it is in humans. We test this assumption, building on previous published work. Circa 40 APIs, including basic/cationic, acidic/anionic and neutral compounds with wide ranging physico-chemical and pharmacokinetic properties, were subjected to plasma protein binding assays using blood plasma sampled from rainbow trout (pH 7.8-7.9, 11-15?C), fathead minnows or Koi carp (pH 7.7, 25?C) or humans (pH 7.4, 37?C). Assays were performed by equilibrium dialysis with pH matched buffers; only unbound API was able to traverse the 8 kDa dialysis membrane from the plasma to the buffer, while protein-bound API remained in plasma samples. The fraction unbound (fu) for acidic/anionic APIs was generally higher for fish relative to humans. Most notably fu rainbow trout / fu humans (Rfu) was 43 and 35 for Ibuprofen and Mycophenolic acid (MPA), respectively. Conversely Rfu was ~0.1 for some basic/cationic APIs. Collectively these data evidence the need to refine the FPM. Therapeutic water concentrations (TWCs) predicted for APIs using the refined FPM, incorporating Rfu_human, were lower for acidic/anionic APIs (up to 43 times) than those predicted without Rfu, while TWCs were up to 10 times higher for some basic/cationic APIs. To help explain these differences, inter-species differences in plasma proteins and their capabilities for binding APIs are being explored alongside API molecular properties. Incorporating these refined predictions of TWC in the fish decision tree would indicate that fish testing may be justified for more anionic APIs than originally identified. This contribution has been prepared within PREMIER, a project that has received funding from the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement No 875508. This Joint Undertaking receives support from the European Union s Horizon 2020 research and innovation programme and EFPIA. The opinions expressed in this study are those of the authors only and do not necessary reflect the opinion of the institutions to which the authors are affiliated or the opinion of all PREMIER partners.

1.07.B.T-03 In Vitro Evaluation of Pharmacokinetics in Fish Exposed to Complex Pharmaceutical Mixtures

Christer Hogstrand[1], Leon Barron[2] and ***Anita Vas**[1]*, *(1)School of Cancer and Pharmaceutical Sciences, King s College London, United Kingdom, (2)MRC Centre for Environment and Health, Imperial College London, United Kingdom*

Animal testing of pharmaceuticals for the safety to the environment follow international standards aimed at assessing the impact of xenobiotics on non-target organisms, particularly in aquatic environments where significant concentrations of pharmaceuticals, especially in fish, are prevalent [1, 2]. Most of the active substances are present in the environment in the form of mixtures. It is rare to detect only one active substance in an environmental sample. Our understanding of the effects of pollutants present in these mixtures is limited compared to that of individual xenobiotics [3,4]. Pharmacokinetic (PK) studies serve as another essential approach for evaluating the risks associated with exposure to potentially harmful chemicals and have long been used in human risk assessment. These studies investigate the fate of chemicals in the body, including absorption, distribution, metabolism, and excretion (ADME), as well as the potential for accumulation and the resulting effects on human health. The adaptations of techniques used in human studies have enabled the application of PK studies in fish [5]. In vivo PK studies have been instrumental in determining the distribution of active pharmaceutical ingredients (APIs) and assessing potential contaminant levels within fish [6, 7, 8]. Another adaptation of PK studies in fish is the development of in vitro fish cell cultures that can be used to evaluate ADME, thereby aiming our understanding of the toxic effects of chemicals and the potential risks to fish health and the environment. This study aims to deploy fish cell culture systems for high-throughput analysis of PK of environmentally-occurring pharmaceuticals. It seeks to guide the development of effective risk management strategies, to protect fish populations and ensure the health of aquatic ecosystems. AV was in receipt of a scholarship (awarded to CJH and LPB).The authors would like to thank the staff in the Biological Facility Unit at the Franklin Wilkins Building, King's College London and Sparsholt College for the care and supply of experimental animals. This work was funded by a Biotechnology and Biological Sciences Research Council (BBSRC) iCASE studentship with AstraZeneca under a BBSRC Collaborative Training Partnership and support from King's College London and Imperial College London.

1.07.B.T-04 Critical review of in vitro dosing methods for hydrocarbon UVCBs

***Aina Charlotte Wennberg**[1]*, *Adam Lillicrap[1], Maria T. Hultman[1], Anastasia Georgantzopoulou[1], Maria Christou[1], You Song[1], Sophie Mentzel[1], Sandrine Estelle Deglin[2], Julie Krzykwa[2], Michelle Rau Embry[2], Philipp Mayer[3], Heidi Birch[3], David MV Saunders[4], Sandrine Sourisseau[5], Kat Colvin[6], George Hinkal[7], Nicholas Synhaeve[7], Delina Lyon[8] and Leslie J Saunders[7], (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Health and Environmental Sciences Institute (HESI), United States, (3)Department of*

Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (4)Shell Global Solutions, United States, (5)TotalEnergies, Paris, France, France, (6)BP, I&E-Applied Sciences, United Kingdom, (7)Concawe, Belgium, (8)CONCAWE, ., Belgium
Alternative approaches to traditional animal testing are being promoted to support regulatory chemical assessments. These approaches include in vitro test methods and can be used in multiple contexts, from prioritization and screening to supporting chemical grouping and read-across. It is anticipated that in vitro tests will eventually replace whole organism in vivo testing. An important challenge of most in vitro testing methods is establishing, maintaining, and confirming defined exposure concentrations throughout typical test durations. This is particularly challenging for petroleum UVCBs (substances of Unknown, Variable composition, Complex reaction products, or Biological origin) that typically contain a large number and variety of hydrophobic and (semi)volatile hydrocarbon constituents (HC) that are prone to evaporative and sorptive losses. The ability to deliver and maintain stable petroleum substance (PS) exposures in in vitro test systems is challenged by several factors, including: the high surface area to volume ratios of most multi-well plates, which increases the likelihood of sorption to plate walls; the inability to seal some test vessels (e.g. volatile constituents can escape open test vessels and may contaminate neighboring plate wells); poor solubility of hydrophobic constituents in biological media; compatibility with small testing volumes; and presence of lipids and proteins in biological media which may differentially bind individual constituents. Here we present the findings from a critical review describing the challenges of dosing UVCBs into conventional in vitro test setups and identifies relevant assays, dosing methods, and potential adaptations that may improve in vitro testing of UVCBs and other difficult-to-test substances. Approaches best suited for regulatory testing of PS and areas of future research are also identified. This work was funded by CONCAWE.

1.07.B.T-05 Predicting the Sensitivity of Reptiles to Dioxin-Like Chemicals: A Quantitative Adverse Outcome Pathway Approach

Cameron Hunter Collins[1]*, Nonnie 'Betsy' Cook*[1]*, Markus Brinkmann*[2]*, Turk Rhen*[3]*, Markus Hecker*[4]*, Anthony Schroeder*[5] *and Jonathon Doering*[1]*, (1)Louisiana State University, United States, (2)University of Saskatchewan, Canada, (3)University of North Dakota, United States, (4)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (5)University of Minnesota Crookston, United States*
Reptiles represent the least-studied group of vertebrates in ecotoxicology. This lack of toxicity data represents a significant uncertainty in ecological risk assessments of this taxon. However, the process for assessing the toxicity of chemicals is undergoing a fundamental shift from an emphasis on whole-animal testing of apical-level toxicities to a greater focus on conserved mechanistic end points. A prior study developed a cross-species quantitative adverse outcome pathway (qAOP) model capable of predicting full dose-response for early life stage mortality following exposure to dioxin-like chemicals (DLCs) in any species of fish or bird using the 50% effective concentration (EC50). Calculated EC50s were derived from a standardized in-vitro aryl hydrocarbon receptor (AHR) transactivation assay of COS-7 cells transfected with an AHR cloned from the species of interest. The objective of this study was to evaluate if this same qAOP could accurately predict toxicities to reptiles. Specifically, the AHR1 and AHR2 isoforms were cloned from the common snapping turtle (Chelydra serpintina) as a model reptile. The four DLCs, namely 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), 2,3,4,7,8-pentachlorodibenzofuran (PeCDF), 2,3,7,8-tetrachlorodibenzofuran (TCDF), and 3,3 ,4,4 ,5-pentachlorodiphenyl (PCB 126), were assessed in the standardized in-vitro AHR transactivation assay. These chemicals are in alignment with a previous study investigating early-life toxicity for snapping turtles in-vivo. Using the qAOP, the fold difference between the model and the experimental data with the snapping turtle was determined to be between 10 and 15-fold across the investigated chemicals. This currently falls roughly within the one order of magnitude acceptability when performing risk assessments, and the larger fold-difference is likely due to inaccuracies during the in-vivo exposures, which is expected given the logistical constraints involved with the exposure method. However, this study demonstrates the successful utility of predictive toxicology in assessing the sensitivity of difficult to test species, such as reptiles, to environmental pollutants of concern. This serves as a proof of concept and suggests that relationships observed in other predictive models may be representative of reptiles as well, ultimately contributing to an increase in available toxicity data without the traditional largescale lethal sampling associated with in-vivo assays.

1.07.C Advancing the Environmental Safety Assessment of Chemicals through New Approach Methodologies (NAMs): From Early Development to Practical Applications

1.07.C.T-01 Advancing Ecological Risk Assessment: Integrating High-Throughput Data for Pesticide Evaluation

***Scott Glaberman**[1] and Leah Sattler[2], (1)University of Birmingham, United Kingdom, (2)George Mason University, United States*
Pesticide ecological risk assessment relies heavily on vertebrate testing, which is time-consuming, costly, and ethically challenging. New approach methodologies (NAMs), including high-throughput assays (HTAs) like U.S. EPA s ToxCast, offer faster, more animal friendly alternatives. This study evaluates the ability of HTAs to approximate risk quotients (RQs) derived from traditional tests for 120 pesticides across chemical classes and modes of action. While most HTAs underestimated risks, certain assays, particularly cytochrome P450 (CYP) enzyme assays, performed well for herbicides and non-target taxa. Acute risks were better predicted than chronic, and nonpolar narcosis chemicals showed strong alignment. However, gaps remain in assay coverage for target-specific risks, especially neurotoxic insecticides. HTAs show promise as supplemental tools but require further development to address critical gaps and improve accuracy, supporting their integration into sustainable pesticide risk assessment frameworks.

1.07.C.T-02 Clearing the Waters: How Daphnids Chart a New Course for Vertebrate-Free Aquatic Toxicity Testing
***Martin Paparella**[1], Christoph Schuer[2], Christopher Fassbender[3], Gilly Stoddart[3], Marco Baity-Jesi[4] and Kristin Schirmer[2], (1)Medical University Innsbruck, Austria, (2)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)PETA Science Consortium International e.V., Germany, (4)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*
Environmental impact assessments of chemicals involve aquatic toxicity tests using algae, daphnids, and fish, targeting different trophic levels. Efforts to reduce vertebrate animal testing necessitate alternatives, such as RTgill-W1 cell line and zebrafish embryo assays. Yet they may not adequately cover neurotoxic modes of action or biotransformation capacities. Moreover, it needs to be cleared if amphibian-specific acute toxicity could be of concern, although few such data are available. We hypothesized that daphnids exhibit greater sensitivity than fish and amphibians in acute toxicity tests, especially for neurotoxic compounds and for allyl-alcohol as the currently unique example of relatively low sensitivity due to different biotransformation in alternative models compared to juvenile vertebrates. If not disproven, our findings could overcome the current limitations of alternative methods for acute aquatic toxicity. Using the EnviroTox Database, we analyzed acute toxicity data, selecting compounds in line with OECD Test Guidelines (TGs) 202 (daphnids) and 203 (fish) and excluding values exceeding water solubility limits. Compounds were categorized based on neurotoxic mode of action (MoAs) from ASTER, TEST, IRAC, and other recent MoA annotations. Median daphnid EC50 and fish LC50 ratios (Rdf) were calculated, yielding about 140 neurotoxic compounds for acute daphnid and fish data and a total of 805 chemicals. We also extracted 93 amphibian EC50 values and calculated daphnid-to-amphibian ratios (Rda) and we analyzed outliers of low sensitivity in the RTgill-W1 and zebrafish embryo assays. Biological variability is characterized by coefficients of variation between 50%-100% for both daphnids and fish. Using median Rdf values, daphnids were protective for 96% of 805 compounds, independent of mode of action. For neurotoxic compounds, only a few chemicals no longer on the market exceeded Rdf >10, identifiable by structural alerts. Allyl-alcohol showed an Rdf below 1 and similar trends were seen in Rda values. Daphnid data covered low sensitivity outliers for the RTgill-W1 and zebrafish embryo tests effectively. Our research supports replacing juvenile fish toxicity tests, aligning with OECD standards, and broadens environmental protection. This shift may eliminate further vertebrate testing in environmental toxicology. We plan to extend the analysis to chronic aquatic toxicity data. The authors declear not to have any conflict of interest. This work was funded by the Swiss data science center (SDSC) grant "Enhancing Toxicological Testing through Machine Learning" (project No C20-04), partly carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union s Horizon Europe research and innovation program under Grant Agreement No 101057014. The work of MP at the Medical University is co-financed via PARC and the Austrian Federal Ministry for Climate Action, Environment, Energy, Mobility, Innovation and Technology, Department V/5 Chemicals Policy and Biocides.

1.07.C.T-03 Fish and Amphibian Eleutheroembryo Assays as New Approach Methodologies for Regulatory Assessment of Endocrine Activity of Chemicals – A European Industry Perspective
***Laurent L.-M. Lagadic**[1], Oliver Korner[2], Tara Miller[3], Valentin Mingo[4], Lennart Weltje,[5] and James Robert Wheeler[6], (1)Bayer AG R&D, Crop Science Division, Environmental Safety, Germany, (2)ADAMA Deutschland, Germany, (3)Syngenta, Jealott s Hill International Research Centre, United Kingdom, (4)Corteva Agriscience, Germany, (5)BASF SE, Agricultural Solutions - Ecotoxicology, Germany, (6)Corteva Agriscience, ., Netherlands*
Regulatory assessment of endocrine-disrupting (ED) properties of chemicals relies upon extensive use of

animals. For aquatic vertebrates, the recommended fish and amphibian tests require hundreds of animals per substance to screen for endocrine activity, and nearly two thousand to investigate adverse effects. Recently, OECD-validated test guidelines (TGs) for eleutheroembryo assays have been introduced as New Approach Methodologies for the assessment of endocrine activity of chemicals in aquatic vertebrates. Because they do not feed independently, eleutheroembryos are not considered as vertebrate test animals. Under certain conditions, defined in the ECHA-EFSA guidance for the identification of ED properties of pesticide and biocide active substances, the Xenopus Eleutheroembryonic Thyroid Assay (XETA, OECD TG 248) can be used to assess the activity of substances on select thyroid pathways. Other eleutheroembryo assays using fish species have also been validated by the OECD for the identification of chemicals acting on the estrogen and androgen axes (OECD TGs 250, 251 and 252). The Rapid Androgen Disruption Activity Reporter assay (OECD TG 251) and the Rapid Estrogen ACtivity Test In Vivo assay (OECD TG 252) provide insights on potential effects on downstream steps of the steroidogenesis as well. The conditions for using fish eleutheroembryo assays as alternatives to chronic fish in vivo tests for regulatory assessment of endocrine activity still need to be defined. However, the use of the XETA as an alternative to the Amphibian Metamorphosis Assay (OECD TG 231) in the context of (re)approval of pesticide active substances in Europe effectively resulted in ca. 60% reduction of animal use. Further animal reduction might be expected from the validation of thyroid-specific endpoints in fish TGs required for regulatory evaluation of pesticide and biocide active substances. Though, the replacement of animal tests with eleutheroembryo assays ultimately relies on a thorough understanding of their applicability domains and acceptance by regulatory authorities, which varies amongst countries and jurisdictions. Discrepancies also exist amongst OECD eleutheroembryo TGs regarding e.g., validity criteria, decision logic or statistical analyses, which may complicate the practical implementation of these approaches. This, coupled with lessons learned from the use of eleutheroembryo assays over the last few years call for harmonization of the corresponding OECD TGs.

1.07.C.T-04 Ensuring the Credibility of New Approach Methodologies in Regulatory Toxicology: The Vital Role of Validation and Ring Trials

Susanne Noreen Kolle *and Robert Landsiedel, BASF SE, Germany*

The validation of New Approach Methodologies (NAMs) is a cornerstone for their acceptance and integration into regulatory toxicology. This talk delineates the critical aspects of relevance and reliability in the validation process, highlighting the indispensable role of ring trials. Relevance pertains to the extent to which NAMs accurately measure or predict the biological effect of interest, ensuring that the data generated are pertinent to hazard and risk assessment. Reliability, on the other hand, involves the consistency of NAMs performance across different laboratories and conditions, which is crucial for their widespread acceptance. Ring trials, also known as inter-laboratory studies, are emphasized as a fundamental component of the validation process. These trials involve multiple laboratories conducting the same experiments independently to verify the reproducibility and robustness of the NAMs. The insights gained from ring trials help in refining the methodologies and establishing standardized protocols, thereby enhancing the overall confidence in NAMs. The transition from traditional animal-based testing to NAMs represents a significant shift in regulatory toxicology. This transition is driven by ethical considerations, advancements in science and technology, and the need for more human-relevant data. However, the success of this transition hinges on the rigorous validation of NAMs to ensure that they can reliably predict human health outcomes. The integration of NAMs into regulatory frameworks requires a concerted effort to standardize validation processes, implement ring trials, and adhere to guidelines such as Good In Vitro Method Practices (GIVIMP). In conclusion, the validation of NAMs is a multifaceted process that requires careful consideration of relevance and reliability. Ring trials play a pivotal role in this process, providing the necessary evidence to support the robustness and reproducibility of NAMs. Adhering to guidelines such as GIVIMP ensures that NAMs are developed and validated to the highest standards, facilitating their acceptance and integration into regulatory toxicology. The insights from key publications highlight the ongoing efforts to refine validation processes and underscore the importance of rigorous and standardized approaches to ensure the reliability and relevance of NAMs.

1.07.C.T-05 Solutions For Regulatory Uptake of NAMs - Perspective From The Science Policy Interface

Leonie Mueller[1]*, Francois Busquet*[1]*, Aleksandra Cavoski*[2]*, Laura Holden*[2] *and Robert Gregory Lee Prof*[3]*, (1)Altertox, Belgium, (2)University of Birmingham, United Kingdom, (3)Law School, University of Birmingham, United Kingdom*

Scientists worldwide have contributed to considerable progress in developing new approach methodologies (NAMs) for the science driven paradigm change in regulatory safety assessments of chemicals. These methods have been welcomed not least because of a desire, reflected in the wider ethical views of society, to curtail the use of animals for toxicity testing but also for their potential to make regulatory safety assessments more efficient and cost-effective. The incorporation of NAMs into the regulatory processes globally has been inhibited by technical uncertainty (including scientific methods and regulation) but there are also societal considerations which affect the appetite for NAMs. These barriers and their inter-relationship have become a subject of research themselves. In the presented study empirical research determined the sociotechnical barriers perceived by key stakeholders and possible solutions defined with the stakeholder input in a follow-up study. Barriers to the uptake of NAMs are characterized by high complexity and the need for an increased focus on societal aspects. Key barriers identified include i) Numerous vicious circles work against the uptake of NAMs ii) Remaining lack of consensus on scientific readiness iii) The need to reconsider the governance framework that underpins NAMs and iv) Lack of familiarity, trust, and confidence. Where there is broad consensus on solutions to overcome the identified barriers, this study was successful in outlining concrete measures for the areas of i) regulatory use of data ii) education and training strategies and iii) routes towards validation. With regards to the remaining areas of moderate and indeterminate consensus, further enquiry to refine the questions at issue and determine what actions are needed for greater acceptance of NAMs for regulatory purposes is needed. It is crucial to keep the different perspectives, needs and doubts of different stakeholder groups in mind when moving forward in creating policy options. Identifying existing, and fostering underdeveloped areas of broad consensus is vital to successful policy transition. This project has received funding from the European Union s Horizon 2020 research and innovation programme under Grant Agreement No. 965406.

1.07.P Advancing the Environmental Safety Assessment of Chemicals through New Approach Methodologies (NAMs): From Early Development to Practical Applications

1.07.P-Mo001 OECD 249 Fish Gill Cell Assay: Evaluating Its Applicability for Industrial Chemical Toxicity Prediction

*Dennis Becker[1], **Jens Bietz**[2], Anika Dreier[3], Dirk Scheerbaum[3], Oliver Buttler[3] and Anna-Maria Falkenhain[2], (1)Clariant , The Woodlands, United States, (2)Clariant, Germany, (3)Noack Laboratorien, Germany*

This study evaluates the practicability and accuracy of the RTgill-W1 fish cell assay (OECD 249) as a promising in vitro method to predict acute fish toxicity, addressing growing animal welfare concerns associated with standard acute fish toxicity tests (OECD 203) and focusing on industrial chemicals including difficult-to-test substances.

We initially tested two distinct groups of industrial chemicals with varying physicochemical properties. The OECD 249 assay was conducted in two laboratories to assess interlaboratory reproducibility. Results were compared with in vivo acute fish toxicity data and in silico predictions. Key findings include strong interlaboratory reproducibility, demonstrating the robustness of the method. Correlation between in vitro and in vivo results varied between the two substance groups, with one group showing excellent alignment, while the other displayed weaker correlation. For one group, in vivo results aligned better with in silico predictions than with in vitro tests. The study highlights both advantages and challenges of the OECD 249 assay. Advantages include faster testing time, animal welfare benefits, and suitability for initial assessments of multiple chemicals. Challenges involve pending regulatory acceptance, optimization of plate pre-coating procedures, and limitations in capturing all modes of action relevant to in vivo fish toxicity. Our findings suggest that an integrated approach, considering multiple lines of evidence, could help address variabilities associated with alternative methods. Further exploration of correlation levels between alternative methods and traditional tests may inform their regulatory acceptance. Ongoing work is expanding the chemical test set to include more difficult-to-test substances to characterize assay performance across diverse chemical classes and solubility profiles, aiming to better define the assay's applicability domain, limitations, and optimization opportunities.

With further refinement, the OECD 249 assay could provide a practicable alternative for rapid, cost-effective environmental toxicity estimation of industrial chemicals, potentially reducing reliance on fish acute toxicity testing. This study contributes to the scientific understanding and potential regulatory acceptance of the fish gill assay as part of a comprehensive strategy for aquatic toxicity assessment, aligning with the 3R principles (Replacement, Reduction, Refinement) in toxicology testing.

1.07.P-Mo002 Setting the Bar: Characterizing Variability Across Standard Acute Fish Toxicity Assays

***Kristin Connors** and Spiro Stilianoudakis, The Procter and Gamble Company, United States*

Regulatory environmental toxicology relies on experimental results from a handful of standardized toxicity tests including the fish acute toxicity assay (e.g., OECD 203, EPA OPPTS 850.1075). Several animal alternative assays have been developed to replace the acute fish toxicity (AFT) assay including the fish embryo toxicity (OECD 236) test, RTgill cell cytotoxicity assay (OECD 249), as well as computational approaches. These new approaches must be easily transferred to new labs, statistically robust, reproducible, reliable, and accurate . That is, the replacement assay must produce the same result as the AFT (e.g., LC50). Implicit in this comparison is the assumption that the AFT is robust, reliable, and reproducible. The reliability and reproducibility of the AFT are largely unknown, and widely taken for granted during animal alternative assay validation exercises. In this presentation, we summarize the development and curation of an AFT reference database containing LC50 values, 95% confidence intervals, and relevant experimental parameters, as available. The database includes over 700 chemicals, 1782 unique studies, and 5 unique freshwater fish species allowed under standard test guidelines. This database was statistically probed to describe variability and uncertainty in the AFT assay. Intra-laboratory, inter-laboratory, and interspecies variability were explored. The influence on physicochemical properties and MOA on AFT variability were also explored. Machine learning models were developed to characterize AFT variability, informed by experimental variability within a CAS and within the calculated LC50 value (e.g., utilizing the 95% confidence interval). This information can be used to set expectations on AFT assay performance and help contextualize results and expectations for alternative assays.

1.07.P-Mo003 Comprehensive Toxicity Profiling of 26 BPA Alternatives Based on Eight Cell-Based in vitro assays and Abiotic CYP Oxidation Test

*Beate Escher, Luise Henneberger, Maria Konig, **Vanessa Srebny** and Julia Huchthausen, Department of Cell Toxicology, Helmholtz Centre for Environmental Research, Germany*

Bisphenol A (BPA, CAS 80-05-7) is an endocrine disruptor linked to numerous negative health outcomes. Many BPA alternatives exist and are marketed, but their environmental and human health hazards are less well-defined than for BPA. High-throughput in vitro bioassays can help fill these gaps with early identification of problematic alternatives. However, no standardized methods exist to interpret and integrate results from multiple bioassays and toxicity domains. This case study proposes a set of four ratios to compare specific effects and cytotoxicity against baseline toxicity for 26 BPA alternatives and BPA across eight bioassays, including phase I metabolic activation. The in vitro test battery covered eight endpoints and cytotoxicity, targeting key toxicity pathways: estrogenicity (ER?), metabolic disruption (PPAR?), xenobiotic metabolism, genotoxicity, oxidative stress, mitochondrial toxicity, and neurotoxicity. Phase I metabolism was simulated using the abiotic CYP (aCYP) catalyst TDCPP (CAS: 91463-17-1). Fifteen bisphenol alternatives showed equal or higher cytotoxicity than BPA. Eighteen bisphenols exhibited specific estrogenic activity, with most specificity ratios highest in compounds structurally most similar to BPA. We also observed PPAR? activation and several compounds showed mitochondrial toxicity. Only trans-TCMD (CAS 2694-23-7) and racemic TCMD (CAS 3010-96-6) exhibited minimal effect concentrations across all assays. After aCYP oxidation minimal decrease of concentrations of the parent compound could be observed for most alternatives. Only Pergafast (CAS 232938-43-1), BTUM (CAS 151882-81-4), BPT (CAS 2664-63-3), and BPF (CAS 620-92-8) showed >25% reduction of parent molecule concentration. Cytotoxicity after activation decreased for BPF and BPT, stayed unchanged for Pergafast, and increased for BTUM. Of the 26 evaluated BPA alternatives, only trans-TCMD, and racemic TMCD have acceptable toxicity profiles, because they had exceptionally low cytotoxicity and did not activate any of the eight specific endpoints below baseline toxicity concentrations. This study illustrates how an in vitro-based approach can improve the selection of non-hazardous chemical alternatives, by evaluating overall cytotoxicity, activity across health-relevant endpoints, and effects of simulated metabolism. This work was carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union s Horizon Europe research and innovation program under Grant Agreement No 101057014. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or the Health and Digital Executive Agency. Neither the European Union nor the granting authority can be held responsible.
The in vitro bioassays and chemical analyses were conducted using the high-throughput screening platform CITEPro (Chemicals in the Environment Profiler), funded by the Helmholtz Association with additional support from the states of Saxony and Saxony-Anhalt. We extend our thanks to Jenny Braasch for her assistance with the bioassay measurements. We also want to thank Martin Krauss for his advice on the analytical detection of the bisphenol A alternatives and

1.07.P-Mo004 Towards Fish-Specific New Approach Methodolgies (NAMs) for Immunotoxicology: Evaluating the Cytokine Tumour Necrosis Factor Alpha (TNFα) as Reference Immunostimulant for Zebrafish In Vitro Studies

***Gian Hobbs**[1], Stewart F. Owen[2], Christer Hogstrand[3] and Luigi Margiotta-Casaluci[1], (1)King's College London, United Kingdom, (2)AstraZeneca, United Kingdom, (3)King's College London, ., United*

Kingdom
Growing evidence suggests that many environmental pollutants can induce immunomodulatory and immunotoxic effects across species, including fish. Considering the critical role played by the immune system in the maintenance of health, the European Chemical Agency (ECHA) has recently classified immunotoxicity as a priority regulatory challenge. The effects of chemicals on the immune system of fish are typically characterised using in vivo experiments. However, scaling up these investigations for the 100,000+ chemicals currently on the market requires the urgent development of fish-specific new approach methodologies (NAMs). In human immunomodulation and immunotoxicity testing, immunostimulants - such as the pleiotropic cytokine tumour necrosis factor (TNF?) - are commonly used to assess the effects of chemicals on activated immune cells. Here, we hypothesise that TNF? can be considered as the reference immunostimulant for fish in vitro immunology studies as it is for human studies. Yet, the effects of TNF? on fish cell lines are largely unexplored, especially in the context of NAMs. Given the lack of fish immune cell lines and the widespread expression of cytokine receptors in non-immune cells, we also hypothesised that ZF4 cells can be used as a proxy to detect the immunomodulatory activity of both endogenous and exogenous substances. To address this knowledge gap, we combined traditional ELISA assays with high-content methodologies to perform an in-depth characterisation of the functional (i.e. interleukin 6 release), morphological, and transcriptomic responses of zebrafish fibroblast-like ZF4 cells to TNF?. Our results indicated that ZF4 cells are highly responsive to TNF?, mimicking the response of human cells. Exposure to 10, 25, 50, and 100 ng TNF?/mL induced a rapid concentration-dependent increase in IL-6 secretion over a 24-hour period, with a peak secretion between 15 and 30 minutes. These results were used to design further studies aimed at characterising short-term (15-30 minutes) and longer-term (24 hours) transcriptomic effects via RNAseq and morphological effects via high-content cell imaging approaches. Our findings suggest that exposure to TNF? at 50 ng/mL can provide a robust method for immunostimulation in non-immune zebrafish cells, supporting its application in fish-specific NAMs for environmental toxicology. This work was funded by a Biotechnology and Biological Sciences Research Council (BBSRC) iCASE studentship co-funded by AstraZeneca under the London Interdisciplinary Doctoral Programme (LIDo) (Ref. 2879914). GH was in receipt of a scholarship (awarded to LM-C) co-funded by AstraZeneca. SFO is an employee and share holder of AstraZeneca, a biopharmaceutical company with an interest in the discovery, development and commercialisation of prescription medicines.

1.07.P-Mo005 Evaluation of an Ontology-Driven In Silico Profiler Representing Mechanisms of Action Related to Endocrine Disruption
***Mark Cronin*[1]**, *Homa Basiri[1], Franklin Bauer[2], Bruno Campos[3], James Firman[1], Steve Gutsell[3], Geoff Hodges[3], Gaspard Levet[2], Jayne Roberts[3] and Paul Thomas[2], (1)Liverpool John Moores University, United Kingdom, (2)KREATiS SAS, France, (3)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom*
The application of in silico profiling has, over the course of the past three decades, become established as a means by which the acute ecotoxicological profile of a substance might be characterised. Through assigning putative mechanisms of action, this approach is capable of facilitating compound grouping ahead of read-across or QSAR application, and thus of supporting toxicity prediction and data-gap filling. Recent work has re-examined existing in silico profilers, with the intention both of establishing consensus and framing judgments within the context of the Adverse Outcome Pathway (AOP). We have, through this study, sought to extend such methodology towards outcomes relevant in chronic ecotoxicity with a primary focus upon endocrine disruption. To this end, a mechanistic-driven ontology, spanning a broad series of endocrine-related domains, has been created. This comprises systems and networks most notably oestrogenic, androgenic, thyroid and ecdysteroid relevant within a wide variety species (mammalian, arthropod, fish, etc.). Each mechanism is defined in terms of its relationship to AOP-supported molecular initiating events (MIEs), amongst which are included direct hormone receptor interactions, inhibition components key within hormone synthesis, and the impairment of hormone distribution. In order to develop structural alerts associated with each of these MIEs, data relating to the activities of substances at the appropriate target sites were retrieved from sources which, alongside the general literature, included ToxCast, ChEMBL and SciBite. Through adoption of techniques such as molecular scaffold analysis, series of defining structural fragments were identified. These were subsequently coded as SMARTS-based rules, ahead of their compilation as a profiling tool the purpose of which, as before, is to facilitate the flagging of compounds which may hold potential to serve as candidates for further toxicological evaluation (be it in silico or experimental). So that the coverage of the profiler might be examined, a modified form of the EU PARC endocrine disruptor inventory was screened against it. Through this exercise, several substance classes, predominantly pesticide forms, were noted as lying beyond its present

domains. The reasoning associated with this observation is discussed. This profiler will be made freely available and the intention is that it will ultimately will be incorporated within the MechoA+ scheme.

1.07.P-Mo006 From Data to Decision: Utilizing NAMs for Aquatic Toxicity Assessment and Regulatory Compliance

Lisa-Marie Krauskopf[1]*, Lidia Ceriani*[2]*, Mojca Fuart-Gatnik*[3]*, Simona Kovarich*[2]*, Aleksandra Mostrag-Szlichtyng*[4]*, Jannik Schmitt*[5]*, Florian Gruener*[5] *and Sarah Mullen-Hinkle*[4]*, (1)University Leipzig / Merck Life Science KGaA, Germany, (2)Merck Life Science S.r.l., Italy, (3)Merck d.o.o., Slovenia, (4)MilliporeSigma, United States, (5)Merck Life Science KGaA, Germany*

The Life Science business of Merck is at the forefront of advancing In Silico New Approach Methodologies (NAMs) for the human and environmental safety assessment of chemicals. With a global portfolio exceeding 300,000 products, we provide high-quality chemicals and tools essential for research and development in both academia and industry. NAMs encompass various technologies, including in silico, in chemico, in vitro, and ex vivo studies, which deliver critical information on chemical hazard and risk assessment without relying on animal testing. As regulatory agencies worldwide increasingly embrace NAMs, their application in regulatory decision-making is becoming a reality, supported by strategic roadmaps and partnerships such as the US EPA New Approach Methods Work Plan, ICCVAM, NICEATM, EU ECHA (REACH, CLP), APCRA, PARC, and EPAA. In this study, we present innovative workflows that integrate in silico NAMs to facilitate global regulatory submissions in compliance with frameworks like the United States Toxic Substances Control Act (TSCA), EU REACH, and REACH-like regulations. These workflows rely on a combination of automated processes and expert evaluations. Our focus on a comprehensive evaluation of aquatic toxicity results obtained by in silico NAMs, highlighting the complexities involved in generating valid, adequate and relevant data for regulatory compliance. Through various use cases, we present the streamlined application of combined (Q)SAR predictions, read-across methodologies, and weight-of-evidence (WoE) approaches while addressing gaps and existing challenges in applying such approaches for aquatic toxicity within the regulatory landscape, particularly for data-poor substances. We aim to illustrate how these methodologies can inform and shape future regulatory frameworks, ultimately promoting a toxic-free environment and minimizing animal use in toxicity testing. At the same time, we acknowledge the current limitations and uncertainties in the application of NAMs for aquatic toxicity.

1.07.P-Mo007 Characterizing Uncertainty in the Disposition of Organic Chemicals in Cellular In Vitro Bioassays

Alessandro Sangion[1]*, James Armitage*[2] *and Jon A. Arnot*[3]*, (1)ARC Arnot Research and Consulting, Canada, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ARC Arnot Research and Consulting AND University of Toronto, Canada*

The potential risk of human and ecological exposures to thousands of chemicals used by society is largely unknown. Traditional in vivo toxicity testing is costly, time-consuming, and there is a need to reduce animal testing, thus driving the development and application of New Approach Methods (NAMs) such as in vitro bioassays. In this context, in vitro-in vivo extrapolation (IVIVE) methods are required to calculate in vivo doses from administered (assumed) in vitro bioassay doses. Calculated in vivo doses can be compared with traditional toxicity data and applied in risk-based contexts by including real-world exposure estimates. Reliable assessments using in vitro data require a comprehensive understanding of chemical distribution within the in vitro test system. One assumption often used in IVIVE dose extrapolation is that the assumed nominal administered in vitro dose directly relates to the response and can be used directly in an in vivo system; however, more than 20 years of experimental and theoretical studies have highlighted that this assumption is invalid for some chemicals and bioassay conditions. Chemical disposition in an in vitro bioassay is a function of the test system parameters (e.g., well-size, cell density, % fetal bovine serum, etc) and the test chemical properties (i.e., octanol-water partition ratio, air-water partition ratio, pKa). In Vitro Mass Balance Models (IV-MBM) help quantify in vitro chemical disposition processes including volatilization, sorption to test materials, and saturation (exceeding solubility limits), and provide estimates of the free and cellular concentrations (CFREE, CCELL). IV-MBM calculations identify when often used assumptions are likely violated and thus aid in vitro data interpretation, application and experimental design to avoid costly errors. This study combines in vitro measurements and IV-MBM calculations to characterize uncertainty in interpreting in vitro bioassay results and to foster confidence in the application of NAMs for chemical assessments. The analysis compares IV-MBM predictions for CFREE and CCELL with available measured data and characterizes the uncertainty in the measured and modelled data as a function of chemical properties and bioassay parameters. General guidance is provided for the expected magnitude of uncertainty when using in vitro cellular dosing data. Recommendations to better characterize and quantify uncertainty in in vitro dosimetry are outlined.

1.07.P-Mo008 Evaluating Methods for Determining Membrane-Water Partitioning of Surfactants as an Alternative to n-Octanol-Water Partitioning

Geoff Hodges[1]*, Steven Droge*[2]*, Eoin Kearney*[3]*, Elin Barrett*[1]*, Adriana C. Bejarano*[4]*, Jens Bietz*[5]*, Liesa-Kristin Beuter*[6]*, Kristin Connors*[7]*, James Dawick*[8]*, Marc Geurts*[9]*, Nina Jansen*[2]*, Mark Miller*[10]*, Diederik Schowanek*[7] *and Sabrina Wilhelm*[11]*, (1)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom, (2)Wageningen Environmental Research, Wageningen University and Research, Netherlands, (3)Durham University, United Kingdom, (4)Shell Global Solutions, United States, (5)Clariant Produkte (Deutschland), Germany, (6)Nouryon, Sweden, (7)Procter & Gamble Brussels Innovation Centre, Belgium, (8)Innospec Limited, United Kingdom, (9)Nouryon, Netherlands, (10)Durham university, United Kingdom, (11)BASF Personal Care and Nutrition, Germany*

The n-octanol/water partition ratio or coefficient (logKow) and n-octanol/water distribution coefficient (log Dow) are key parameters in environmental fate and bioaccumulation assessment of chemicals. Surfactants provide challenges when considering Kow/ Dow since they are amphiphilic structures. Consequently technical difficulties and uncertainties using currently available experimental methods occur due to their specific phase behaviour, complicated by the fact that aqueous solubility is not properly defined for surfactants. In addition Kow/ Dow is poorly representative of the interaction energy of ionic surfactants with organic/ inorganic phases and tissue matrices. The phospholipid membrane-water partition ratio (Kmw) is a promising alternative chemical descriptor for surfactants instead of Kow, as it relates to partitioning into a critical cellular component and accounts for ionic interactions. Kmw can be determined by several experimental methods using artificial phospholipid material. Here we present the results of a study which systematically evaluates three experimental and three computational methods for determining Kmw values for a diverse set of twelve surfactants, covering nonionic, anionic, cationic, and zwitterionic classes. Values derived using experimental approaches using unilamellar liposomes dialysis systems, solid-supported lipid membranes (SSLM) and HPLC columns with Immobilized Artificial Membrane coated silica (IAM-HPLC) are compared with values derived using computational approaches of polyparameter Linear Free Energy Relationships (ppLFERs), Conductor-like Screening Model for Membranes (COSMOmic) and coarse-grained molecular dynamics (MD) simulations. The pros and cons of each method will be discussed in the context of generating reliable and relevant estimates of Kmw for surfactants as a key input into in silico bioaccumulation prediction tools as well as baseline toxicity potential.

1.07.P-Mo009 Effect-Based Screening of Chemical Pollutants Present in Suspended Particulate Matter of German Rivers

Erica Selin[1]*, Geeta Mandava*[2]*, Fredric Sodergren Seilitz*[1]*, Javad Mottaghipisheh*[3]*, Anna Karrman*[1]*, Lutz Ahrens*[3]*, Maria Larsson*[1]*, Johan Lundqvist*[3]*, Jan Koschorreck*[4] *and Magnus Engwall*[5]*, (1)orebro University, Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)SLU, Sweden, (4)Federal Environmental Agency Germany (UBA), Germany, (5)School of Science and Technology, Orebro University, Örebro, Sweden*

Suspended particulate matter (SPM) plays a vital role in the aquatic ecosystem and can be used to assess the water quality and contamination level. This study employed a panel of effect-based in vitro methods to evaluate the potential toxicity of SPM samples over a 17-year period from two sites at the Rhine River (collected between the years 2005 and 2022), focusing on the presence of chemical contaminants. The samples were extracted by sequential ultrasonication using both a non-polar (hexane:dichloromethane, 1:1) and a polar (methanol) solvent. Both the non-polar and polar extracts were then assessed using effect-based methods, measuring estrogen receptor ? agonistic, androgen receptor antagonistic, aryl hydrocarbon receptor and oxidative stress responses. Notably, polar extracts exhibited high bioactivity 35 out of the 36 tested - in the oxidative stress assay, where the highest bioequivalent concentration was recorded in a sample from Koblenz (2021). The non-polar extracts, on the other hand, showed no oxidative stress response in the concentrations tested. This suggests that polar compounds are driving the oxidative stress response. Initial screening of estrogen receptor ? agonistic and androgen receptor antagonistic activities appears to be affected solely by polar compounds based on the results from a 2015 sample from Koblenz. In contrast, the non-polar extract exhibited a higher activity in the aryl hydrocarbon receptor assay compared to the polar extracts. Ongoing analyses with liquid and gas chromatography coupled with high-resolution mass spectrometry aim to clarify the chemical profiles contributing to these effects. This study highlights the benefits of using effect-based methods as an early warning system to detect chemical hazards in the aquatic environment, as it provides a comprehensive view of water quality assessment.

1.07.P-Mo010 Mechanism-Based Toxicity Screening of Organophosphate Flame Retardants Using Tox21 Assays and Molecular Docking Analysis

*Donghyeon Kim, **Kimoon Na** and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of*

As brominated flame retardants are phased out and regulations on their use become stricter, concerns over organophosphate flame retardants (OPFRs) have increased due to their high production. In response, this study aimed to screen the potential toxicity of emerging OPFRs using in vitro Tox21 assays and in silico molecular docking analysis. For 48 OPFRs collected from the literature, we investigated their bioactivity with human nuclear receptors using Tox21 data, focusing on pathways related to endocrine disruption (ERs, AR), stress response (GR), energy homeostasis (PPARs, FXR), and detoxification (PXR, CAR). For OPFRs not tested in Tox21 assays, molecular docking simulations were performed to predict binding potential. Results showed that CAR/PXR and FXR had relatively high reactivity with diverse OPFRs, indicating potential molecular initiating events (MIEs). Among the 48 OPFRs, 28 interacted with one or more receptors, suggesting they may act as potential stressors of adverse outcome pathways (AOPs) leading to various human diseases. Aryl- and halogenated-OPFRs displayed higher bioactivity compared to alkyl-OPFRs. Additionally, as the logKow value and carbon number of OPFRs increased, their interaction with nuclear receptors also increased. These structure- and physicochemistry-dependent bioactivities provide insights for designing safer OPFRs to avoid regrettable substitutions. Of these prioritized OPFRs, 13 showed low oral points-of-departure (POD) values under 100 mg/kg/day. In contrast, the other 15 OPFRs lacked sufficient data or exhibited less severe toxicity, despite being predicted to be of high concern in our analysis. Since several OPFRs are commonly used in consumer products that can lead to daily human exposure, we suggest that these OPFRs have the potential to reveal undisclosed effects and should therefore undergo further assessment. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE)(RS-2023-00215309)

1.07.P-Mo011 Cytotoxicity of Tire-Related Chemicals in Cells from Diverse Fish Species

Akihiro Moriyama[1]*, Yusuke Hamada*[2]*, Masanori Horie*[2]*, Katsuhide Fujita*[1] *and Wataru Naito*[1]*, (1)Research Institute of Science for Safety and Sustainability, National Institute of Advanced Industrial Science and Technology, Japan, (2)Health and Medical Research Institute, National Institute of Advanced Industrial Science and Technology, Japan*

Recent studies have shown that 6PPD-quinone, which forms as a result of the transformation of the antioxidant 6PPD in tire rubber, displays marked acute toxicity in some salmonid fish species. Furthermore, similar toxic effects have been observed in cultured cells derived from these fish species. This study aims to evaluate the cytotoxicity of 6PPD and related chemicals, with the goal of identifying safer alternatives, using cultured cells from three salmonid species and two phylogenetically distant fish species, Bluegill (BF-2) and Fathead minnow (FHM). First, to confirm the general sensitivity of each fish cell line to common chemicals, we assessed the toxicity of 3,4-dichloroaniline (3,4-DCA) as a model compound for environmental pollutants. We further evaluated 6PPD and its quinone form, along with other tire-related chemicals. The endpoint was the assessment of cellular metabolic activity measured by the Alamar Blue assay. The results showed no major species-specific differences in the toxicity of 3,4-DCA across the fish cell lines. Additionally, no toxicity was observed for 6PPD in any cell line; however, 6PPD-quinone exhibited toxicity in Rainbow trout (RTG-2) and Coho salmon (CSE-119) cells. This study highlights the species-specific toxicity of 6PPD-quinone at the cellular level by utilizing cell lines derived from phylogenetically diverse fish species. Ongoing evaluation of potential alternative substances will be presented in detail at the poster session.

1.07.P-Mo012 Cytotoxicity Assay on the Fish Cell Line RTgill-W1 to Assess the Acute Toxicity of Nanomaterials

Mariia Goncharova[1]*, David Hernandez-Moreno*[1]*, Rocio Fernandez-Saavedra*[2]*, Ana Isabel Cardona*[2]*, Laura Molinero*[2]*, Ana Valdehita*[1]*, José María Navas*[1] *and Maria Luisa Fernandez-Cruz*[1]*, (1)Department of Environment and Agronomy, National Institute for Agriculture and Food Research and Technology (INIA), CSIC, Spain, (2)Chemistry Division, Research Centre for Environment, Energy and Technology (CIEMAT), Spain*

Nowadays, in vitro methods are seen as a reliable tool to generate appropriate information for the assessment of chemicals and nanomaterials. OECD test guideline (TG) 249 (Fish Cell Line Acute Toxicity - The RTgill-W1 cell line assay) has been originally developed for soluble toxicants. The present work aims to assess the applicability of this test to nanomaterials (NMs) by using NMs of different composition, size and shape, and comparing the obtained results with these generated in other fish cell lines and in in

vivo fish tests. For this purpose, the following NMs were investigated: Ag, 10 nm; BaSO4, 32 nm; Bentonite Nanoclay, 288 nm; CeO2, 33 nm; Cu, 25 nm; Cu, 50 nm; Cu,100 nm; CuO, 15-20 nm; CuO, <50 nm; Multi-walled Carbon Nanotubes, length 4.05 µm, thickness 67 nm; TiO2, 6 nm; TiO2, 20 nm; ZnO, 34 nm; ZnO, 42 nm. The Nanogenotox protocol was applied to obtain stable dispersions. The stability of the stocks and exposure suspensions was characterized by the measurement of the concentration and size frequency distribution/zeta potential during 24 h exposure period, by ICP-MS or ICP-OES and dynamic light scattering, respectively. The size distribution of the 14 NMs tested was stable during this period. Real concentrations at time 0 were within the 20% range allowed of the nominal concentrations, except for BaSO4, CeO2, TiO2, and ZnO (34 nm). Real concentrations after 24 h dropped significantly for BaSO4, CuO, and TiO2 (6 nm) due to deposition. RTgill-W1 cells were seeded in 24-well plates (35×104 cells/well) following the TG249 procedure. L-15ex medium was used for treatment with NMs. A triple cytotoxicity assay (Alamar Blue, CFDA-AM, and neutral red) was performed according to TG249. Potential interferences of NMs with the measures were assessed. The EC50 values obtained for the 14 NMs were similar to those reported in acute toxicity tests in fish and were significantly lower in comparison to other cell lines. Interferences with the NRU assay at the highest concentrations were registered for most of the investigated NMs, and several NMs interfered with AlamarBlue and CFDA-AM.
This study suggests that NMs can be tested following the TG249 protocol, but the stability of the exposure suspension and the possible interference effect needs to be assessed previously. Results also indicated that the assay could predict the acute toxicity in fish, although further data are needed to make a clear conclusion. CSIC Program of Scientific Cooperation with Ukraine Call 2022 and General Protocol of Action for the Assessment of Chemicals and Nanomaterials between MITECO and CSIC.

1.07.P-Mo013 Suitability Of the Rtgill-W1 Cell Line Assay (OECD TG 249) to Predict Acute Fish Toxicity for Surfactants

*Jayne Roberts[1], Geoff Hodges[1], **Kristin Connors**[2], Erin Maloney[3], Jay Dawick[4], Lauren McAnally[4], Jens Bietz[5], Frank Seitz[6], Marc Geurts[7], Liesa-Kristin Beuter[7], Kristin Schirmer[8], Roman Li[8] and Stephan Fischer[8], (1)Unilever, United Kingdom, (2)The Procter and Gamble Company, United States, (3)Shell Global Solutions, Netherlands, (4)Innospec Limited, United Kingdom, (5)Clariant Produkte (Deutschland), Germany, (6)Sasol, Germany, (7)Nouryon, Netherlands, (8)aQuaTox-Solutions, Switzerland*

The OECD TG 203 fish acute toxicity test is a key requirement in global regulatory frameworks and environmental risk assessment. However, evolving legislation under the Chemical Strategy for Sustainability (CSS) incorporates attempts to reduce vertebrate animal testing. To ensure the continued safety of chemicals, robust, reliable, and regulatory-compliant alternatives must be available. One such option is the RTgill-W1 Fish Cell Line Acute Toxicity assay (OECD TG 249) as a proposed alternative to the fish acute toxicity test. Previously this assay has been shown to have a good correlation with existing in vivo acute fish data for a variety of chemicals. However, the available data are scattered, and despite some surfactants having been tested, a clear applicability domain for this group of chemicals has not been definitively established. Surfactants are used in various home and personal care (HPC), industrial and institutional (HI&I) applications and encompass diverse chemical classes, with variation in alkyl chain length, structure (branched vs. linear), solubility, lipophilicity, functional head-groups, and ionizable potential (cationic, anionic, amphoteric and nonionic), all of which can pose challenges in successfully executing standard (or adapted) test methodologies. Therefore, it is essential to evaluate the suitability of surfactants within in vitro test designs. Here we present initial progress of the work of this Environment and Health Risk Assessment & Management (ERASM) Task Force which aims to address these uncertainties by generating new and/or collating existing in vitro Rtgill-W1 data for a selection of non-ionic, anionic, cationic, and amphoteric surfactants. These data will subsequently be compared with existing high quality in vivo and fish embryo toxicity (FET; OECD TG 236) data to provide recommendations and potential limitations around the application of the method for regulatory frameworks and environmental risk assessment of surfactants.

1.07.P-Mo014 Comparing the Sensitivity of Three Rainbow Trout Cell Lines Through Cytotoxicity and Targeted Gene Expression For Aquatic Testing

***Bennett Upton**[1], Justin Scott[1] and Matteo Minghetti[2], (1)Oklahoma State University, United States, (2)Integrative Biology, Oklahoma State University, Stillwater, United States*

The International Organization for Standardization recently approved the RTgill-W1 cell line as an in vitro alternative for acute toxicity testing in fish. While RTgill-W1 reflects acute toxicity in rainbow trout (Oncorhynchus mykiss), it represents only one tissue type. Testing with various tissue types can elucidate tissue-specific mechanisms of toxicity that may be overlooked when using a single cell type. In this study, the rainbow trout cell lines RTL-W1 (liver), RTgut-GC (intestine), and RTgill-W1 (gill) were exposed to a range of 3,4-dichloroaniline (DCA) and cadmium (Cd) concentrations. Cytotoxicity levels and effective concentrations for 50% cell viability (EC50) of Cd and DCA were determined using a multi-endpoint viability assay with alamarBlue, CDFA-AM, and neutral red as markers of cell metabolic activity, cell membrane integrity, and lysosomal integrity, respectively. Results indicated Cd EC50 values of 72.5 µM, 92.6 µM, and 234.5 µM for RTgill-W1, RTgut-GC, and RTL-W1 cells, respectively. For 3,4 DCA, EC50 values were 442.8 µM, 622.3 µM, and 653.3 µM for RTgill-W1, RTgut-GC, and RTL-W1 cells, respectively. Across all cell types, RTgill-W1 was the most sensitive to both 3,4 DCA and Cd, with cadmium exhibiting higher toxicity in all cell lines compared to 3,4 DCA. RTL-W1 cells displayed greater resistance to these chemicals, suggesting that, similar to tissues in vivo, this cell line may possess more robust detoxification mechanisms. To test this hypothesis, cells were exposed to non-toxic and toxic concentrations of cadmium (18.5 µM and 185 µM, respectively) and DCA (0.445 µM and 6.67 µM, respectively) for 24 hours. Following exposure, total RNA from each cell type was extracted and reverse-transcribed for quantitative PCR (qPCR) analysis. Metallothionein and Cytochrome P450 1A messenger RNA levels will be measured by qPCR as biomarkers of cadmium and DCA exposure and toxicity. With this approach, we aim to assess variability in the sensitivity of different cell types to chemical toxicity and determine whether differences in sensitivity can be explained by molecular detoxification mechanisms across cell types.

1.07.P-Mo015 Applicability of the OECD 249 RTgill-W1 Cell Line Assay for Predicting the Acute Fish Toxicity of Glycol Ethers and Glycol Ether Esters

Erin Maloney[1]*, Dennis Becker*[2]*, Carolina Di Paolo*[3]*, Gregg Hancock*[4]*, Andrew Scott*[4]*, Anne Diez*[5]*, Aurelie Carlier*[6] *and Karen Smet*[6]*, (1)Shell Global Solutions, Netherlands, (2)Clariant Corporation, United States, (3)Dow Benelux B.V., Netherlands, (4)Dow Chemical Company, United States, (5)Abteilung GBP/RA, BASF SE, Germany, (6)INEOS Europe AG Division Oxide, Switzerland*

Glycol ethers (GE) and GE esters are a group of industrial chemicals typically used as solvents in a wide range of applications. Most are registered under high tonnage bands in EU REACH (> Annex VII), thus require acute fish toxicity data. As part of a voluntary dossier improvement project, the Glycol Ethers REACH Consortium (https://www.reachcentrum.eu/consortia/glycol-ethers-reach-consortium/) has been conducting new testing. This involves improving the current acute fish toxicity dataset through strategic testing efforts. Specifically, QSAR predictions and existing OECD 203 data (which demonstrated no or low hazards to fish but often lacked analytical monitoring) were used to prioritize candidate substances for further testing. Subsequently, with the aims of avoiding additional and unnecessary animal testing, OECD 249 was employed to predict acute fish toxicity. Outcomes from the OECD 249 tests were targeted to be used as additional lines of evidence for the acute fish endpoint. For GE substances preliminary OECD 249 results confirmed the previous conclusions that these substances pose no hazards to fish. However, direct comparison of these results to in vivo data demonstrated that the OECD 249 tended to underpredict the toxicity for both GE and GE esters. For example, OECD 249 EC50 values were around 2-fold higher for GE and up to 18-fold higher for GE esters than in vivo LC50 values. Currently, the reasons for this toxicity underprediction are unclear. The OECD 249 has been shown to underpredict the toxicity of chemicals with specific modes of action or substances that are metabolically activated to reactive forms. Moreover, previous studies indicate that there may be differences in enzymatic expression of certain enzymes in rainbow trout gill cells compared to other metabolic organs. Thus, one hypothesis is that diverse toxicokinetics in the in vivo and OECD 249 assays are driving these differences in predicted effect. Overall, this work can be considered as part of the greater available evidence to help define the applicability domain of the OECD 249. Moreover, these findings can be used to inform future testing strategies for other industrial chemistries, and spur further research focusing on deriving fit-for-purpose alternatives to classic vertebrate ecotoxicity tests.

1.07.P-Mo016 Real-Time Chemical Toxicity Monitoring with a Microfluidic Multi-Cell Line Fish-on-Chip Model

Jenny Maner[1]*, Philippe Renaud*[2] *and Kristin Schirmer*[3]*, (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland, (3)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Fish toxicity testing is a crucial component of chemical risk assessment and effluent testing, and there is a growing need for alternative methods to reduce the use of live animals. Fish cell lines can be used as an effective in vitro alternative to predict adverse outcomes. However, most in vitro assays using cell lines are carried out under static exposure conditions and assess cell viability only at a single time point, upon termination of chemical exposure. Thus, no information is gained on how toxicity develops over time. In this work, we established a microfluidic biosensor for acute toxicity testing under flow conditions in real-time. We employ Electric Cell-substrate Impedance Sensing (ECIS), which measures resistance to an electric current of a cell monolayer on a chip. This label-free and non-invasive technique allows continuous monitoring of cell viability during chemical exposure. We use cell lines from the rainbow trout (Oncorhynchus mykiss), a standard species in ecotoxicity testing, of which there are several established cell lines derived from various organs. Using a cell line from the gill, RTgill-W1, we have previously shown that ECIS can be used for time- and concentration-dependent toxicity testing under flow conditions. Moreover, as ECIS is a sub-lethal endpoint, permanent and reversible changes could be distinguished during depuration. This versatile platform has application with chemical toxicity screening as well as the evaluation of water samples. To investigate chemical impacts across multiple organ systems, we have incorporated cell lines from the liver and brain of rainbow trout. We hypothesise that different cell lines may have different sensitivities to certain chemicals. Moreover, by serial connection of channels containing different cell lines, sensitivity of cells in downstream channels may be altered, e.g. by means of biotransformation of chemicals by cells in upstream channels. Thus, by combining multiple cell lines connected in series on the same chip, we make a simple fish-on-chip model for chemical toxicity monitoring.

1.07.P-Mo017 Comprehensive Characterization of Rainbow Trout Hepatic 3D Spheroids: Morphological and Transcriptional Insights
Maria T. Hultman[1], *Prem Chand*[2], *You Song*[1], *Awadhesh Jha*[3] *and Coen Campsteijn*[4], *(1)Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian institute for water research, University of Oslo, Norway, (3)University of Plymouth, United Kingdom, (4)University of Oslo, Norway*
The demand for alternative ecotoxicology methods is increasing, especially with a focus on New Approach Methodologies (NAMs) to provide reliable in vitro models for chemical hazard assessments. Many existing cell-based assays rely on primary or continuous cell cultures effective for acute toxicity but often lack the necessary complexity for long-term exposure studies. However, few alternative models support comprehensive, long-term toxicity evaluations, essential for understanding chronic impacts. A novel 3D spheroid model derived from rainbow trout (Oncorhynchus mykiss) primary hepatocyte (RT-HEP-SP) has emerged as a promising NAM, preserving key morphological, physiological, and biochemical properties for weeks, making it suitable for chronic toxicity studies. However, broader application of the RT-HEP-SP system requires thorough characterization and validation. In this study, high-resolution confocal microscopy was employed to assess various markers, such as spheroid morphology (cytoskeleton, DNA and nuclear integrity, bile canaliculi formation), viability (metabolic activity, hypoxia within the spheroid core), and physiological response (reactive oxygen species [ROS] induction, mitochondrial membrane potential, ethoxyresorufin-O-deethylase [EROD] activity, and Phase II metabolism components like uridine 5?-diphospho-glucuronosyltransferase [UGT]) during chemical exposure. RNA sequencing (RNA-seq) and targeted bioassays were used to evaluate RT-HEP-SPs responses to various toxicants. A Biomarker Toolbox was developed with sensitive and reproducible markers for oxidative stress, biotransformation (e.g., aryl hydrocarbon receptor, EROD,), and viability (e.g., lactate dehydrogenase). These biomarkers were validated through short-term (24 96 hours) exposures to model chemicals with distinct toxic modes of action (MOAs), including copper, 17 ?-ethinyl estradiol (EE2), benzo[a]pyrene, and carbonyl cyanide m-chlorophenyl hydrazone (CCCP), confirming the model s responsiveness and reproducibility. Initial findings indicate that RT-HEP-SP are a reliable model for assessing cytotoxicity, membrane integrity, and oxidative stress, with no core hypoxia detected. RNA-seq analyses reveal their molecular complexity and suitability for the assessment of chemicals with different MOAs. This model shows strong potential as an ecotoxicity screening tool for various chemicals.

1.07.P-Mo018 Development of an Atlantic Cod (*Gadus morhua*) Estrogen Receptor TR-FRET Assay for Assessment of Xenoestrogens in a Non-model Teleost Species
Odd Andre Karlsen, *Rhîan Gaenor Jakobsen, Fekadu Yadetie and Anders Goksoyr, University of Bergen, Norway*
The 3Rs directive (Directive 2010/63/EU), to replace, reduce and refine animal experiments, has been a driving force to move from in vivo studies towards in vitro and in silico approaches. Establishing standardized and validated new approach methodologies (NAMs) is essential to this transition and important for reliable toxicity testing and risk assessment of chemicals. Cell-based luciferase reporter gene assays with ligand-activated transcription factors have been frequently used for chemical toxicity testing and assessment of potential endocrine disrupting properties. Although these assays are sensitive and to some extent adjustable to high-throughput testing, they still suffer from being labour intensive and time consuming. In the recently funded XENOSENSE project, we aim to develop receptor-based molecular tools that are more efficient, less time consuming, and as sensitive as cell-based assays. Time-resolved

fluorescence resonance energy transfer (TR-FRET) has emerged as a promising cell-free technology for assessing the interaction of nuclear receptors with various chemicals. Although some TR-FRET receptor assays are commercially available, these are still limited to model species such as rat and human. In the present work, we have developed TR-FRET assays for the Atlantic cod estrogen receptor alpha (Era). The TR-FRET assay is based on the ligand-dependent recruitment of the steroid receptor coactivator (SRC-1) and uses recombinantly expressed and purified estrogen receptor ligand binding domain. Its performance regarding the sensitivity towards binding of estrogenic compounds is currently evaluated towards a suite of bisphenol A (BPA) analogs, and compared against recently publish data obtained with the traditional cell-based luciferase reporter gene assay with the same library of compounds. Our data indicate that Era demonstrate similar ligand-activation profiles in the cell-free TR-FRET assay as in the cell-based luciferase reporter gene assay, but the TR-FRET appears to be more sensitive, producing EC50 values that are between one and two orders of magnitude lower than those obtained for corresponding compounds in the traditional reporter gene assay. Thus, TR-FRET appears as a promising NAM for toxicity assessment that can be established for ligand-activated receptors from non-model species. The authors thank the Research Council of Norway for funding the XENOSENSE project (project no. 342186)

1.07.P-Mo019 Identification and Validation of Biomarkers of Reproductive Toxicity in Fish Cells
Roman Li[1]*, Vid Modic*[2]*, Katharina Klotz*[3]*, Stephan Fischer*[3]*, Kristin Schirmer*[1] *and Anze Zupanic*[2]*, (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)NIB, Slovenia, (3)aQuaTox-Solutions, Switzerland*
New approach methodologies (NAMs) include in vitro assays that aim to replace animal tests in chemical risk assessment. Because NAMs reduce the reliance on animal data, they are both more practical and ethical compared to traditional methods. Additionally, NAMs may provide more precise mechanistic data and more reproducible results, making them scientifically more desirable. Here we aim to develop NAMs that can replace in vivo fish reproductive toxicity tests in environmental risk assessment with assays that utilise permanent cells of rainbow trout (Oncorhynchus mykiss). We undertake this project within the NC3Rs CRACK IT Challenge SAFE .We have previously presented a novel computational pipeline to identify a panel of biomarkers based on mechanistic information of reproductive toxicity in fish. We also identified biomarkers that show robust regulation under reprotoxic chemical exposure as well as poorly studied proteins that demonstrate an association to reproductive signalling pathways in fish. We have now undertaken the first steps towards validating a subset of the identified biomarkers by measuring their expression in the rainbow trout liver cell line (RTL-W1). We exposed the cells to two endocrine chemicals, 17b-Estradiol and Testosterone, and measured the biomarker expression on the BioMarkHD Fluidigm system in a medium throughput manner. With this approach we identified Insulin-like growth factor 1 (Igf1) signalling as a key mechanistic player. We are currently exposing additional rainbow trout cell lines to a larger panel of endocrine disrupting chemicals to gain more insights into highly regulated pathways in cultured cells, which will form the basis for future endpoints in fish reproductive NAMs. This work is funded by the NC3R CRACK IT Challenge 41 SAFE https://nc3rs.org.uk/crackit/safe

1.07.P-Mo020 Using NAMs and Probabilistic Modelling in Component-Based Mixture Risk Assessment: A Case Study on the Risk to Aquatic Environments From Pesticides Causing Mitochondrial Toxicity
Seta Noventa[1]*, Jannicke Moe*[2]*, Knut Erik Tollefsen*[2]*, Walter Zobl*[2]*, You Song*[2]*, Loredana Manfra*[1] *and Adam Lillicrap*[2]*, (1)Italian Institute for Environmental Protection and Research (ISPRA), Italy, (2)Norwegian Institute for Water Research (NIVA), Norway*
The next-generation environmental risk assessment vision advocates the transition to i) assessing exposure to chemical mixtures, and ii) employing mechanism-based hazard assessment based on new approach methodologies (NAM). Here, we explore the potential of a refined version of component-based risk assessment (CBMRA) methodology, using high-throughput-screening (HTS) bioactivity data combined with a quantitative adverse outcome pathway (qAOP) approach for hazard assessment. The project centres on the quantitative AOP #263, which models growth inhibition through uncoupling of mitochondrial oxidative phosphorylation by chemicals using model aquatic organisms. As a case-study, it uses monitoring data on pesticide concentrations in freshwater from the European Environmental Agency s Pesticide Indicator dataset (Waterbase and WISE statistics). Bioactivity profiles from ToxCast and Tox21 are mapped to an OECD endorsed AOP (#263) to establish equipotent mixture concentrations compared to the model chemical, providing input data to the qAOP model. Uncertainty associated with the different risk components is estimated by statistical modelling, and subsequently integrated and propagated throughout the whole risk characterisation process using Bayesian network modelling. The resulting probabilistic risk characterisation will be compared to risk predictions based on other lines of evidence. This poster presents preliminary results from the application of probabilistic NAM-based CBMRA for this

case-study, addressing conceptual, technical and modelling aspects. It also highlights connections to the European Food Safety Authority s guidance on cumulative risk assessment.

1.07.P-Mo021 In Vitro Comparison of the Sensitivity of Zebrafish to Five Model Marine Fishes to Dioxin-Like Chemicals and Polycyclic Aromatic Hydrocarbons

__Cameron Hunter Collins__[1], Justin Dubiel[2], Andreas N.M. Eriksson[2], Nonnie 'Betsy' Cook[1], Benjamin Patrick de Jourdan[3], Steve Wiseman[2] and Jonathon Doering[1], (1)Louisiana State University, United States, (2)University of Lethbridge, Canada, (3)Huntsman Marine Science Centre, Canada

Evaluations of the sensitivity of fish when exposed to ubiquitous environmental contaminants such as dioxin-like compounds (DLCs) and polycyclic aromatic hydrocarbons (PAHs) have historically utilized freshwater species. However, studies have shown differences in sensitivity between various freshwater species ranging over 400-fold, highlighting the significant variability within the taxa. Considering the zebrafish (Danio rerio) is a popular model freshwater species used as a benchmark for sensitivity assessments, the difference in relative sensitivity compared to marine fish is not currently understood. Thus, the objective of this study was to evaluate the sensitivity of five marine model species, namely the Gulf Killifish (Fundulus grandis), Mummichog (Fundulus heteroclitus), Inland Silverside (Menidia beryllina), Atlantic Silverside (Menidia menidia), and Sheepshead Minnow (Cyprinodon variegatus). Exposures for each species were performed by conducting a standardized in-vitro aryl hydrocarbon receptor 2 (AHR2) transactivation assay of COS-7 cells transfected with an AHR2 cloned from the species of interest. A diversity of chemical structures were investigated, namely the model DLC, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), a chlorinated dibenzofuran (TCDF), a non-ortho and a mono-ortho polychlorinated biphenyl (PCB 77 and 118), PAHs with 5 (BaP), 4 (BAA), and 3 rings (Anthracene), and a methylated PAH (8MBAA). The 50% effective concentrations (EC50) were compared to the corresponding EC50s for zebrafish and the relative sensitivity was calculated. Results suggest that zebrafish AHR2 has different sensitivities to agonists relative to common model marine fishes, with relative sensitivities of the 5 marine species ranging from 1 to 50 times more sensitive. While zebrafish AHR2 might have similar sensitivity to some PAHs, it appears to be substantially less sensitive than the marine fishes to TCDD and TCDF. This further highlights the variability in sensitivity within fishes when exposed to DLCs, as well as the shortcomings of relying on zebrafish toxicity data, particularly for fish families in marine environments. The capacity of in-vitro assays to quickly and accurately generate information for a variety of species, while eliminating the need for largescale lethal sampling, suggest that they are a viable way to fill the current knowledge gaps and ultimately conduct more accurate risk assessments.

1.07.P-Mo022 The Development of a Three-Dimensional Ex Vivo Respiratory Model For Nanomaterial Exposure Using The Air Breathing Organ of *Clarias gariepinus*

Entle Xhallie, Refilwe Lukhwareni and __Tarryn Lee Botha__, University of Johannesburg, South Africa

Due to their multifunctional biomedical and industrial applications, nanomaterials, have seen an increase in synthesis, use and waste disposal to the natural environment. The use of copper oxide nanomaterials (nCuO) is emerging throughout various industries including environmental remediation, agriculture and renewable energy, the biodistribution and accumulation of nCuO is however poorly understood in biological organisms. As each characteristic of the nCuO is altered so is the toxicity which leads to a battery of animal testing to ensure safety by design. The African Sharptooth catfish is a niche organism which can respire through an air breathing organ (ABO) which assists it to move between pools when water levels are depleted. A previous study showed nanomaterial uptake specific to the ABO. This study aimed to investigate the interaction, biodistribution and uptake of nCuO in live excised respiratory ABO tissue of Clarias gariepinus was compared to a developed three-dimensional model of a similar structure. The ex vivo structures were acutely exposed to nominal concentrations of 350 µg/L and 3.5 mg/L and spiked at 35 mg/L nCuO. Materials were characterized in RO water. Uptake, biodistribution and agglomeration of particles were analysed using CytoViva dark field hyperspectral imaging, light microscopy and scanning electron microscopy and where possible Image J was used to quantify the number of foreign bodies found. Characterization results suggest a dose-dependent hydrodynamic size distribution and agglomeration of nCuO in both live and synthetic tissue. Attachment to the surface of tissue was observed in both groups however the synthetic group statistically resulted in more accumulation and agglomeration. It is hypothesised that might be due to the stability or charge of PLA in water. Toxicology testing of ENM can attempt to include alternate methods, mentioned in this study, as an ethical consideration in reducing animal studies.

1.07.P-Mo023 From Fish Embryo to Fish Early Life Stage – Prediction of effects on growth via effect modelling

Daniel Faber, Yvonne Wolf, Christoph Paul Linder, ***Daniel Burkow****, Markus Ebeling and Jutta Agert, Bayer AG, Crop Science, Environmental Safety, Germany*
In the context of the environmental risk assessment (ERA) according to the European Union regulations 283/2013 and 284/2013 for plant protection products, numerous animal studies must be performed. Based on the physico-chemical characteristics, for many substances a fish early life stage study (FELS, OECD 210) investigating aquatic chronic effects needs to be conducted to fulfil the current data requirements. This project investigates whether it is possible to predict chronic effects on growth and survival in FELS studies from fish embryo toxicity test data (FET, in acc. to OECD TG 236), with additional length measurements at different time points, by using toxicokinetic-toxicodynamic (TKTD) and Dynamic Energy Budget (DEB) models. DEB models modify growth rate based on an internal energy reserve and translate this growth across maturity stages. A DEB model parameterization for fathead minnow (Pimephales promelas) exists in the publicly accessible AddMyPet (AMP) database that we use as a base model onto which we attach a TKTD component to fit the FET growth and survival endpoints. The interaction of TKTD effects in a DEB model enables us to extrapolate from FET results into simulated FELS tests and compare simulated FELS endpoints for growth retardation and survival against existing tests to validate the modeling assumptions and goodness of fit. With this approach a combination of different already existing New Approach Methodologies is used. This is in line with the 3R (Reduction, Replacement, Refinement) principle: Reduction of animal numbers by using embryos for specific ERA questions and Replacement of further animal experiments.

1.07.P-Mo024 Is it safer? Evaluating the Hazards of Bisphenol A Alternatives in Zebrafish Embryos
Maria S. Costa, Marta S. Monteiro, ***Susana Loureiro*** *and Ines Domingues, Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal*
Bisphenol A (BPA), a chemical widely used in manufacturing polycarbonate plastics and epoxy resins, is a known environmental and health concern due to its endocrine-disrupting properties and links to reproductive harm and chronic conditions. To address these issues, alternative compounds such as bisphenol AF (BPAF) and bisphenol Z (BPZ) have been developed. However, these substitutes may not be inherently safer, as emerging evidence suggests they can pose comparable or greater risks to human health and ecosystems. To assess whether these alternatives are truly less hazardous than BPA, zebrafish (Danio rerio) embryos were exposed to both BPA and its alternatives in two experimental setups. In the first experiment, embryos were exposed to seven concentrations over 120 hours, with mortality, hatching, and malformation rates monitored at 24-hour intervals, alongside a heart rate assay at 48 hours. The second experiment involved exposure to three concentrations below the EC10 for malformations (determined in first experimental setup), following a similar design. At the end of this exposure, behavioural tests and biochemical analyses were conducted, focusing on neurotoxicity, oxidative stress, and energy-related biomarkers. Results indicate that the alternatives tested were more toxic than BPA, with lower lethal concentrations (LC50) values and lower effect concentrations for malformations (both EC10 and EC50). These findings highlight the critical need for continued efforts to identify truly safer BPA alternatives. This work was carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union s Horizon Europe research and innovation programme under Grant Agreement No 101057014 and CESAM (UIDP/50017/2020 + UIDB/50017/2020 + LA/P/0094/2020) through national funds.

1.07.P-Mo025 Tissue-Specific Responses to a Binary Mixture of Bisphenol A Substitutes in Zebrafish Embryo-Based Bioassays Assessing Estrogenic and Metabolic Activities
Florian Geffroy[1]*, Nathalie Hinfray*[2]*, Benjamin Piccini*[2]*, Xavier Coumoul*[3]*, Cleo Bodin*[4] *and Francois Brion*[2]*, (1)INERIS, Ecotoxicology of Substances and Environment (ESMI) Unitt / Universite Paris Cite, Inserm UMR-S 1124, France, (2)INERIS, Ecotoxicology of Substances and Environment (ESMI) Unit, France, (3)Universite Paris Cite, Inserm UMR-S 1124, France, (4)INERIS, Experimental Toxicology and Modeling (TEAM) Unit, France*
Mixtures of chemicals, notably endocrine-disrupting chemicals (EDCs), represent a major issue as current regulations often underestimate their risks by assessing individual substances only. Most approaches for evaluating EDCs mixtures rely on cellular models, thereby precluding to take into account the complexity of whole-organism systems and capture potential tissue-specific interactions. In this study, we aimed to address this gap by using in vivo transgenic zebrafish embryo models to assess the effects of a binary mixture of bisphenol A substitutes, bisphenol B (BPB) and bisphenol C (BPC), on estrogenic and metabolic pathways in two distinct target organs, the brain and the intestine. Through in vivo fluorescence imaging, we observed that both BPB and BPC induced the expression of the estrogen-regulated aromatase B gene (cyp19a1b) in the brain, as well as the intestinal expression of cyp3a65, each in a concentration-dependent manner. For each substance and target gene, EC50 values were derived and used to set-up an

experimental ray design for binary mixtures (5 mixture ratios chosen by considering relative potency and 5 exposure levels around the EC50). The observed tissue-specific effects of these mixtures will be compared with predictions from the commonly used concentration addition model for our two differentially regulated target genes. These findings could reveal new insights on mixture interactions in whole-organism systems, across differentially regulated genes expressed in two distinct organs, supporting a better hazard assessment of EDCs mixtures. This work was carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union s Horizon Europe research and innovation programme under Grant Agreement No 101057014

1.07.P-Mo026 Is There Evidence for Omitting the Water Control in Fish Early-Life Stage Toxicity Tests When Solvents are Used?

***Christopher Fassbender**[1], John W. Green[2], Daniel Faber[3], Lennart Weltje,[4] and Gilly Stoddart[1], (1)PETA Science Consortium International e.V., Germany, (2)John W Green Ecostatistical Consulting, United States, (3)Bayer AG, Germany, (4)Agricultural Solutions - Ecotoxicology, BASF SE, Germany*

If a solvent is used in the fish early-life stage (FELS) toxicity test (OECD Test Guideline 210), both a water control and a solvent control are currently required. We investigate the feasibility of using only the solvent control and omitting the water control when a solvent is used. The number of fish and resources used in tests for which solvents are required would substantially be reduced by doing so, following the 3Rs principles. A FELS toxicity test database including solvent and water controls and concentration-response data from existing studies was compiled and analysed to determine whether there are systematic differences between the water and solvent controls. The distributions of control data (means, between- and within-replicate variances) for each response variable were investigated for water, solvent and pooled controls. The impact of control choice on the NOEC and EC10 was investigated using FELS concentration-response data. Computer simulations were conducted to determine the potential impact of using only the solvent control on the ECx estimation and NOEC values. The simulations covered the observed ranges of variability and concentration-response shapes for each type of response for fathead minnow, sheepshead minnow, and rainbow trout and the solvent dimethylformamide (DMF). In the study, the measurement endpoints including fish length and weight at study end, hatching success, time to hatch, and larval survival were analysed. In addition, ECx values were estimated both by selecting the statistical model and applying model averaging. There is little evidence that an actual solvent effect exists, at least for DMF and fathead minnow. If there is a solvent effect, the scientific literature provides evidence that the solvent effect acts additive to the treatment effect. Simulation studies based on the variability and distributions of responses assessed in the FELS test and the additivity principle show that basing the EC10 or the NOEC on water control data often leads to significant bias, whereas basing these on the solvent control is relatively free of bias. Altogether, there is preliminary statistical evidence to support omitting the water control in FELS studies using a solvent. The views, conclusions, and recommendations expressed in this presentation are those of the authors and do not necessarily represent the policies or positions of their affiliated organisations.

1.07.P-Mo027 Comparative Effect Assessment of Bisphenol Analogs by High Content Analysis in Zebrafish Embryos

*Muhammad Arslan Aslam and **Stefan Scholz**, Helmholtz Centre for Environmental Research, Dpt. Ecotoxicology, Germany*

Bisphenol A (BPA), a common bisphenol plastic additive, has been banned from certain products because of its endocrine-disrupting properties. As a result, substitutes such as BPE, BPG, BPAP, and BPZ were developed and are in use. Many of these substitutes are not thoroughly characterized and may have similar biological activities as BPA. Using a high content screening assay a comparative and comprehensive assessment of BP substitutes was conducted for the zebrafish embryo model with the focus on non-endocrine (neuro)developmental effects. In contrast to previous analyses in the zebrafish embryo, the comparative effect assessment was based on an automated image and video analysis approach reducing the observer bias and increasing the reproducibility of results. The effects were quantified using behavior endpoints, heart rate assessment and quantification of deviation of morphological endpoints from controls. For all endpoints concentration-response modelling was applied to derive effect concentrations. The lack of swim bladder was the most sensitive endpoint for all of the tested bisphenols, particularly for BPE. The specificity of responses was estimated by applying the baseline toxicity concept and calculating effect ratios. Moreover, the effect profile of bisphenols was compared with 2 baseline toxicants and a screening approach to prioritise further bishphenol A analogues for detailed assessment was developed. Comparison to baseline toxicity indicated that the developmental effects were primarily driven by unspecific baseline toxicity with BPE representing the most specific compound. Cluster analysis on effect ratios supported that BPE was more specific than the other BPA substitutes, also in terms of the number of affected endpoints. The study was supported by the EU projects PARC and PrecisionTox. This work received funding by the European Union s Horizon 2020 research and innovation program project Toward Precision Toxicology: New Approach Methodologies for Chemical Safety (PrecisionTox) , grant agreement no. 965406 and the project "European Partnership for the Assessment of Risks from Chemicals (PARC)", grant agreement no 101057014.

1.07.P-Mo028 Assessing Contaminant Sensitivity in Early Life Stage Fishes using Transcriptomic Points of Departure

Jessica Head[1]*, Ryan Chui*[2]*, Florence Page-Lariviere*[3]*, Kristin Mueller*[4]*, Aylish Marshall*[2]*, Emily Boulanger*[1]*, Hugo Marchand*[2]*, Janet Cermak*[3] *and Allison Dunn*[3]*, (1)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (2)McGill University, Canada, (3)ECCC, Canada, (4)Centre d expertise en analyse environnementale du Quebec, Canada*

Chemical regulatory assessors require hazard data from multiple species spanning a range of sensitivities to develop environmental quality guidelines. Due to lengthy exposures, high costs, and ethical concerns, chronic chemical hazard data for diverse species are currently lacking. New Approach Methods (NAMs) have been touted as potential alternatives that could provide toxicity data quickly and more ethically. Our group is developing a NAM that uses early life stage fish exposures to obtain transcriptomic points-of-departure (tPODs) for environmental chemicals. Previous studies support the possibility of substituting chronic apical PODs (aPOD) with tPODs generated from short-term exposures given their high degree of correlation. The overall objective of our project is to validate tPODs as suitable toxicity data for the derivation of environmental quality guidelines. As a first step, we assessed the reliability of tPODs to predict sensitivity to 6PPD-Quinone (6PPD-Q), and Bisphenol A (BPA) in several listed and model fishes in an early life stage test. Eleutheroembryos (0 to 24 hours post-hatch) were exposed to test chemicals for 24 hours at 12 different concentrations . This concentration range spanned 9 orders of magnitude in an attempt to capture both transcriptomic and organismal level responses. RNA was isolated from pooled eleutheroembryos, followed by RNA sequencing and data processing using ExpressAnalyst. Our current results show that species differences in sensitivity at an organismal level are reflected in variability in tPOD values. Future work will focus on comparing tPODs across fish species relative to chronic apical endpoints, paving the way for the potential use of tPODs in guideline development for chemicals of concern.

1.07.P-Mo029 EMERGE, a New Transgenic Zebrafish Embryo-Based Assay to Assess Metabolic Disrupting Chemicals (MDCs) in the Intestine

Florian Geffroy[1]*, Chedi Erradhouani*[1]*, Benjamin Piccini*[2]*, Edith Chadili*[2]*, Nathalie Hinfray*[2]*, Selim Ait-Aissa*[2]*, Xavier Coumoul*[3] *and Francois Brion*[2]*, (1)INERIS, Ecotoxicology of Substances and Environment (ESMI) Unitt / Universite Paris Cite, Inserm UMR-S 1124, France, (2)INERIS, Ecotoxicology of Substances and Environment (ESMI) Unit, France, (3)Universite Paris Cite, Inserm UMR-S 1124, France*

Metabolic disrupting chemicals (MDCs) are increasingly associated with metabolic disorders such as obesity, type 2 diabetes and hepatic steatosis. To identify MDCs, new approach methodologies based on mechanisms of action are needed. Despite the intestine's key roles in metabolism, gut disruption by MDCs remains poorly studied compared to the alteration of liver and adipose functions. To adress this gap, we developed EMERGE (Effect of Metabolic Endocrine disRuptors in Gut of zebrafish Embryos), a new bioassay based on a zebrafish transgenic line (tg(cyp3a65 :GFP)). This transgenic line expresses GFP under the cyp3a65 promoter, an ortholog of human CYP3A4, a cytochrome involved in both endogenous and exogenous metabolisms of the liver and the intestine. CYP3A4 expression is regulated by several transcription factors, including the pregnane X receptor (PXR) and aryl hydrocarbon receptor (AhR), which are key mediators of xenobiotic responses and detoxification process. The tg(cyp3a65:GFP) zebrafish line was created using Tol2 transgenesis to visualize cyp3a65 responses to MDCs exposure. Embryos were exposed to sublethal concentrations of chemicals, followed by fluorescence imaging of the intestine, GFP quantification and data analysis. The bioassay was validated using zebrafish PXR and AhR agonists, confirming concentration-dependent induction of GFP expression correlated with cyp3a65 mRNA levels.
Subsequently, screening of 22 suspected MDCs from diverse chemical families (e.g bisphenols, biocides, pharmaceuticals) revealed varied effects : 14 induced, 4 inhibited, and 4 had no impact on GFP expression. The assay also highlighted the potential role of additional regulatory pathways (e.g glucocorticoid receptor) and demonstrated a good reproducibility across independent trials. EMERGE offers a sensitive and robust tool to screen the presence and/or the effects of MDCs complementing existing models and providing new informations on chemicals property to target the intestine. To confirm the relevance of the assay for human health assessment and further regulatory validation and

implementation, comparison of our results with MDCs effects on cyp3a4 through mammalian systems should be interesting. This study was funded by the H2020 OBERON project (grant agreement no. 825712).

1.07.P-Mo030 Applicability of the Fish Plasma Model to the Wide Pharmaceutical Landscape: Influence of Physico-chemical and Pharmacokinetic Parameters in Two Fish Species

Mirco Weil[1]*, Andrew Ross Brown*[2]*, Maciej Trznadel*[2]*, Alison Nimrod Perkins*[3]*, Anja Coors*[4] *and Charles Tyler*[2]*, (1)ECT Oekotoxikologie, Floersheim am Main, Germany, (2)Biosciences, University of Exeter, United Kingdom, (3)Eli Lilly and Company, Indianapolis, Indiana 46285, United States, United States, (4)ECT Oekotoxikologie, Germany*

The fish plasma model (FPM) is a theoretical model to predict the concentrations of pharmaceuticals in the blood plasma of exposed fish, based on the lipophilicity of the pharmaceutical. By comparing to effective pharmaceutical plasma concentrations in humans, the risk for unintended effects in exposed fish can be assessed without conducting animal testing. Within the research project PREMIER (Priorisation and Risk Evaluation of Medicines in the Environment), the FPM was challenged by application to substances that to date are underrepresented in FPM testing. Based on their physico-chemical and pharmacokinetic parameters and the margin between available chronic fish toxicity and the predicted API concentration in fish plasma, the following substances were selected: quetiapine hemifumerate (an anti-psychotic, cationic at pH 7), olaparib (an anti-neoplastic, not ionizable) and mycophenolic acid (an immunosuppressant, anionic at pH 7). All three compounds were investigated in adult male and female fathead minnow (Pimephales promelas) and sub-adult female rainbow trout (Oncorhynchus mykiss). The exposures were performed for 14 days in flow-through systems with the respective APIs dosed via water. Each exposure involved three test concentrations per substance and a control. The test concentrations were selected to avoid any possibly toxicological effects whilst seeking to maximize internal API concentrations for enabling analytical chemistry. Fish were sampled at days 10 and 14. For all three investigated compounds, analytical methods were developed, validated and applied to the various sampled matrices (water, blood plasma and body tissue for each fish species). All exposure experiments have been successfully completed. Lack of any substance-related apical effects in the exposed fish and the ability to quantify the target substances in most samples confirm the appropriateness of test concentrations. The evaluation of data is currently ongoing and will be presented at the SETAC meeting. Preliminary analyses indicate differences in plasma concentration between male and female fathead minnow as well as differences between the two fish species. Pharmacokinetic parameters underlying differences in API concentrations in blood plasma between test compounds and test species, as well as departures from API concentrations predicted by the FPM are being determined. Ongoing quantification of API metabolite concentrations in blood plasma is helping in this regard.

1.07.P-Mo031 Expanding the Applicability Domain Of Fish Cell Lines for Measuring the Bioaccumulation Potential of Zwitterionic Pollutants

Marco Enrique Franco*, Juliane Hollender and Kristin Schirmer, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Scientific and ethical constraints associated with in vivo bioaccumulation assessments with fish have triggered the development of animal alternatives, such as cell-based systems. Among these systems, fish cell lines have been previously highlighted as suitable models to estimate bioaccumulation parameters, such as bioconcentration factors (BCFs), by assessing chemical partitioning between e.g., culture medium and the intracellular compartment. While most of the existing data using this approach have been generated for neutral organic pollutants, previous studies have successfully employed fish cell lines to assess the bioaccumulation of a few anionic and cationic compounds. However, molecules with different structural properties (e.g., hydrophobic tail lengths) and that display both positive and negative charges (i.e., zwitterions) may undergo complex uptake and distribution patterns that influence their bioaccumulation dynamics. Therefore, to further explore the applicability domain of fish cell lines in conducting bioaccumulation studies for different chemical classes, we here explore the bioaccumulation potential of four zwitterionic surfactants: (Lauryldimethylammonio)acetate and the analogs N,N-Dimethyl(C10-C14)amine N-oxides, using rainbow trout (Oncorhynchus mykiss) cell lines. Cytotoxicity assays using the gill cell line RTgill-W1 indicated that these zwitterions do not compromise cell viability at concentrations lower than ~1.5 µM, allowing for bioaccumulation tests to be conducted at environmentally relevant levels (e.g., less than 0.5 µM). As bioaccumulation data for these chemicals is limited, the on-going work employing gill (RTgill-W1) and liver (RTL-W1) cell lines aims to provide important insight about their bioaccumulation potential, thus contributing important evidence to the environmental risk assessment of zwitterionic substances.

1.07.P-Mo032 In Vitro Hepatic Biotransformation Assays for Pesticides in Livestock: Opportunities and Limitations

*Marc Lamshoft, **Kristin Diercks** and Maria Hahn, Bayer AG, Germany*

To date, human safety testing for novel pesticide active substances involves a series of different in vivo studies in vertebrates, including livestock studies to assess residue levels in edible commodities. According to OECD Test Guidelines 503 and 505, at least one lactating ruminant and one laying poultry species must be examined. Mechanistic data on the metabolism and kinetics of pesticides in these species is, however, limited, but would be crucial for reliable early-phase predictions aiding the development process and species extrapolations, for example to other bird and mammal wildlife species in the context of in silico ecotoxicological risk assessment. In line with the ongoing efforts to replace, reduce and refine animal testing (3R principles), new approach methodologies (NAMs) could address these data gaps regarding livestock metabolism and kinetics. Metabolically relevant in vitro systems, like rainbow trout sub-cellular liver fractions or rat primary hepatocytes, have already gained regulatory acceptance for specific applications, including intrinsic clearance and comparative metabolism studies. This study aimed to validate an in vitro model for livestock metabolism by evaluating the capacities and limitations of sub-cellular liver fractions from the model species, goat (capra hircus) and hen (gallus gallus). For this purpose, two well-characterized pesticide active substances, labelled with radioactive 14C, were applied to the test systems following initial metabolic characterization. After incubation in a shaking water bath, supernatants were analyzed using high-performance liquid chromatography coupled with high-resolution mass spectrometry (HPLC-HRMS). Recoveries and mass balances were determined by liquid scintillation counting and selected samples subjected to radio-HPLC. The evaluation of the metabolic profiles, including metabolite identification, revealed that the majority of biotransformation products detected in vivo were also formed in vitro. The qualitative overlap was, however, substance-dependent, and the quantitative ratios of the metabolites did not match the in vivo situation in most of the cases. Consequently, while sub-cellular fractions are suitable for qualitative metabolite screening, they provide limited quantitative information on livestock metabolism. Future studies may address some of these limitations by using more physiologically relevant in vitro systems, such as primary hepatocytes.

1.07.P-Mo033 A Novel Multiplex Bioassay Technology for Detection of Emerging Contaminants in Water

***Tatiana Siniakova**[1], Maurice Henquet[1], Paul van den Brink[2] and Milou M. L. Dingemans[3], (1)Wageningen Plant Research, Business Unit Bioscience, Cluster Applied Plants Metabolomics, Netherlands, (2)Wageningen University, Aquatic Ecology and Water Quality Management group, Netherlands, (3)KWR Water Research Institute, Institute for Risk Assessment Sciences, Utrecht University, Netherlands*

Environmental pollutants, such as pharmaceuticals, personal care products, and pesticides, are a growing concern globally due to their potential adverse effects on aquatic ecosystems and human health. Water quality analyses to assess their risks are generally based on a combination of chemical and biological analyses. Yet, these methods are often resource-intensive and time-consuming in practical application. To implement effective measures for improving water quality and assess risks to humans and the environment, quick, comprehensive, and cost-effective methods are required. In this project we aim to develop and validate a novel multiplex biosensor technology. The technology, called receptomics, is based on a flow cell with a printed array of hundreds of receptors in a square centrimeter. which are expressed on a surface of living human cells (HEK293). The results are obtained based on light signals (fluorescence or luminescence). Upon binding of the pollutant (ligand) to the receptor, the receptor is activated, resulting in Ca²?-triggered luminescence or fluorescence. The emitted light signal is then captured by a microscope (www.receptomics.com). Since the assay is flowcell based it allows for a measurement every 5 minutes. Previous studies have demonstrated that human hormone receptors, such as human estrogen, androgen, nuclear pregnane X receptors, can bind water pollutants like pesticides, PFAS and hormones. These receptors will first be tested in the receptomics setup using pure ligands and at a later stage this approach can also be used to study complex water samples. The receptomics technology can support water managers and drinking water companies to continuously monitor water quality, ensure it remains at a high level by providing target compounds to mitigate. Moreover, the developed system can also be used as an early warning system and as a screening method in the development of risk-driven measurement programs in the (drinking) water sector. We will present our first results using this bioassay for water quality assessment.

1.07.P-Mo034 Endocrine Disruptive Potential of Chemical Mixtures From Settled Dust Samples Collected in Seven European Countries

*Jiri Novak[1], Lisa Melymuk[2] and **Klara Hilscherova**[1], (1)RECETOX, Masaryk University, Czech Republic,*

(2)Masaryk University, Brno, Czech Republic
Humans are continuously exposed to complex chemical mixtures, with indoor environments being a significant source due to prolonged occupancy, limited ventilation, and the presence of chemical sources. Many chemicals found indoors exhibit endocrine-disrupting properties, which may pose health risks. This study employed a battery of NAMs in vitro bioassays to assess the endocrine-disrupting potentials of complex chemical mixtures extracted from indoor settled dust samples sampled across households with small children in seven European countries (Czech Republic, Estonia, Italy, Netherlands, Portugal, Slovenia, and UK). The battery consisted of human cell-based reporter gene assays, namely AZ-AhR model for Aryl hydrocarbon receptor (AhR)-mediated effect, HeLa9903 for estrogenicity and anti-estrogenicity, MDA-kb2 for androgenicity and anti-androgenicity and PZ-TR for thyroid hormone receptor-mediated effects. The battery detected some endocrine-disrupting activities in most of the samples. However, the study revealed diverse effect patterns, the intensity of the effects, and the main modes of action of the chemical mixtures associated with settled dust among households from different parts of Europe. Namely antiestrogenic and AhR-mediated effects were frequently detected across the studied countries. To contextualize these findings, observed bioactivities will be compared with data from iceberg modeling obtained using available toxicity potencies based on available data from the target and non-target chemical analyses. The pervasive endocrine-disrupting activity in indoor environments and the challenges in identifying responsible pollutants highlight potential health risks associated with indoor exposure. This project received funding from the European Commission Horizon Europe, HADEA, research and innovation programme under grant agreement Project No 101057499 - INQUIRE.

1.07.P-Mo035 Systematic Evaluation of High-Throughput Toxicokinetic (HTTK) Model Predictions For The Terminal Elimination Half-Life (HLT) in Humans

***Alessandro Sangion*[1]*, Shenghong Wang*[1]*, James Armitage*[2] *and Jon A. Arnot*[3]*, (1)ARC Arnot Research and Consulting Inc, Canada, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ARC Arnot Research and Consulting AND University of Toronto, Canada*

Quantifying toxicokinetic (TK) processes is essential for chemical assessments. New Approach Methods (NAMs), such as in vitro-in vivo extrapolation (IVIVE) and high-throughput toxicokinetic (HTTK) modelling, are instrumental in generating TK data required for chemical priority setting, screening, and risk assessment. However, there is a critical need to systematically evaluate existing data and NAMs to build confidence in their application for scientific evaluations and decision-making. This includes defining the applicability domain (AD) and characterizing the uncertainty of IVIVE and HTTK models. One TK parameter required for IVIVE and other chemical assessment objectives is the whole-body total (terminal) elimination half-life (HLT), which relates directly to the terminal elimination rate constant (kT) and total clearance (CLT). Various HTTK models and their necessary input data are incorporated in the free online Exposure And Safety Estimation (EAS-E) Suite platform (www.eas-e-suite.com). These models can be used to calculate HLT and other TK parameters and include (i) multiple Quantitative Structure-Activity Relationship (HLT-QSAR) models that have been validated following OECD QSAR developmental guidance, ii) the EAS-E Suite one-compartment physiologically based biokinetic (1Co-PBK) model, which can be parameterized to simulate TK for different mammals, and iii) the 3 Compartment steady-state model developed by the US EPA and implemented in the "httk" R package. These different models were applied to more than 15,000 discrete organic chemicals to assess the AD of each model and to compare their predictions against (i) available measured in vivo HLT data from humans (n~1,000) and (ii) each other. There are strong positive correlations (e.g., r2 = 0.5 0.9) for the HLT predictions between the 1Co-PBK, HLT-QSAR and in vivo HLT data. There are weak positive correlations (e.g., r2 < 0.2) for the HLT predictions between EPA httk model and the other types of models and in vivo HLT data. However, most HLT predictions for the same chemical are within about an order of magnitude providing opportunities for consensus based modeling which considers uncertainty and assumptions in the various modelling approaches. The results provide some guidance for the application of IVIVE and HTTK models in chemical evaluations. Future research should seek to better understand why the models give highly divergent predictions for certain chemicals.

1.07.P-Mo036 The Parhyale hawaiensis Testing Platform as a Potential Eco-NAM

Gisela de Aragão Umbuzeiro[1]*,* ***Marina Tenório Botelho***[1]*, Amanda dos Santos*[2]*, Karin Baldauf*[1]*, Kaue Chinaglia*[1] *and Jose Luiz da Costa*[1]*, (1)Universidade Estadual de Campinas (UNICAMP), Brazil, (2)Universidade Estadual Paulista Julio Mesquita Filho, Brazil*

Eco New Approach Methodologies (ECO-NAMs) are of growing interest in the ecotoxicology community. Invertebrates are being accepted under REACH requirement as alternative methods, e.g., bioconcentration in the Hyalella azteca. As a step forward in reducing testing with vertebrate model, this work aims to introduce a testing platform using the Parhyale hawaiensis model organism. This amphipod has a circumtropical distribution and inhabits coastal areas. As it is epibenthic, it is possible to evaluate water and sediment, including via feeding. Its genome (3.6 giga bases) has been already sequenced and the animal is explored as a model in EVO-DEVO studies. Organisms collected from the field in 2010 have been maintained in the laboratory. They are fed with fish food 4 times a week, maintained at 26oC, 12h photoperiod, salinity of 30 g/L. Several substances were used as proof of concept and hazard characterization including benzo[a]pyrene, dyes from natural origin (emodin, alizarin, dermocybin, dermorubin) or synthetic (disperse and direct azo class), metals (Cd, Cu, Zn, Ag), 3,4-Dichloroaniline, pesticides (diflubenzuron), 6PPD-quinone and Ag based nanomaterials. In the laboratory, miniaturised assays were conducted to verify acute and chronic toxicity. Toxicokinetics studies performed in the lab using hemolymph internal doses were conducted for metals (Ag), dyes and PFAS. Differential gene expression was explored after exposure to metallic nanomaterials (Ag). PFAS bioconcentration factors, were determined in the hemolymph. Comet and micronuclei assays were established in the hemolymph. Sperm cell viability and comet assay were developed. For field studies a cage was constructed, and adults survived at least for 96h when placed in two sites with low levels of contamination. The concentrations of PFOS, Br- PFOS and PFOA, in the hemolymph of those organisms, were <LD. Studies in higher contaminated sites are being conducted. We believe that the Parhyale testing platform is a powerful tool for both lab and field testing. Protocols for immunotoxicity, behavior, and embryo abnormalities are being developed. Metabolic capacities studies are being conducted to improve toxicokinetic information. More substances should be tested in this platform to confirm its utility, but the results obtained so far are promising making P. hawaiensis an attractive potential NAM for future applications. The authors thank FAPESP (2023/10693-5), CNPq and CAPES code 001.

1.07.P-Mo037 Ecdysone Receptor Agonism in S2 cells for Insect-Specific In Vitro Assay Development

Rebeka Darmati[1]*, Bruno Campos*[2]*, Paul Carmichael*[3] *and Nico van den Brink*[1]*, (1)Wageningen University and Research, Netherlands, (2)Unilever, Bedford, United Kingdom, (3)Unilever, United Kingdom*

The traditional approaches to Environmental Risk Assessment (ERA) of chemicals are generally limited to in vivo exposure studies assessing only apical endpoints of a small number of representative model species serving as proxies for entire ecosystems. To better address the heightened challenges posed by the increasing variety of chemicals entering the environment - and to align with the evolving regulatory and ethical landscape towards reducing or eliminating animal testing - New Approach Methodologies (NAMs) introduce a more mechanistic framework for ERA. The operationalization of NAMs relies on the development and validation of in vitro and in silico approaches, including the use of Adverse Outcome Pathway (AOP) frameworks, which represent the foundational elements of mechanistic-based next-generation ERA. This project aims to develop an in vitro assay based on the Ecdysone Receptor (EcR) Agonism AOP using Drosophila melanogaster and its embryonic (S2) cell line. Ecdysone is a hormone responsible for development and metamorphosis of insects and is often targeted in pesticide development as a highly specific insecticide. However, EcRs are also found in a range of non-target species, such as pollinators, highlighting the need for a more protective ERA, and a deeper mechanistic understanding of the pathways involved. The first step towards this goal is characterising the molecular response to Ecdysone in the S2 cell line. In vivo, an Ecdysone pulse triggers a genetic cascade that initiates moulting, a process that requires both the presence and the subsequent removal of the hormone for full completion. Therefore, continuous exposure to an EcR agonist was incorporated into the AOP. This work investigates two exposure scenarios in vitro: the relevant (short-term) exposure scenario, imitating a pulse of ecdysone, and continuous exposure scenario. Results demonstrate the in vitro model can illustrate the initial key events of the EcR Agonism AOP as well as mimic the natural events in vivo. This project will be taken a step further delving into the adverse effects in vivo, including morphology of EcR agonism as well as the molecular events underlying the processes.

1.07.P-Mo038 High-Throughput Assessment of Pesticide Toxicity Using *C. elegans*: Impacts on Growth and Life Stage Development

Leah Sattler[1] *and Scott Glaberman*[2]*, (1)George Mason University, United States, (2)University of Birmingham, United Kingdom*

C. elegans is a versatile and efficient model for toxicity testing across diverse endpoints, leveraging its transparency, rapid growth, and compatibility with high-throughput formats. Its well-characterized genetic and signaling pathways, extensive mutant libraries, and CRISPR adaptability enable mechanistic studies with relevance to both human health and ecological systems. To assess the value of a high-throughput assay (HTA) system, we tested 60 pesticides, evaluating its potential to complement the current battery of human health and ecological models. The results highlight opportunities for enhancing predictive capabilities and broadening the applicability of toxicity screening frameworks. Partial funding for this project came from Bayer AG.

1.07.P-Mo039 New Approach Methodologies (NAMs) for Identifying Endocrine-Disruption Using the Model Organism *Caenorhabditis elegans*: The Case of Bisphenol A Alternatives

Sophie Limbeck[1]*, Sebastian Hoss*[2]*, Marina Ohlig*[1]*, Henner Hollert*[3] *and Martina Fenske*[1]*, (1)Federal Institute of Hydrology (BfG), Germany, (2)Ecossa, Germany, (3)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Many alternative compounds to bisphenol A (BPA) have already shown to be regrettable substitu-tions because they also demonstrate endocrine disrupting properties. The European Partnership for the Assessment of Risks from Chemicals (PARC) therefore uses the BPA alternatives as a case study to address shortcomings in regulatory approval processes, e.g. by developing New Approach Meth-odologies (NAM). To bridge the gap from in-vitro to suitable, whole organism testing approaches with a focus on endo-crine disruption, Caenorhabditis elegans emerges as a promising model. Its transparency, short lifespan (3 days @ 25°C), well-known genome, the comparably high degree of vertebrate gene ho-mology makes it a suitable organism for NAM development. We use C. elegans to combine the apical test endpoints growth, reproduction and behavior, with mo-lecular effects at gene transcription level. The focus is on endocrine effects and the elucidation of underlying mechanistic key events. BPA alternatives, such as Bisphenol E and AP, for which limited data exist, were tested in liquid medium either in 96 well plates with one worm per well and up to 10 worms per concentration or in cell culture flasks. As reference substance and to compare with litera-ture results, tests with BPA were also conducted. Around 1000 worms were pooled per sample to gather enough material for RNA extraction and subsequent long-read RNA Sequencing and qRT-PCR. First results on growth, reproduction and behavior (head trashes) showed effects only at concentra-tions above environmentally relevant levels. In contrast, molecular endpoints are more sensitive and instrumental for the identification of key biological pathways involved in endocrine disruption and other modes of action caused by BPA alternatives. Possible next steps in the development of C. elegans based NAMs may be to study metabolism changes or explore the use of fluorescent reporter lines for the key pathways identified. Overall, the potential of C. elegans as an alternative invertebrate animal model for testing endocrine disruptors is being evaluated.

1.07.P-Mo040 Automatization of a Sea Urchin Teratogenicity Test (STT) to Improve Marine Assessment of Chemicals and Mixtures

Noemie de Croze*, Cyril Sweetlove, Catherine Lacherez and Veronique Poulsen, L'Oreal Research & Innovation, France*

The marine environment faces increasing pressure from chemical pollutants originating from various sources, including industrial discharge, agricultural runoff, and pharmaceutical waste. Understanding the potential impact of these chemicals on marine organisms is crucial for ecosystem health. Traditional toxicity tests often focus on lethality, but sublethal effects on development can have significant long-term consequences on populations. Sea urchins offer a powerful model for evaluating the developmental toxicity of marine pollutants. Their external fertilization and transparent embryos allow easy observation of morphological abnormalities. Sea urchin embryo developmental tests, including larval development assays, and assessment of skeletal formation, can provide valuable insights into the mechanisms of toxicity [1]. Nonetheless the observation and measurement of these parameters under a microscope is time consuming, operator dependent and poorly compatible with industry needs for chemicals screening. Here we present an automated version of STT through automated image analysis. In a first step we evaluate the dynamic of the response obtained after the exposure to reference compound. Then we adress the interest of sea urchin teratogenicity test in a more global testing strategy by comparing the impact of different mixtures four marin organisms: bacteria (Microox assay), Diatoms (ISO 10253:2024), corals [2] and our automated sea urchin larval developmental test. Here we present an automated version STT. This methods allows to test up to 40 chemicals in parallel, to limit the operator subjectivity, and is compatible with hightrouput screening strategy for both raw materials and fsformulas. We propose to include this test in a global strategy to assess the potential impact of formulas on the marine environment and support the relevance of environmental claims.

1.07.P-Mo041 Developing High Throughput Metametabolomics in Freshwater Periphyton to Enhance Chemical Risk Assessment

Lin Zi[1]*, Melissa Eon*[1]*, Cedric Cassans*[2]*, Remy Cordazzo*[2]*, Chloe Bonnineau*[1] *and Nicolas Creusot*[1]*, (1)INRAE, EABX, France, (2)Bordeaux Metabolome, MetaboHUB, France*

The increasing chemical pollution of aquatic ecosystems presents a challenge in linking chemical exposure to impacts at higher biological levels. While various descriptors exist for individual and population-level effects, assessing impacts at the microbiome community level remains underdeveloped. Aquatic periphyton, a diverse microbial assemblage critical to ecosystem functions, is emerging as a model for studying ecological impacts on microbiomes. Among available techniques, metabolomics enables simultaneous characterization of exposure, associated effects and toxicity pathways, offering a promising approach to detect early, sensitive responses of microbiomes to chemical stress. However, applying metabolomics to aquatic microbial communities (i.e., metametabolomics) is still limited by its relatively low throughput for screening. Therefore, this work aims to develop a high throughput workflow with miniaturized exposure setups, automated sample preparation, data acquisition, and data analysis to enhance chemical risk assessment in aquatic ecosystems. Periphyton samples (0.5 10 mg dry weight) were analysed to determine the minimum quantity for accurate metabolomics profiling. Our results showed no marked differences between 1 to 10 mg, while 0.5 mg displayed distinct differences from other quantities. Metabolite intensities were higher for 0.5 mg and 1 mg compared to 5 mg and 10 mg, likely due to reduced matrix effects. Therefore, 1 mg was considered as an optimal balance, providing sufficient intensity and comparable results across different matrix quantities. By testing different microplates and glass discs (48, 24 and 12-well) for periphyton colonization, we found that different size of discs led to similar periphyton quantity after 14 days, averaging around 1 mg. Thus, 48-well size discs and microplates will be further used for the exposure setup. Automated extraction is under development. A standardized data analysis pipeline will be developed to determine community metabolism sensitivity threshold based on aggregated metametabolome dose response (DRomics) and metametabolome annotation. This workflow will soon be applied to screen pesticides and pharmaceuticals, addressing regulatory gaps in evaluating chemical toxicity on microbial communities and their impact on aquatic ecosystem functions.

1.07.P-Mo042 Application of Electric Cell-Substrate Impedance Sensing (ECIS) Technology in the Ecotoxicological Evaluation of Industrial and Wastewater Effluents

***Shu-Ju Chuang**, Chun-Yu Kuo, Siao-Yi Jin, Chih-Hsien Tsai and His-Nan Yang, National Environmental Research Academy, Ministry of Environment, Executive yuan, Taiwan*

This study utilizes Electric Cell-Substrate Impedance Sensing (ECIS) to evaluate the ecotoxicological impacts of wastewater effluents. Samples were collected from industrial raw influents, treated effluents, influents and effluents from wastewater treatment plants (WWTPs). Cytotoxicity assays were conducted using human HepG2 and rainbow trout RTgill-W1 cell lines, alongside acute aquatic toxicity tests using fish and daphnia. The biological response data were further integrated with water pollutant analyses to evaluate the correlation between toxic substances and biological responses. Correlation analysis was applied to determine the toxic units (TUa) derived from cell-based assays and acute aquatic toxicity tests. Results demonstrated a significant correlation between RTgill-W1 cell responses and acute fish toxicity outcomes, highlighting the potential of the RTgill-W1 cell line as a promising in vitro alternative to acute fish toxicity test. Furthermore, RTgill-W1 cell line in ECIS system exhibited higher sensitivity to pollutants compared to HepG2 cell line, indicating its superior applicability for detecting waterborne toxicants. We further compared bioassay results with pollutant analyses, revealing correlations between toxicity responses and certain water pollutants (e.g. ammonia). Moreover, daphnia acute toxicity demonstrated a correlation with other water pollutants, including heavy metals, indicating species-specific sensitivity to different pollutants. The variability observed between bioassays highlights the importance of a multi-species approach for comprehensive ecotoxicity evaluation, as each organism may respond differently to specific contaminants based on their unique physiological and metabolic pathways. These findings further underscore the feasibility of real-time biological monitoring systems for detecting water pollution using live-cell systems. Traditional water quality monitoring primarily relies on physico-chemical parameters, which may fail to capture the dynamic interactions between pollutants and living organisms, such as synergistic, additive, or antagonistic toxic effects. Incorporating biological endpoints, such as cell-based toxicity data, into water quality surveillance systems can fill this gap, offering a more holistic, real-time assessment of water quality and environmental health.

1.07.P-Mo043 New Approach Methodologies To Evaluate The Toxicity Of Anticoagulant Rodenticides In Target And Non-Target Organisms

*Noelia Marin-Prat, Azucena Bermejo-Nogales and **David Hernandez-Moreno**, Instituto Nacional de Investigacion y Tecnolog a Agraria y Alimentaria (INIA-CSIC), Spain*

Anticoagulant rodenticides (ARs) are widely used to control rodent populations. Nevertheless, there is a potential risk for the environment and non-target organism derived from their use. The aim of the present study, as part of the PECAURA project, was to stablish a protocol to be further applied to alternative substances. Comparisons among data from new approach methodologies (NAMs) and in vivo studies in model species were perfomed. This allowed to evaluate the usefulness of NAMs to check the toxicity of six ARs (brodifacoum, bromadiolone, chlorophacinone, coumatetralyl, difenacoum and warfarin). In vivo data (LC/D50) was collected from literature for a target, Mus musculus, and non-target species, Oncorhynchus mykiss and Daphnia magna. Cytotoxicity (EC50) was evaluated checking for mithocondrial, plasma membrane or lysosomal activity effects in murine (Hepa1-6) and rainbow trout (RTH149) hepatoma cell lines after exposure to a range of concentrations (0.78-100 mg/L) for 24, 48 and 72 h. In vitro and in vivo data were categorized according to their toxicity, following the Regulation (CE) nº 1272/2008. Computational biology methodology was applied as a predictive tool of binding affinities of the three species vitamin K epoxide reductase (VKORC1) and ARs (AutoDockVina, PyRx 0.9.8 package). For M. musculus, in vitro and in vivo toxicity data, together with the docking analysis, suggested that the ARs leading to toxicity in cells and animals had a higher binding affinity (BA) to the VKORC1. This was observed after any time of exposure in Hepa1-6. For fish, in vivo and in vitro data did not follow the same pattern. Indeed, bromadiolone, coumatetralyl and warfarin did not show cytotoxicity (24h), but they were toxic to animals. However, bromadiolone turned into cytotoxic after 48 h. In this case, coumatetralyl and warfarin showed the lowest BA, being also the less toxic ARs in vivo and in vitro. Even when the BA pattern is similar for both species, values are lower for O. mykiss. In this sense, the higher toxicity showed by both molecules in fish denotes their higher sensitivity. For D. magna, it was also possible to stablish an association between in vivo and in silico data for all ARs. The differences between the species should be considered for ecological risk assessment, and in silico data should be interpreted case-by-case. Funding: Project TED2021-131186B-I00 supported by MCIN/AEI/10.13039/501100011033 and the EU NextGenerationEU /PRTR.

1.07.P-Mo044 An Integrated Testing Strategy (ITS) for Acute Fish Toxicity: Fish Embryo and RTgill-W1 Cell Line with Threshold Approach
Tzu-Ning Li*, Zi-Yu Chen, Yun-Jui Chih, Yen-Yu Chen, Ching-Ju Hung and Ying-Jan Wang, Department of Environmental and Occupational Health, College of Medicine, National Cheng Kung University, Taiwan (Greater China)*
Acute fish toxicity (AFT) tests typically use mortality as the endpoint to assess the toxicity of environmental pollutants. However, current regulatory policies require a large number of fish for testing. In recent years, in vitro alternative methods, such as fish embryo toxicity test (FET) and fish cell line toxicity (FCT) tests, have been developed. However, no single alternative test can fully replace traditional animal testing. To address this, an ITS has been proposed to combine various alternative methods effectively, supporting regulatory decision-making. These alternative methods have demonstrated a certain level of predictive ability. Therefore, we aim to establish an ITS for predicting AFT, coupled with a threshold concentration (TC) method, to reduce the need for fish in testing. We collected data from the literature to determine the correlation between alternative tests and fish tests, as well as the feasibility of using ITS. Additionally, we selected common heavy metals and organic pollutants found in wastewater to perform alternative tests for external validation of ITS. The results showed that NAMs have significant correlation with AFT test. Combining QSAR Toolbox and TC methods aids in preliminary toxicity screening and reduces the likelihood of false negatives in predictions. The predictive accuracy of ITS for AFT reaches 74-90%. Additional wastewater-related substances were selected for external validation of ITS, achieving a predictive accuracy of 66.7-88.9%. We developed four ITS using NAMs to predict fish toxicity. All the strategies demonstrated a high predictive power. Users or institutions can select from four ITS, each optimized for flexibility, animal welfare, or sensitivity, to predict fish toxicity.

1.07.P-Mo045 In Silico Prioritization of Water Micropollutants for Quantification of Their Contribution to the Aryl Hydrocarbon Receptor (AhR) Mediated Toxicity
Katar na Lorinczova*, Jiri Komprda, Zuzana Tousova, Marie Smutna, Klara Hilscherova and Klara Komprdova, RECETOX, Masaryk University, Czech Republic*
The complexity of chemical mixtures in the environment challenges their in-depth risk assessment due to the diverse list of compounds in use and the lack of toxicity data, as they can induce toxic effects through multiple biological mechanisms. Quantifying the contribution of individual compounds to biological effects requires experimental data to calculate their toxic potency, which is often limited or not available. To address this issue, in silico models can be used to fill in data gaps for compounds with unknown toxic potency. In this study, a quantitative structure-activity relationship (QSAR) model was developed and applied to predict the aryl hydrocarbon receptor (AhR) activity of compounds detected in a monitoring study along the Danube River and to prioritize them for experimental testing. The QSAR model developed in this study was built on the ToxCast data and the prioritized compounds with predicted AhR activity were experimentally validated by the CAFLUX bioassay. The combination of ToxCast data (measured AhR activity) and QSAR model predictions (predicted AhR activity) was used to calculate site-specific AhR mediated activity, which was compared to the overall AhR activity detected in bioassay at sampling sites. Experimental testing confirmed the ability of the QSAR model to identify compounds with high

AhR activity and to prioritize the most relevant suspect effect drivers. Nevertheless, the QSAR model also predicted a high number of AhR inactives as false positives (specifically, as compounds with low AhR activity). Thus, when calculating AhR mediated activity, it is essential to critically assess QSAR prediction results in terms of applicability domain and consider reliability of the predictions according to a defined prioritization scale. The QSAR model contributed to explaining a significant portion of the unexplained AhR activity in the Danube River samples and facilitated the identification of novel environmentally relevant micropollutants accountable for this endpoint. The results also emphasize that despite an extensive list of target compounds and modelling of their activity, part of the AhR effect remains unexplained and the causative compounds unknown. Despite the inherent limitations, framework of this approach has proven to be applicable for priority screening of compounds and quantifying their contribution to detected biological effects in environmental monitoring studies. The work was supported by the European Union s Horizon Europe programme, grant agreement no.101057014 (PARC).

1.07.P-Mo046 Machine Learning Ecotoxicity Assessment of Pharmaceuticals

*Laura Candido[1], Rui G. Morgado, **Maria D Pavlaki** and Tiago Galvio, University of Aveiro, Portugal*

In recent years, the massive emergence of new chemical compounds for various uses, such as industrial, medicinal, etc., has been observed, accompanied by the need for ecotoxicological studies and risk analysis on these compounds. To this end, in vivo approaches are generally used with living organisms, which raise major ethical concerns and experimental difficulties, such as time and costs. As an alternative, New Approach Methodologies (NAMs), more specifically, in vitro and in silico approaches, emerge using biological models isolated in controlled environments, and computational models, respectively. Despite still being underexplored, in silico approaches have become increasingly relevant as potential alternatives to address several limitations of animal testing methods, taking advantage of the large amount of data already available and of the capacity of specific algorithms to learn from data to increase the potential for predicting ecotoxicity and risk assessment. The present work aims to develop machine learning models to predict the toxicity of pharmaceutical compounds in order to reduce the use of in vivo tests, in addition to reducing the time and cost of ecotoxicological analyses. To this end, data were collected from the ADORE database to create models based on the ML algorithms for classifying the acute toxicity (LC50) of pharmaceutical products, using both cheminformatics and biomolecular descriptors as input variables. The preliminary results highlight the importance of the study and the potential of these models to reduce animal testing, serve as valuable auxiliary tools and, in the future, completely replace in vivo methodologies when integrated with in vitro strategies. Further validation and refinement of these models will be crucial to maximize their accuracy and applicability, paving the way for a more sustainable and ethical scientific approach.

1.07.P-Mo047 The Applicability Domain Concept, A Must for all NAMs: Focus on Machine Learning QSAR models

***Floriane Larras**, Emel Ay-Albrecht and Paul Thomas, KREATiS, France*

New Approach Methodologies (NAMs) play a crucial role in the era of the 3Rs (Replacement, Reduction, and Refinement) to reduce or replace animal testing. Among the numerous approaches encompassed by the term NAMs, in silico methods, notably Quantitative Structure-Activity Relationship (QSAR) models stand out from the crowd in terms of their significant potential. These approaches are not only less expensive than experiments but also offer rapid results, often with the added benefit of providing mechanistic insights. To gain confidence in QSAR models and their predictions, criteria were also established by the OECD in 2014 and more fully in 2023 with the advent of the QSAR Assessment Framework (QAF). One of the most important aspects to consider when dealing with prediction reliability is the third OECD principle of the defined applicability domain (AD), which limits the response and chemical space covered by the model. This work is an overview of the existing AD assessment method of QSARs and aims to discuss pros and cons of current approaches. To predict ecotoxicity endpoints, in silico models ranging from simple linear regression to more sophisticated models like artificial neural networks can be used. Once the model is developed, there are different ways to characterize the chemical space depending on the chosen modelling approach. These methods are various and present different levels of complexity such as range-based approaches, geometric methods, distance-based approaches, and probability density methods. While these techniques are effective for simpler models, they may lack robustness for more complex applications, as they often focus exclusively on the model chemical space. It is also essential to consider the response space, ensuring that the compound is within the range of chemical space but also that the prediction aligns well with expected outcomes. Advanced AD methods integrate both chemical and response spaces, providing a more comprehensive and accurate model applicability. Numerous advanced techniques address these complexities, enhancing AD accuracy and ensuring that predictions are reliable across diverse scenarios. The examples presented in this presentation will focus on QSAR approaches. However, since the concept of the AD is relevant to both experimental and computational methods, this work aims to serve as a starting point for broader discussions across all NAMs.

1.07.P-Mo048 Computational Predictions of the Binding Activity of Endocrine Disrupting Compounds to the Estrogen Receptor Alpha: Evaluation of the Applicability of Molecular Docking and Simulations

Robert Franz Wild*, Anders Goksoyr, Odd Andre Karlsen and Nathalie Reuter, University of Bergen, Norway*

Molecular docking, a well-established computational method to aid drug discovery, has found widespread application in endocrinological applications to study the interaction between environmental pollutants and the estrogen receptor alpha (ERa). By screening large chemical spaces and identifying substances of high concern for further testing using in-vivo or in-vitro assays, molecular docking is often used to improve the effectiveness and sustainability of chemical risk assessment. However, the scoring functions used in molecular docking to evaluate binding poses disregard well-known effects associated with ligand binding. Moreover, they provide a coarse approximation of binding affinity while commonly used in-vitro assays report the transcriptional activity induced by ligand binding. This discrepancy necessitates a critical assessment of the capabilities of molecular docking to provide a prediction of binding activity and compare different ligands in a toxicological context. To this end we used AutoDock Vina 1.2.5 to dock known or suspected endocrine disrupting compounds from various classes including alkylphenols, phytoestrogens, parabens, bisphenols and perfluorinated compounds into the ligand binding pocket of the estrogen receptor alpha. Utilizing the relative abundance of structural information on the ERa, we calibrated the docking procedure, with results showing significant improvements in pose prediction when allowing for sidechain flexibility within the binding pocket. The final binding poses predicted through our docking approach show good agreement with known experimental poses, demonstrating the applicability of scoring function to study receptor-pollutant interactions. Additionally, the docking scores determined using VinaXB were compared to available experimental measures from cell-based transactivation assays and cell-free receptor binding measurements, as well to more rigorous relative binding free energy calculations using an alchemical route. However, our results show low correlation between docking scores and receptor activity, advising against the use of molecular docking to rank compounds based on the predicted potency.

1.07.P-Mo049 Integration of In Vitro Mechanism Data from ToxCast/Tox21 Bioassays and In Vivo Toxicity Data into Adverse Outcome Pathway (AOP) Network to Develop Explainable AI Models

Donghyeon Kim*, Siyeol Ahn and Jinhee Choi, University of Seoul, Korea, Republic of*

Artificial intelligence (AI) models offer immense potential for evaluating the toxicity of a wide range of environmental chemicals. However, many existing toxicity prediction models function as 'black boxes,' making them difficult for toxicologists to interpret and limiting their acceptance in regulatory contexts. The complexity of mechanisms leading to apical toxicity further complicates the reliability of these models, as results can lack supporting process evidence and, in the worst cases, may be coincidental. The adverse outcome pathway (AOP) framework offers a promising solution by connecting molecular toxicity endpoints to apical outcomes. To address these challenges, this study focused on creating explainable AI models for toxicity prediction using ToxCast/Tox21 data within the AOP framework. The first step involved identifying AOPs relevant to regulatory endpoints. Next, in vitro bioactivity data from ToxCast/Tox21 and in vivo toxicity data aligned with OECD test guidelines from eChemPortalDB were integrated into AOPs. Machine learning models were then developed to predict toxicity at both mechanistic and regulatory endpoints, achieving strong performance with AUC-ROC values ranging from 0.56 to 0.88. A proof-of-concept case study using reference chemicals further demonstrated that these models effectively screened toxic chemicals with high sensitivity. This research establishes a foundational approach for developing explainable machine learning models using AOPs, addressing a critical limitation in the adoption of AI models for chemical risk assessment. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through 'Core Technology Development Project for Environmental Diseases Prevention and Management', funded by Korea Ministry of Environment (MOE) (2021003310005).

1.07.P-Mo050 Calibration of Chemical Agnostic Quantitative Adverse Outcome Pathways Based on Multiple Chemical Data using Hierarchical Modelling

Zheng Zhou[1] *and Ullrika Sahlin*[2]*, (1)Lund University, Sweden, (2)Lund University, Sweden*

The Adverse Outcome Pathway (AOP) framework facilitates evidence extrapolation from animal and non-animal testing for inferring adverse outcomes, with quantitative AOPs (qAOPs) supporting next-generation risk assessments. While chemical agnosticity is a fundamental of AOPs, many current qAOP studies faces challenges in accounting for cross-chemical heterogeneity, particularly in response-response relationships where chemical-specific patterns need to be separated from chemical-agnostic pathways. We propose a hierarchical model that explicitly separates chemical-specific from chemical-agnostic patterns in response-response relationships. The method implements chemical-specific parameters sampled from an overarching distribution representing chemical-agnostic patterns, allowing the model to capture varying levels of heterogeneity in multi-chemical datasets. Here, model parameters are inferred in a Bayesian framework, where parameter uncertainty is quantified by the resulting posterior probability distribution. Model evaluation employs Pareto-smoothed leave-one-out cross-validation and stacking for model averaging, with performance assessment through both simulated and real in vitro data from the Risk-Hunt3R project. The proposed calibration approach aims to enhance the generalizability of qAOPs while maintaining their chemical-agnostic nature, potentially supporting more robust next-generation risk assessments. Results from simulation studies showed that our hierarchical model performed better than a model without a hierarchical structure on the response-response relationship, especially when the heterogeneity is high. A case study with real data is presented to demonstrate the model's generalizability in realistic scenarios for derivation of points of departure. The RISK-HUNT3R project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 964537. The opinions expressed in this document reflect only the author's view. The European Commission is not responsible for any use that may be made of the information it contains.

1.07.P-Mo051 The Development and Use of an Adverse Outcome Pathway (AOP)-Informed Cellular Oxidative Stress NAM for Hazard Screening

Mona Connolly[1], Elena Garcia Sanchez[2], Maria Jimenez Lara[1], Stefany Mendoza Burgos[3], Gerardo Pulido-Reyes[3] and ***José María Navas****[1], (1)National Institute for Agricultural and Food Research and Technology (INIA), CSIC, Spain, (2)Universidad de Alcala (UAH) Madrid, Spain, (3)Universidad Autonoma de Madrid, Spain*

Oxidative stress has been described as a prominent mechanism of xenobiotic toxicity and a common denominator in many disease states yet a standalone test does not exist. The conceptual adverse outcome pathway (AOP) framework allows us to organise the key processes involved and monitor them at each level of biological organisation. Thus, a likely series of key events (KE) that leads to oxidative stress and ultimately oxidative cell death can be proposed and tested for. Oxidative stress can occur in any species from bacteria to humans, therefore, as a biomarker it has a wide domain of applicability across species. In this investigation we have used the rainbow trout fish species, Oncorhynchus mykiss, as a test model and the RTgill W1 and RTL W1 cells lines to develop such an oxidative stress AOP-informed testing strategy, focusing on monitoring upstream and downstream key events involved in its processes as well as the cells redox status. These events included increases in cellular reactive oxygen species (ROS) levels (KE 1940) and increased lipid peroxidation (KE 1445). The cellular redox status at different exposure times was characterised by monitoring levels of oxidation of glutathione (KE 926). The information from this multi-parametric NAM was integrated and in this way the intensity of an oxidative insult could be characterised into low, intermediate or high intensity. Such an approach can be used to help interpret data from multiple assays, for hazard ranking or indeed to group substances based on their oxidative stress potential. Property-effect relationships can then be established for these different reactivity groups to identify the descriptors that can be linked to such reactivity and used in a predictive toxicology space. This developed NAM was applied when testing the hazard of multi-component mixed metal oxide perovskites. As a benchmark material a CuO nanomaterial was included, for which there is large evidence of oxidative stress association. To provide in vivo anchorage levels of these key events, biomarkers were also assessed in tissues of perovskite exposed fish. Data generated from such cellular based NAMs can be used in weight of evidence (WoE) approaches for hazard assessment and for hazard screening in safe and sustainable by design (SSbD) strategies. HARMLESS grant agreement No. 953183 and General protocol of actions between MITECO and INIA, CSIC for carrying out activities related to substances and chemical mixtures.

1.07.P-Mo052 To What Extent Do Fish Toxicity Studies Drive Acute and Chronic Aquatic Hazard Classification?

Marta Sobanska, ***Anna-Maija Nyman****, Pia Talja, Shoko Furuno, Jani Honkanen, Konstantinos Prevedouros, Flavio Marchetto, Marco Mattiuzzo and Simon Uphill, European Chemicals Agency, Finland*

The scheme for classification and labelling of substances and mixtures for aquatic hazards, as defined in Europe under the CLP Regulation (EC) No 1272/2008, relies on identification of the intrinsic hazards posed by chemicals to the environment. Currently, the classification for aquatic hazards focuses solely on organisms that live in the water column, more precisely on the results of aquatic toxicity tests performed on organisms belonging to the three trophic levels (fish, aquatic invertebrates and algae or other aquatic plants) that are considered as surrogate for all aquatic organisms. Using in vivo fish data for classification purposes raises animal welfare concerns. Therefore, in the light of the ongoing discussions on replacing in vivo vertebrate data within various regulatory frameworks for example through the use of New Approach Methods (NAMs), this study analyses the role and impact of in vivo fish toxicity studies on the harmonised classification and labelling for aquatic hazards in the EU. In this study we have compared the most sensitive study results indicated by the Risk Assessment Committee (RAC) for all three trophic levels per substance, examining whether the substances exhibited similar toxicity across different trophic levels. We investigated whether the same classification would likely have been assigned in the absence of fish data. The study covers formal proposals for Harmonised Classification and Labelling (CLH) and RAC opinions proposing CLH at EU level, published on the ECHA website between July 2009 and December 2023. The final dataset resulted in 281 unique substances whose data led to a classification for aquatic hazards, with data considered scientifically robust and GLP-compliant. The current analysis shows that all three trophic levels play an important role in overall environmental hazard classification. The RAC derived aquatic hazard classification for both acute and chronic hazards was based on fish data (as most sensitive species) in 20% of cases. When comparing the sensitivity difference between three trophic levels, for over half of those cases, the classification would be less stringent if fish data were unavailable. The outcome of this study contributes to ongoing discussions on acute fish IATA and introduction of NAMs. To ensure an adequate level of environmental protection, it is important to investigate how future NAMs could detect, as a minimum, those substances that are most toxic to fish.

1.07.P-Mo053 Development of Acute to Chronic Ratios (ACRs) Applicable to Surfactant Ecotoxicity

***James Firman**[1], Baile Xu[2], Homa Basiri[1], Mark Cronin[1], Geoff Hodges[2], Jayne Roberts[2], Simran Sandhu[2] and Andrea Gredelj[2], (1)Liverpool John Moores University, United Kingdom, (2)Unilever, United Kingdom*

Surfactants find extensive use within a variety of settings, both industrial and domestic. Although typically removed in an efficient manner during the process of wastewater treatment, these substances nevertheless remain liable to enter into the environment. Whilst their safety within such contexts has been widely investigated, the presence of data gaps particularly as relates to chronic toxicity continues to form an obstacle towards meeting regulatory standard information requirements. A potential solution to this issue lies within the leveraging of existing toxicity data, in order to develop acute-chronic ratios (ACRs). In essence, the ACR represents an empirically-derived ratio between corresponding acute and chronic ecotoxicological endpoints (within defined chemical groups), applicable for the estimation of chronic potency in instances where only acute values are otherwise available. Previously, this approach has demonstrated robustness within certain (non-surfactant) substance classes possessing non-specific mechanisms of action. However, surfactants hold several unique structural and physicochemical characteristics. Accordingly, the aim of this investigation was to examine the suitability of ACR methods for application towards such compounds. Details of relevant surfactants, such as Chemical Abstract Service (CAS) number, name and molecular structure (as available), were traced. Using these identifiers, historical, publicly-accessible toxicity data concerning fish, daphnid and algal species were sought, recorded and curated, in order that robust toxicity outcomes acute and chronic might be identified. Several hundred surfactants, spanning anionic, cationic, zwitterionic and non-ionic classes (including mixtures), were ultimately represented. From this pool, ACRs appropriate to each trophic level were determined. Comparison relative to existing ratios revealed that acute-chronic relationships within these chemicals are broadly equivalent to those noted across other narcotic (non-specific acting) substances. As such, evidence for the apparent applicability of the approach within a wider series of risk assessment contexts is provided.

1.07.P-Mo054 Surfactant Endpoint Read-Across Strategies under REACH: A Review of and Guidance for Future Submissions

***Geoff Hodges**[1], Barbara Schmitt[2], Jay Dawick[3], Nicole Frijus-Plessen[4], Erik Houthoff[5], Lauren Kavanagh[3], Joanna Klapacz[6], Diederik Schowanek[7], Quan Shi[8], Mengying Zhang[7] and Jayne Roberts[1], (1)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom, (2)Evonik Operations, Germany, (3)Innospec Limited, United Kingdom, (4)Sasol Germany, Germany, (5)Nouryon, Netherlands, (6)The Dow Chemical Company, United States, (7)Procter & Gamble Brussels Innovation Centre, Belgium, (8)Shell Global Solutions International BV, Netherlands*

One of the common approaches for addressing standard information requirement (SIR) datagaps in registration dossiers under REACH is the use of read-across or grouping argumentation where information from one or a number of analogous (or source) substance(s) is used to support or predict missing endpoint data for a target substance. Methods to support read-across arguments are outlined in the Read Across

Assessment Framework (RAAF) which defines six scenarios. Each scenario is associated with a set of pre-defined Assessment Elements (AEs) which cover the essential scientific aspects needed for that scenario to be acceptable. Most high volume surfactant dossiers were submitted before the RAAF guidance was developed suggesting that it may be possible to develop other acceptable scenarios relevant for surfactants which are not presently listed in the RAAF. Many surfactants grouped into REACH categories share identical/common hydrophilic head-groups, and differ by variations in alkyl chain length/type (linear/branched/unsaturated). Here we provide outputs of a review of current read-across and category/grouping approaches for surfactants focused on the ongoing discussions between ECHA and the relevant REACH consortia, to assess the key scientific limitations covering Human Health and Environmental hazard endpoints. Read across approaches for dossiers which were submitted pre-RAAF' were allocated to scenarios synonymous with those defined in the RAAF. The outcome demonstrates a low rate of success of acceptance of the proposed approaches. Key reasons for lack of acceptance included (although not limited to) lack of test item composition, toxicity similarity arguments or data. The aim is to leverage learnings from surfactant dossier compliance check (CCH) decisions and evaluations by ECHA to provide recommendations for appropriate grouping and read-across approaches for surfactant dossiers which have yet to be reviewed.

1.07.P-Mo055 Aquatic Toxicity Profile of Neurotoxic Substances

Pia Talja[1]*, Marco Evangelista*[2]*, Anna-Maija Nyman*[1]*, Shoko Furuno*[1]*, Ulla Simanainen*[1]*, Kai Craenen*[1] *and Marta Sobanska*[1]*, (1)European Chemicals Agency, Finland, (2)European Chemicals Agency and Department of Theoretical and Applied Sciences, University of Insubria (current), Italy*

The classification hazardous to the aquatic environment under CLP regulation relies on data from fish, and generation of such data raises animal welfare concerns. The Fish Embryo Acute Toxicity (FET) test is a potential alternative to acute fish toxicity study, but neurotoxic substances are considered out of the applicability domain of the method. The aim of this study was to analyse the aquatic toxicity profile of neurotoxic substances to assess whether acute studies on invertebrates would reveal similar toxicity as fish and thus cover the acute aquatic hazards classification of neurotoxicants. Acute data on the aquatic toxicity was collected from Harmonised Classification and Labelling (CLH) reports and ECHA Chemicals Database for 113 substances, which are considered to be neurotoxicants due to the identification of the nervous system as target organ in their harmonised STOT SE and/or STOT RE classifications, or because they induced narcotic effects. The lowest toxicity value of each trophic level was selected to assess which aquatic toxicity test would result in the most stringent classification. If the difference between the lowest toxicity values between the different trophic levels was >10-fold, it was considered that it could lead to difference in classification. Reliable acute toxicity data on fish and invertebrates was available on 50 substances. Comparing the available data on fish and invertebrates, for 26 neurotoxicants the tests with fish resulted in the lowest toxicity value. However, when assessing the impact on the classification, there was a >10-fold difference only for one neurotoxicant. Based on these results, we observed that the acute invertebrate study could mostly cover acute aquatic hazards of substances with neurotoxic properties. For substances where fish was the most sensitive species, the difference between EC/LC50 for fish and invertebrates would not result in a different hazard classification. The findings of this study support the application of FET as an alternative to acute fish studies. For neurotoxic substances falling out of the scope of the FET test, it is likely that the data on invertebrates would result in the same classification. However, this is based on a limited dataset and further research is needed to confirm this outcome. Also, more research is required to determine if FET is suitable for other substances and if it covers acute fish toxicity when fish studies result in the most stringent classification.

1.07.P-Mo056 Use of Read-Across to Fulfil REACH Information Requirements – A Case Study with A Fragrance Ingredient

Georg Kreutzer[1]*, Heike Laue*[2]*, Gordon Sanders*[3] *and Aurelia Lapczynski*[4]*, (1)RAPS, Givaudan, Switzerland, (2)Givaudan, Switzerland, (3)Product Safety Sciences, Givaudan, Switzerland, (4)Research Institute for Fragrance Materials, United States*

The REACH Regulation promotes and supports the 3Rs principles (reduction, refinement, replacement) with obligations to reduce animal use via data sharing, read-across and the implementation of alternative methods. For chemicals manufactured or imported at ? 100 t/y, or already at lower tonnage bands for sparingly water soluble chemicals, information on chronic aquatic toxicity is required, even when safe use can be demonstrated based on PNECs derived from acute aquatic toxicity data, applying high safety factors and con-servative exposure scenarios. If new fish chronic data are needed, a Fish Early-life Stage Toxicity Test according to OECD 210 is the default option. The number of fish used in these studies is approximately 700-850 per study. In this poster, we present how read-across from dodecanal and 2,6,10-trimethylundec-9-enal (source substances) to 2-methylundecanal (target substance) has been used for the

REACH registration to replace the need for such an in vivo study. The case study demonstrates: Practical challenges in conducting the daphnia and fish chronic studies for the two difficult-to-test source substances (volatile, low water solubility, degradation of test item due to oxidation, presence of degradation products, etc.). Comparison of physico-chemical properties and environmental endpoints. Read-across justification based on similar carbon chain length and same mode of action (e.g. ECOSAR class, mono aldehyde) for target substance and source substances. Impact of new data generation on Predicted No Effect concentrations (PNEC), the Chemical Safety Report (CSR) and environmental classification and labelling of source and target substances. Based on the above, conducting an OECD 210 study on the target substance was not considered necessary, and was therefore waived. The application of animal-alternative methods to the above REACH registered substance covered by the above case study save in excess of 800 fish, and demonstrates that alternative, yet conservative, evaluation approaches can be adopted to fill higher-tier hazard end-points without compromising safe use.

1.07.P-Mo057 Application of NAMs and Refinement Strategies in the Petrochemical Industry

Maria Blanco-Rubio*, Erin Maloney, David MV Saunders and Mathijs Smit, Shell Global Solutions, Netherlands*

To comply with global regulations and properly assess environmental risk, petrochemical companies develop hazard information for products, substances, and wastewater effluents. New approach methodologies (NAMs), including in silico and in vitro tools, together with refinement strategies for existing in vivo tests, are being explored to generate this hazard data while limiting animal testing. This poster demonstrates the different areas where NAMs and refinement strategies are being used in the petrochemical sector and the challenges associated with their application. In silico tools (including QSARs; e.g., EPISuite or PETROTOX), prioritization approaches and read-across strategies (e.g., hydrocarbon block methodologies) are often used to generate petrochemical hazard data while avoiding animal testing. However, the potential applicability of in vitro NAMs for petrochemical hazard data generation is still being assessed. Current projects include exploring the applicability of the OECD 249 fish cell line test to predict the toxicity of consumer-use petrochemicals (solvents, surfactants), and the use of the OECD 321 HYBIT test to assess petrochemical bioconcentration. These projects have highlighted challenges associated with the application of NAMs for petrochemical substances. For example, use of in silico tools can be limited for some petrochemical substances which display physico-chemical and structural characteristics outside of model applicability domains. Similarly, petrochemical substances tend to be associated with difficult test properties, which introduce technical issues when designing and interpreting output from in-vitro tests. Given that in vivo fish data are still required for registration of high-tonnage substances regulated under EU REACH and for off-shore chemicals governed through the Oslo-Paris Convention (OSPAR), the refinement of current in vivo testing protocols and alignment of current regulatory practices is also being evaluated along with the use of the OECD 236 FET test for petrochemical testing. Notably, the lack of alignment of chemical regulations, e.g, OSPAR and REACH, can result in a duplication of animal testing for petrochemicals. Altogether, this poster highlights the efforts and challenges associated with the application of NAMs in the petrochemical industry and the importance of continuous exploration of their use to ensure the safety of the products and wastewater effluents while reducing animal testing.

1.08 In silico New Approach Methodologies for Enhancing Understanding of Chemical Safety: Getting your Questions Answered by the Developers

1.08.T-01 The Exposure And Safety Estimation (EAS-E) Suite Platform to Aid Chemical Assessments

***Alessandro Sangion**[1], Li Li[2], Liisa Toose[3], Trevor N Brown[3] and Jon A. Arnot[4], (1)ARC Arnot Research and Consulting Inc, Canada, (2)University of Nevada, Reno, United States, (3)ARC Arnot Research and Consulting, Canada, (4)ARC Arnot Research and Consulting AND University of Toronto, Canada*

Environmental and human health risk assessments require quantitative exposure data for thousands of chemicals in various systems. Understanding the processes that determine chemical exposure provides critical insights for risk management decisions for the safe and sustainable use of chemicals by society. Multi-media mass-balance fate, toxicokinetic (bioaccumulation), and exposure models are often necessary for exposure and risk estimation. These mechanistic (process-driven) models require chemical-specific input data such as physical-chemical properties, toxicokinetic data, environmental degradation half-lives, production volumes and emission rates. However, for many of the chemicals requiring evaluation, these data are limited, not standardized and documented across multiple databases. To reduce animal use and address significant data gaps, New Approach Methods (NAM) like in vitro bioassays and validated Quantitative Structure Activity Relationships (QSARs) can be used; however, their application often requires expert judgement and a careful evaluation of the results (e.g. Applicability Domain). Most importantly databases and models are not integrated; chemical evaluators need to gather information from many diverse sources to perform assessments. Here we introduce the Exposure And Safety Estimation (EAS-E) Suite platform to bridge the gap between evolving scientific research and regulatory assessment challenges. EAS-E Suite is a free on-line platform developed to facilitate knowledge translation to various stakeholders on issues in exposure assessment and environmental health. EAS-E Suite is comprised of chemical information databases, QSARs for predicting chemical information if measured data are unavailable, and models and tools to aid chemical assessment decision-making. EAS-E Suite provides opportunities to address regulatory challenges for new and existing chemical assessments for ecological and human health objectives to support a One Health approach to chemicals management and to guide the safe and sustainable production and use of chemicals in society. A case study illustrates how the platform integrates various data sources and knowledge across multiple disciplines to reduce uncertainty, improve chemical management and support decision-making.

1.08.T-02 Web-Based Platforms for Toxicogenomics Data Analysis: EcoToxXplorer and ExpressAnalyst

Niladri Basu[1]*, Jessica Ewald*[2]*, Guangyan Zhou*[1]*, Peng Liu*[3]*, Doug Crump*[4]*, Jessica Head*[5] *and Jianguo Xia*[6]*, (1)McGill University, Canada, (2)Broad Institute of MIT and Harvard, Canada, (3)Environment and Climate Change Canada (ECCC), Canada, (4)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada (ECCC), Canada, (5)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (6)McGill University, QC, Canada*

Toxicogenomics data are likely to play a key role in the transition from traditional to alternative toxicity testing methods. The costs of acquiring such data continue to drop, and an ever-increasing number of researchers and regulators would like to get involved in the world of toxicogenomics. However, these data are complex, and analyses typically require advanced programming skills and a deep knowledge of statistics and genomics resources, and as such, are usually handled by expert bioinformaticians. The objective of this presentation is to outline two freely accessible web-based tools that we have been developing: ExpressAnalyst (www.ExpressAnalyst.ca) and EcoToxXplorer (www.ecotoxxplorer.ca). ExpressAnalyst has been designed to process, analyze, and interpret RNA-sequencing data from any eukaryotic species. EcoToxXplorer has been designed to analyze qPCR data measured with custom EcoToxChip arrays from six ecological species (model organisms: Japanese quail, fathead minnow, African clawed frog; native species: double-crested cormorant, rainbow trout, northern leopard frog). Both are viewed as next-generation bioinformatics tools that are high performance, intuitive, and universally accessible to handle transcriptomics data for the purpose of chemical risk assessment and environmental management. The pipeline for each includes steps for QA/QC, filtering and normalization, differential analysis, interactive functional analysis, and report generation. Both contain FAQs, tutorials, and case studies to aid the user. The functional analysis is toxicology-focused, including integration with the AOPwiki and our custom EcoToxModule gene sets that were designed for high-level interpretation of toxicogenomics data (for EcoToxXplorer), and in ExpressAnalyst users can generate transcriptomic points of departure (tPOD) values. The development of these tools was organized around design-thinking principles in that we iteratively presented the tool to various user groups from academia, government, and industry for testing, and then refined it based on their feedback. These tools were developed through funding from several Genome Canada grants.

1.08.T-03 EnviroTox: A Curated Aquatic Toxicology Database

Julie Krzykwa[1]*, Kristin Connors*[2]*, Ryan R Otter*[3] *and Michelle Rau Embry*[1]*, (1)Health and Environmental Sciences Institute (HESI), United States, (2)The Procter & Gamble Company, United States, (3)Grand Valley State University, United States*

Chemical safety assessments require innovative approaches to predict ecological hazards efficiently while reducing reliance on animal testing. One such method is the ecological threshold for toxicological concern (ecoTTC). The underlying data are crucial for a robust ecoTTC computation, but existing individual databases were not directly suitable to support ecoTTC development. This presentation will focus on the EnviroTox database, which was developed to provide a robust, curated database containing high-quality aquatic toxicity studies traceable to the original information source that can be leveraged to support the development of New Approach Methodologies (NAMs) such as ecoTTC. Version 2.0.0 of the EnviroTox database contains 80,912 records representing 1,641 species and 4,267 unique chemical CAS numbers. Data was sourced from 11 different data sources, including the US EPA ECOTOX knowledgebase, ECHA REACH registration information, and the OECD QSAR toolbox. Stepwise Information-Filtering Tool (SIFT) criteria were implemented to identify which data should be included in the EnviroTox database to ensure relevance and quality. The data includes relevant identifiers, physical-chemical properties, taxonomic information, MOA classifications, and toxicity endpoint information. All entries are traceable to their original source. A search interface allows users to search the database by substance, taxonomy, test, and/or substance properties. In addition to the database, additional tools allow for the generation of regional Predicted No Effect Concentrations (PNECs), ecoTTCs, and Chemical Toxicity Distributions (CTDs). EnviroTox exemplifies how well-curated databases can aid in chemical safety assessments. While this database was initially developed to calculate ecoTTC and CTD values, it provides a unique resource due to the many data sources and the curation of the datasets. It has been leveraged for many project types. A search of publications citing the database in 2024 yields manuscripts that leveraged the database for QSAR development, creation of species sensitivity distributions6, machine learning-based predictions, and other uses, demonstrating the broad range of applications for the database and the included tools.

1.08.T-04 Leveraging Molecular Docking Techniques to Support Virtual Screening of Cross-species Susceptibility to Chemical Effects

Rama Krishnan[1]*, David Spurgeon*[2]*, Stephen James Short*[2]*, Bruno Campos*[3]*, Claudia Rivetti*[3]*, Claire Peart Dr*[3] *and Peter Kille*[4]*, (1)Cardiff University, Cardiff, United Kingdom, (2)UK Centre for Ecology and Hydrology (UKCEH), United Kingdom, (3)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom, (4)Cardiff University, United Kingdom*

Understanding cross-species susceptibility to chemical exposures poses challenges in toxicology and environmental risk assessment. Traditional experimental methods to evaluate these effects are resource-intensive and impractical for high-throughput screening. A significant knowledge gap exists in how variations in protein structures influence chemical binding and subsequent biological effects. Bridging this gap is essential to augment predictions of chemical sensitivities across species and support environmental risk assessment and biodiversity protection. This study presents a computational framework that leverages the availability of genomic data, advancements in ortholog prediction tools, and AI-based protein folding technologies to facilitate accurate prediction of molecular initiating events (MIEs) within the Adverse Outcome Pathway (AOP) framework. These advancements enable the integration of molecular docking to unravel mechanisms underlying species-specific susceptibility to chemical agents. As a case study, we applied this approach to acetylcholinesterase (AChE), a key enzyme involved in neurotransmission across various taxa. Homology modelling was used to generate AChE ortholog protein structures from Lepidopteran species, followed by molecular docking to evaluate interactions and binding affinities with chlorpyrifos and its active metabolite, chlorpyrifos oxon. The framework also aimed to predict off-target effects through flexible docking and evaluate ligand interactions across diverse protein targets. Molecular simulations were used to assess the stability and conformational dynamics of protein-ligand complexes, providing deeper insights into the kinetics of binding. The analysis added biological context by identifying unintended interactions and mapping enzymes underpinning phase I metabolism, such as cytochrome P450-mediated detoxification, thereby elucidating species-specific chemical processing pathways. This approach addresses critical gaps in understanding protein chemical interactions by incorporating advanced protein structure prediction techniques and molecular docking simulations to refine predictions of species-specific chemical impacts. It contributes an additional line of evidence within New Approach Methodologies (NAMs) and supports Next-Generation Risk Assessment (NGRA), enhancing the accuracy of ecological risk assessments and informing regulatory decisions to safeguard ecosystems and public health.

1.08.P-Tu050 QSAR-ME Profiler 2025: QSAR Predictions, Similarity Analysis, Domain Inspection and Metabolites Profiling

Nicola Chirico, ***Marco Evangelista*** *and Ester Papa, QSAR Research Unit in Environmental Chemistry and Ecotoxicology, Department of Theoretical and Applied Sciences, University of Insubria, Italy*

In the context of environmental risk assessment, in silico tools play a pivotal role in the prediction of chemical activity. Among these tools, Quantitative Structure/Property Activity Relationships, abbreviated as QSA(P)Rs, are well-known alternatives to in vivo / in vitro experiments. In the last 20 years, more than 100 QSA(P)Rs were developed by the QSAR research unit of the University of Insubria, targeting physical-chemical properties, global indexes, ecotoxicology and metabolic transformations. To streamline the application of these QSA(P)Rs, and to simplify the evaluation of their predictions, a new multiplatform software called QSAR-ME Profiler 2025 has been developed, which improves and restyles the previous version published at http://dunant.dista.uninsubria.it/qsar/. This new version continues to detail QSA(P)Rs data and corresponding predictions, to check the applicability domain compliance of the QSA(P)Rs, and to allow for automatic detection of the most similar chemicals, to further aid assessment of the chemicals under scrutiny. However, the new version now also provides the possibility to transform endpoints of MLR QSA(P)Rs to better suit regulatory purposes. In addition, the new version now provides uncertainties of the predictions by the classification models and defines the applicability domain in

classification which can be checked for new chemicals of interest. Combined predictions can still be calculated when multiple QSA(P)Rs are available for a certain endpoint. Like the previous version of the QSAR-ME Profiler, Toxtree software with the SMARTCyp module is used to automatically select QSARs for the prediction of in vitro biotransformation, that were developed according to the cytochrome P450-mediated drug metabolism predicted by SMARTCyp. The new version of the QSAR-ME Profiler also allows for the identification of the metabolites of the chemicals under scrutiny, detected by SMART Cyp, which can be profiled using multiple QSARs. This new option allows for better screening of the potential total hazard of the studied chemicals and their metabolites. QSAR-ME Profiler 2025 is available free of charge at http://dunant.dista.uninsubria.it/qsar/.

1.08.P-Tu052 Computational Approach to Evaluate Cross-Species Binding Affinity and Susceptibility of Endocrine Disrupting Chemicals in Consumer Products

***Keon Kang**, Kimoon Na and Jinhee Choi, University of Seoul, Korea, Republic of*

Endocrine Disrupting Chemicals (EDCs) have been widespread in consumer products, potentially impacting human health and ecosystems by targeting androgen (AR) and estrogen receptors (ER). Currently, data on the impacts of most consumer product chemicals on non-target species are limited or lacking. This study aims to assess cross-species susceptibility to selected EDCs and chemicals in cleaning products by identifying species with high orthologous similarity to human AR and ER and comparing binding affinities across humans and other species. To achieve these goals, we employed Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) to identify species with receptor structures orthologous to human AR and ER, verified using AlphaFold modeling. Molecular docking was then performed on chemicals present in cleaning products, as well as on other high-toxicity chemicals, to analyze their binding affinities with identified orthologous receptors across 9 species (fish, birds, and endangered species). Chemicals frequently found in consumer products, such as Bisphenol A, triclocarban, and triclosan, demonstrated high binding affinity to the Estrogen Receptor (ER). SeqAPASS analysis identified 800 orthologous species for ER, enabling predictions of binding affinities and corresponding susceptibilities across these species. This analysis encompassed all species included in the molecular docking queries, highlighting the interconnectedness between protein similarity and binding affinity. However, this study integrates orthologous alignment and molecular docking approaches to offer a cross-species susceptibility assessment, identifying species particularly sensitive to chemical exposure in consumer products. Insights derived from this computational approach could inform future chemical safety assessments by enhancing predictions of species-specific susceptibility to EDCs across human and non-human species. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE)(RS-2023-00215309)

1.08.P-Tu053 An Open-Source Computational Pipeline for Predicting Binding Affinity and use in Chemical Hazard and Species Sensitivity Ranking

*Fernando Calahorro Nunez[1], Parsa Fouladi[2], Alessandro Pandini[2], **Nicolas Bury**[1] and Matloob Khushi[2], (1)Ocean and Earth Science, University of Southampton, United Kingdom, (2)Brunel University, United Kingdom*

A challenge in environmental and ecological risk assessment is to identify which chemicals are of most concern and which species are most vulnerable particularly for endocrine disrupting chemicals. A mechanism of endocrine disruption is the binding of chemicals to the steroid receptor outcompeting the natural ligand to act as either agonists or antagonists. Synthetic glucocorticoids are steroids used extensively to treat a variety of health conditions and are a growing environmental concern in the aquatic environment. The current study presents a computational pipeline using open-source software to predict the binding affinity of 12 synthetic glucocorticoids, 5 other chemicals that have been reported to interfere with glucocorticoid receptor functioning and the natural ligand cortisol to 163 teleost fish glucocorticoid receptors. It is those chemicals with the highest binding affinity that will out compete cortisol at the receptor binding site and pose the greatest hazard. In this exercise the glucocorticoid halcinonide was predicted to be the most hazardous chemical based on the predict binding affinity and species from the superorder Protacanthopterygii, containing the Esociformes and Salmonidforms as the most vulnerable. This pipeline can be extended to more chemicals, species and other proteins as an in silico chemical hazard assessment too and for species sensitivoty ranking based on interference at the molecular initiating event of an adverse outcome pathway. Funding source - UKRI Natural Environmental Research Council grant reference NE/X000192/1

1.08.P In silico New Approach Methodologies for Enhancing Understanding of Chemical Safety: Getting your Questions Answered by the Developers

1.08.P-Tu048 The Many Pros and a Few Cons of Mechanistic In Silico NAMs

***Paul Thomas**[1], Floriane Larras[2], maxime Edelblout[2], Franklin Bauer[1], Gaspard Levet[2], Marie Darracq[2] and Carole Charmeau[3], (1)KREATiS, France, (2)KREATiS, France, (3)KREATiS, L'ISLE-D'ABEAU (38080), France*

It is critical that NAMs rapidly obtain the same recognition and support by regulatory authorities as empirical methods if the Green Deal is ever to attain the speed and precision necessary to meet the demands of eco-design. Mechanistic QSARs (i.e. any quantitative relationships observed between structures and effects on biological organisms) can help us to the necessary paradigm shift. But we must define Mechanistic in the context of in silico (eco)toxicology. In the context of in silico expert-knowledge-based models (Q)SARs, mechanisms of toxic action (MechoA) are inextricably linked to two keystones: on one side structural features and on the other biological matrix interactions. Unlike read-across methods, more than one structural group can have the same mechanism of action (thus, the same impact at the same molar concentration). Mechanistic insight (i.e., Structural Alerts or SARs) is a necessary first step in producing a reliable QSAR with a well-defined applicability. MechoA was developed to do this rapidly. It provides an understanding of the interactions between the test substance and the biological matrix that can explain the observed toxicity and link it to structurally similar (or different) chemicals. Any endpoint can ultimately be related to a MechoA (SAR) but the QSAR produced will be related to the species, biology, timeframe of the study, compartment of concern and apical endpoint of interest (e.g. chronic toxicity to fish following OECD 210 Guideline). Moreover, working on the MechoA (merging structures within a same QMAR) allows the development of more robust models with greater chemical space coverage rather than being limited to one structural group. Furthermore mechanistically understanding limits the need for a validation set (for the regulatory purposes). Limitations: Mechanisms only work when we know them. Thus, it is useful to use complementary NAMs (e.g. in vitro) to validate outcomes. some datapoints cannot fall under OECD 5 Principles (poor goodness of fit for flat lines; no unambiguous algorithm if toxicity > solubility). To conclude, Mechanistic NAMs not only add a new arm to the battery of modern alternatives but they add additional advantages that rarely exist in empirical tests. Not only can they replace an experimental endpoint but they can explain it, fit it within the context of an Adverse Outcome Pathway and indicate the potential for more or less insidious toxic mechanisms that need supplementary attention.

1.08.P-Tu049 Performance Evaluation of QSAR Model “KATE2020” in Algal Toxicity Prediction using CSCL Newly Announced Chemical Substances as Validation Set

***Yuto Itami**[1], Koichi Ohno[1] and Hiroshi Yamamoto[2], (1)National Institute for Environmental Studies, Japan, (2)Health and Environmental Risk Division, National Institute for Environmental Studies, Japan*

As there is no or little hazard information on most of the organic chemicals currently in the market, expectations have been growing for the use of alternative methods to toxicity testing such as quantitative structure-activity relationships (QSAR). National Institute for Environmental Studies has been developing QSAR model "KAshinhou Tool for Ecotoxicity (KATE), which predicts acute and chronic toxicity of industrial organic chemicals to aquatic organisms by classification based on chemical structure and linear regression using octanol/water partition coefficient as a descriptor, and judges applicability domain (AD) regarding structure and descriptor. In this presentation, we will report on the performance evaluation results of KATE2020 ver. 5.1 in the algal toxicity prediction using newly announced chemical substances under Chemical Substances Control Law of Japan (CSCL new chemicals). Measured acute and chronic toxicity data on CSCL new chemicals to algae were collected from the web site (www.nite.go.jp/chem/jcheck/list7.action?category=240). In addition, data on OECD high production volume chemicals (OECD HPV chemicals) were also used as a comparison because CSCL new chemicals can be structurally more complex, and the predictive performance can be different between the datasets accordingly. Toxicity values of chemicals in the datasets were predicted using KATE2020 and US EPA s ECOSAR2.2 model that predicts ecotoxicity by classification and regression, which is similar methods to KATE, and (i) percentage of chemicals predicted within AD, (ii) for those within AD, percentage of predicted toxicity values that fall within a factor of 10 in ratio to measured toxicity values were computed. (i) 45% and 57% of CSCL new chemicals were predicted within AD by KATE2020 for acute and chronic toxicity, respectively. (ii) For predictions within AD, 80% and 79% of those in KATE2020 fell within a factor of 10 in ratio to measured toxicity values for acute and chronic, respectively. In comparison to ECOSAR2.2, KATE2020 predicted less chemicals within AD but obtained higher prediction accuracy for chemicals judged within AD. This would be because KATE2020 judges AD regarding structure and descriptor to ensure interpolation, even though predictions within AD are not necessarily used as alternative to toxicity testing. It is expected that including CSCL new chemicals in the training set of KATE2020 will expand its AD.

1.08.P-Tu050 QSAR-ME Profiler 2025: QSAR Predictions, Similarity Analysis, Domain Inspection and Metabolites Profiling

*Nicola Chirico, **Marco Evangelista** and Ester Papa, QSAR Research Unit in Environmental Chemistry and Ecotoxicology, Department of Theoretical and Applied Sciences, University of Insubria, Italy*

In the context of environmental risk assessment, in silico tools play a pivotal role in the prediction of chemical activity. Among these tools, Quantitative Structure/Property Activity Relationships, abbreviated as QSA(P)Rs, are well-known alternatives to in vivo / in vitro experiments. In the last 20 years, more than 100 QSA(P)Rs were developed by the QSAR research unit of the University of Insubria, targeting physical-chemical properties, global indexes, ecotoxicology and metabolic transformations. To streamline the application of these QSA(P)Rs, and to simplify the evaluation of their predictions, a new multiplatform software called QSAR-ME Profiler 2025 has been developed, which improves and restyles the previous version published at http://dunant.dista.uninsubria.it/qsar/. This new version continues to detail QSA(P)Rs data and corresponding predictions, to check the applicability domain compliance of the QSA(P)Rs, and to allow for automatic detection of the most similar chemicals, to further aid assessment of the chemicals under scrutiny. However, the new version now also provides the possibility to transform endpoints of MLR QSA(P)Rs to better suit regulatory purposes. In addition, the new version now provides uncertainties of the predictions by the classification models and defines the applicability domain in classification which can be checked for new chemicals of interest. Combined predictions can still be calculated when multiple QSA(P)Rs are available for a certain endpoint. Like the previous version of the QSAR-ME Profiler, Toxtree software with the SMARTCyp module is used to automatically select QSARs for the prediction of in vitro biotransformation, that were developed according to the cytochrome P450-mediated drug metabolism predicted by SMARTCyp. The new version of the QSAR-ME Profiler also allows for the identification of the metabolites of the chemicals under scrutiny, detected by SMART Cyp, which can be profiled using multiple QSARs. This new option allows for better screening of the potential total hazard of the studied chemicals and their metabolites. QSAR-ME Profiler 2025 is available free of charge at http://dunant.dista.uninsubria.it/qsar/.

1.08.P-Tu051 Predictive Model for Identifying Thyroid Endocrine Disrupting Chemicals Using the Comptox Chemicals Dataset

***Inhye Lee**[1], Hanseul Kim[2] and Kyunghee Ji[3], (1)Department of Environmental Health Sciences, Seoul National University, Korea, Republic of, (2)National Strategic Technology Research Institute, Seoul National University Hospital, Korea, Republic of, (3)Department of Occupational and Environmental Health, Yongin University, Korea, Republic of*

Thyroid hormones are essential to the endocrine system, and their disruption by chemicals is a major toxicological concern. Traditional methods, such as animal experiments and epidemiological studies, are limited in scope and not efficient for evaluating the vast number of novel chemicals. To efficiently screen the toxicity of a large number of chemicals, it is more effective to first predict toxicity using existing data and then validate the results with an alternative animal toxicity test model, such as zebrafish, rather than relying solely on traditional methods. In this study, we developed a deep learning model to classify chemicals based on their potential to disrupt thyroid hormone activity. Chemical structures were encoded as SMILES and then converted into 2048-bit Morgan fingerprints using RDKit. The deep learning framework was designed as a hybrid architecture employing a multi-branch structure. Convolutional Neural Networks (CNN) and Long Short-Term Memory (LSTM) networks were integrated to extract relevant features, and the Dense Layer and Attention mechanism combined and improved the features for the final prediction. This approach leverages the strengths of different neural network architectures to effectively capture important patterns in chemical fingerprints for binary classification. A sigmoid activation function was applied to the output layer, and Focal Loss was used to address class imbalance. The final model consistently achieved an F1 score exceeding 0.8 in most test cases, indicating its robust and reliable predictive capabilities. To validate the model, zebrafish embryos were exposed to sub-lethal concentrations of selected chemicals for 96 h and changes in gene expression were measured. This study demonstrates the potential of computational models to efficiently screen large chemical datasets for endocrine-disrupting chemicals. Future studies are needed to expand the scope of model to other hormone-related pathways and enhance its predictive accuracy with additional chemical descriptors. This study was supported by the National Research Foundation of Korea (NRF; Project no. RS-2023-00251751)

1.08.P-Tu052 Computational Approach to Evaluate Cross-Species Binding Affinity and Susceptibility of Endocrine Disrupting Chemicals in Consumer Products

***Keon Kang**, Kimoon Na and Jinhee Choi, University of Seoul, Korea, Republic of*

Endocrine Disrupting Chemicals (EDCs) have been widespread in consumer products, potentially impacting human health and ecosystems by targeting androgen (AR) and estrogen receptors (ER).

Currently, data on the impacts of most consumer product chemicals on non-target species are limited or lacking. This study aims to assess cross-species susceptibility to selected EDCs and chemicals in cleaning products by identifying species with high orthologous similarity to human AR and ER and comparing binding affinities across humans and other species. To achieve these goals, we employed Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) to identify species with receptor structures orthologous to human AR and ER, verified using AlphaFold modeling. Molecular docking was then performed on chemicals present in cleaning products, as well as on other high-toxicity chemicals, to analyze their binding affinities with identified orthologous receptors across 9 species (fish, birds, and endangered species). Chemicals frequently found in consumer products, such as Bisphenol A, triclocarban, and triclosan, demonstrated high binding affinity to the Estrogen Receptor (ER). SeqAPASS analysis identified 800 orthologous species for ER, enabling predictions of binding affinities and corresponding susceptibilities across these species. This analysis encompassed all species included in the molecular docking queries, highlighting the interconnectedness between protein similarity and binding affinity. However, this study integrates orthologous alignment and molecular docking approaches to offer a cross-species susceptibility assessment, identifying species particularly sensitive to chemical exposure in consumer products. Insights derived from this computational approach could inform future chemical safety assessments by enhancing predictions of species-specific susceptibility to EDCs across human and non-human species. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE)(RS-2023-00215309)

1.08.P-Tu053 An Open-Source Computational Pipeline for Predicting Binding Affinity and Use in Chemical Hazard and Species Sensitivity Ranking

Fernando Calahorro Nunez[1], Parsa Fouladi[2], Alessandro Pandini[2], ***Nicolas Bury***[1] *and Matloob Khushi[2], (1)Ocean and Earth Science, University of Southampton, United Kingdom, (2)Brunel University, United Kingdom*

A challenge in environmental and ecological risk assessment is to identify which chemicals are of most concern and which species are most vulnerable particularly for endocrine disrupting chemicals. A mechanism of endocrine disruption is the binding of chemicals to the steroid receptor outcompeting the natural ligand to act as either agonists or antagonists. Synthetic glucocorticoids are steroids used extensively to treat a variety of health conditions and are a growing environmental concern in the aquatic environment. The current study presents a computational pipeline using open-source software to predict the binding affinity of 12 synthetic glucocorticoids, 5 other chemicals that have been reported to interfere with glucocorticoid receptor functioning and the natural ligand cortisol to 163 teleost fish glucocorticoid receptors. It is those chemicals with the highest binding affinity that will out compete cortisol at the receptor binding site and pose the greatest hazard. In this exercise the glucocorticoid halcinonide was predicted to be the most hazardous chemical based on the predict binding affinity and species from the superorder Protacanthopterygii, containing the Esociformes and Salmonidforms as the most vulnerable. This pipeline can be extended to more chemicals, species and other proteins as an in silico chemical hazard assessment too and for species sensitivoty ranking based on interference at the molecular initiating event of an adverse outcome pathway. UKRI Natural Environmental Research Council grant reference NE/X000192/1

1.08.P-Tu055 Evidence-Based Model-Informed Platform to Integrate Knowledge and Data Towards Prediction of Apical Toxicities

Huan Yang*, onehealthsimulation, Netherlands*

Traditional animal testing in pesticide and drug development faces increasing scrutiny due to ethical concerns and limitations in predicting human outcomes. This study presents an innovative framework integrating in silico New Approach Methodologies (NAMs) through two case studies to predict apical toxicity about ecological and human health risk assessment.

The first case study combined PBPK modeling with QSAR methods to predict bobwhite quail toxicity. The methodology involved careful curation of the ECOTOX database, considering parameters like observation duration and compound purity. The PBPK model incorporated cross-species extrapolation of ADME parameters from humans, chickens, and rats, scaled for quail physiology. The integrated approach achieved exceptional accuracy (R^2=0.92, Q^2=0.83) across 33 compounds for QSAR analysis and 12 compounds for PBPK modeling with prediction capability about mortality for untested prolonged exposure of new compounds. The second case study investigated apical lipotoxicity caused by chemical-induced inhibition to efflux of lipids through systems modeling of lipid metabolism, focusing on gender-specific responses in liver and small intestine. The model incorporated omics data from preclinical species, and pharmacology review data from NDA reports and utilized SeqAPASS for cross-species extrapolation. The results demonstrated successful prediction of more severe lipotoxicity in female rats and accurate modeling of organ-specific responses across nonrodent species. The framework represents a significant advancement in toxicological assessment by creating a unified platform that reduces animal testing while prediction point of departure on apical level. The modular design ensures transparency and adaptability, allowing seamless integration of emerging technologies and high-throughput data. This approach aligns with regulatory requirements while offering several advantages: (i) reduced animal testing and associated costs, (ii) improved prediction accuracy through integrated data analysis (iii) enhanced understanding of species/gender-specific responses (iv) flexible adaptation to emerging technologies. This modeling framework demonstrates the potential for NAMs to transform toxicological assessment while addressing ethical concerns and improving scientific outcomes.

1.08.P-Tu056 Let's FOCUS: Temperature in Population Models

Annika Mangold-Doring, Jan Baas, Hans Baveco, Wim Beltman, ***Anna Huang*** *and Bas Buddendorf, Environmental Risk Assessment team, Wageningen Environmental Research, Netherlands*

Effect models like the Dynamic Energy Budget (DEB) and the General Unified Threshold Model of Survival (GUTS), when integrated with Individual-Based Models (IBM), provide a tool for higher tier ERA. This study enhances a previously published DEB-IBM framework to improve realism and applicability for case-study scenarios. Key advancements include: (1) evaluating temperature correction mechanisms using experimental data, (2) incorporating feedback mechanisms such as surface-to-volume scaling and growth dilution into the GUTS module, and (3) applying a dynamic temperature scenario derived from the D3 FOCUS profile. Experimental datasets of Gammarus pulex exposed to imidacloprid and flupyradifurone at four temperatures (7°C, 11°C, 15°C, and 18°C) were analyzed. Individual datasets were fitted separately to assess temperature-dependent parameter behavior, and subsequently used to fit a temperature-explicit GUTS-RED-T. Results revealed a negative temperature dependence for kd (dominant rate constant) and mw (threshold value). These trends were incorporated into the DEB-GUTS-T model. Two population model versions DEB-GUTS and DEB-GUTS-T were simulated under two different dynamic temperature scenarios (i.e., reference and future climate). Simulations showed reduced dose-response relationships in DEB-GUTS-T compared to DEB-GUTS. However, the observed laboratory data indicated increased toxicity with higher temperatures, underscoring discrepancies between population model predictions and experimental findings. These results highlight the complexity of temperature effects on toxicity and emphasize the need to refine temperature corrections in DEB and GUTS modules when used combined in a population model. Overall, this work advances our understanding of DEB-IBM frameworks, facilitating their potential for use in higher-tier environmental risk assessments.

1.08.P-Tu057 Initial Experience with the Application of In Silico Methods in the Context of the New EFSA/ECHA Guidance on the Impact of Water Treatment Processes on the Production of Drinking Water

Antje Gerloff-Elias[1] *and Claudia Ileana Cappelli*[2]*, (1)knoell Germany, Germany, (2)knoell Germany - Italy Branch, Italy*

The impact of water treatment processes on residues or metabolites of active substances used in plant protection or biocidal products has recently become a major topic in the EU. Starting from April 1st 2026, applicants for approval of actives substances used in plant protection or biocidal products and applicants for authorisation of respective products in the EU need to comply with the new EFSA/ECHA guidance on the impact of water treatment processes for the production of drinking water (EFSA Journal 2023;21(8), 1-108). Within a tiered framework, the new guidance implements the use of in silico modelling techniques to assess transformation products (TPs) that may be formed during disinfection treatment processes. The guidance stipulates a parallel assessment of predicted TPs provided by in silico models and existing literature data. A prioritised list for the predicted TP is to be created based on the likelihood of their production and the documented detection in the water. The overall aim is to determine which kind of functional groups could be formed due to various treatment processes. The outcome of this exercise will be used to support suspect screening analysis in the follow up experimental step and possible hazard assessment, to avoid challenging, expensive and unnecessary testing, especially vertebrate testing. In this poster, we will present initial experiences - but also address limitations when using a battery of in silico tools as proposed in the guidance, to assess the impact of drinking water treatment.

1.09.A Impact of Micro- and Nanoplastics on Environmental and Human Health: Monitoring, Fate, Exposure, Toxicity and Mechanisms of Toxic Action

1.09.A.T-01 Microplastics in Irrigation Water: Spatiotemporal Changes Reveal Their Source and Distribution Characteristics

Anggraini Widyastuti[1], *Marwa Daud Abada Robby*[1], *Jihan Nabillah Hanun*[1] *and Jheng-Jie Jiang*[2], *(1)Advanced Environmental Ultra Research Laboratory (ADVENTURE) & Department of Environmental Engineering, Chung Yuan Christian University, Taoyuan 320314, Taiwan, Indonesia, (2)Advanced Environmental Ultra Research Laboratory (ADVENTURE) & Department of Environmental Engineering, Chung Yuan Christian University, Taoyuan 320314, Taiwan, Taiwan (Greater China)*

This study investigates microplastic pollution in Taiwan's Taoyuan irrigation system, emphasizing spatial-temporal distribution, polymer composition, sources, and ecological risks. Six sampling sites (IC1 IC6), representing agricultural, residential, and industrial areas, were strategically selected across the irrigation zone, which sources water from Shihmen Reservoir, storage ponds, and river weirs, flowing through Pingzhen, Zhongli, Yangmei, and Xinwu districts. Field sampling was conducted monthly from November 2019 to October 2020, with approximately 5 L of surface water collected per site using a stainless-steel sampler, accompanied by three replicate samples per location. Samples were treated with 30% hydrogen peroxide (H?O?) at 65℃ to remove organic materials and pretreated with ACS-grade sodium chloride (NaCl) to ensure microplastics remained suspended. The suspended particles were filtered (0.45 ?m), examined microscopically, and categorized by shape (fiber, film, fragment, foam) and color (white/transparent, black, multicolor). Microplastics (20 5000 ?m) were analyzed using micro-Fourier transform infrared (?-FTIR) spectroscopy with ATR mode, and polymer types were verified with ?70% matching accuracy against a spectral library. The findings revealed that microplastics were unevenly distributed, with higher concentrations near densely populated areas and urban runoff sites. Seasonal variations showed peak concentrations during rainy seasons and typhoon events, with the highest abundance recorded in May, ranging from 1.88 to 141 items/L. Predominant polymers included polypropylene, polyethylene, and polystyrene, with fibers (36 64%) being the most common shape. Microplastics were primarily 333 1000 ?m in size and white/transparent in color. Principal component analysis (PCA) and hierarchical cluster analysis (HCA) identified population density, lateral canals, and climatic factors as key influences on microplastic distribution. Risk assessments using the polymer risk index indicated significant ecological risks throughout the year, except for the lower risks observed in November and January. This study establishes a baseline database on microplastic pollution in Taiwan's irrigation systems, highlighting the land-based contribution of microplastics and supporting the development of strategies for environmental sustainability.

1.09.A.T-02 Evaluation of Toxicological Characteristics of Airborne Nano/Microplastic Particles From the Industrial Environment

Paul-Tiberiu Miclea[1], *Emilia Visileanu*[2], ***Korinna Altmann***[3], *Hardik Vaghasiya*[4], *Raluca Stepa*[5], *Catalin Grosu*[2] *and Maria Haiducu*[5], *(1)Fraunhofer Center for Silicon Photovoltaics, Germany, (2)The National Research and Development Institute for Textile and Leather, Bucharest, Romania, (3)Bundesanstalt fur Materialforschung und Prufung, Germany, (4)Institute of Physics, Martin Luther University Halle-Wittenberg, Germany, (5)The National Research and Development Institute on Occupational Safety and Health Alexandru Darabont , Bucharest, Romania*

Micro and nano plastic (MNPs) particles and fibres represent a global scale contamination source with hazard potential. They can be identified all around our environment, even in air, soil and water. One of the major global MNPs polluters is the textile industry, which generates plastic particles (nylon, polyester, polyurethane, polyolefin, acrylic etc.) during the manufacturing processes. The study analyses the level of particle concentration outside a company that processes textile yarns, but also from the proximity of workplaces using an online air samplers with cascade and mono filter holders for silicon (Si) and quartz filters, respectively. A laser detector was used for real- time counting of particles of six size classes (PM0.3-PM10). Silicon (Si) filters with a diameter of 9 mm and pore sizes of 10 µm and 1 µm and quartz filters with a diameter of 25 mm and a pore size of 1.2 µm were used for particle sampling. A special holder was designed and made for selective sampling (PM10 and PM1.0) on Si filters. Quartz filters were pre-calcined (8000C) before collection. Sampling parameters: airflow (GilAir Plus pump) -2 l/m3, collection time -3 hours; starting time 7.00 am (T1)/2.00 pm (T2), intermittent natural ventilation, average temperature and humidity: 23.3 0C, RH: 52.5%. The weight of particles collected (µg) on the quart filters was 4.9E-05 (T1) and 5.1E-05 (T2) and on the Si filters 3,2 E-05(T1) and 5E-06(T2). The total number of the outside particles (PM0,3-PM10) was situated between 3584,58 (T1)-15165,05(T2) and inside 9901(T1) and 12921,61(T2). The highest number of PM 10 particles inside was 72/m3 and of PM0.3 particles 71979/m3. The samples were characterized using electron microscopy and µRaman spectroscopy. All samples showed a high concentration of particles on the filter. Samples show only particles with irregular shapes. The equivalent particle diameter was for PM10: 1-5 µm and PM1<1 µm. The total Ion Chromatogram shows the presence of PET-type polymer and the TED GS-MS analysis

shows that the weight of the collected particles is PET. After extracting the particles from the quartz filters, they were tested for evaluation of the cytotoxic potential of preparations on human monocyte-macrophage cell cultures and peripheral lymphocytes. In the first case, the level of cytotoxicity was at the border between non-cytotoxic and cytotoxic and in the second test the result was moderate cytotoxic.

1.09.A.T-03 Nanoplastics in Terrestrial Ecosystems: Linking Exposure to Effects Through Dose-Response Assays and Toxicokinetic Modelling

***Christopher Whitshaw*[1]*, Michael Peter Meissle[2], Thomas D, Bucheli[3] and Denise M Mitrano[4], (1)ETH Zurich, Agroscope, Switzerland, (2)Research Division Agroecology and Environment, Agroscope, Switzerland, (3)Environmental Analytics, Agroscope, Switzerland, (4)ETH Zurich, Switzerland*

To date, many studies have focussed on the toxicity of nanoplastics (NPs) on aquatic species, yet there is little information available about their impacts on terrestrial organisms. Moreover, studies which have exposed terrestrial organisms to NPs often could not fully assess particle ingestion due to the methodological difficulties of NPs identification and quantification. Here, we achieve NPs quantification within arthropods with Pd-doped NPs, which are detected via ICP-MS and can be quantified at magnitudes of orders lower concentrations than previously observed in NPs research. We investigated the bioaccumulation, trophic transfer and toxicity of NPs to terrestrial organisms through a suite of assays and toxicokinetic modelling. First, to compile a dose-response curve, we exposed the arthropod detritivore Folsomia candida to NPs (0 10,000 mg/kg) through spiked feed for 28 days, assessing toxicity via biological endpoints comprising growth, reproduction, and mortality. Subsequently, feeding studies were performed to create a one-compartment model of NP ingestion and depuration over one month. This enabled the calculation of bioaccumulation factor (BAF) and NP half-life within both F. candida and the predatory arthropod Dalotia coriaria. Finally, the biomagnification potential of NPs was investigated, by feeding F. candida to D. coriaria, quantifying NPs within organisms at two trophic levels of a terrestrial food chain and calculating the resulting biomagnification factor (BMF). We successfully quantified NPs ingestion within organisms; NPs LOD was 520 mg/kg (0.05% w/w), with a difference in uptake observed between F. candida and D. coriaria. While no significant effects were observed on biomarkers in the concentration range tested, NPs half-life and BAF within F. candida (9.4 days and 0.033, respectively) suggest short-term bioaccumulation within organisms. Uptake and depuration of NPs has been quantified in D. coriaria, and subsequent BAF and BMF will be presented alongside these results. Through this work, we demonstrated the utility of Pd-doped NPs in quantifying the bioaccumulation of NPs at trace concentrations within organisms, and in enabling dose-response ecotoxicology studies for NPs. Furthermore, we elucidated the risks of NPs to terrestrial organisms beyond growth and reproduction. Collectively, these results on exposure and impact will contribute to the assessment of risks of NPs to terrestrial and agricultural systems.

1.09.A.T-04 Emission of Microplastics to Water, Soil and Air – What Can We Do About It?

Anne Hids*, Joris T.K. Quik, Michelle Steenmeijer, Yvette Agnes Maria Mellink and Anne van Bruggen, Dutch National Institute for Public Health and the Environment (RIVM), Netherlands*

Microplastics are plastic particles smaller than 5mm. Sources of microplastics are wear and tear of plastic products (such as car tyres), intentional production (such as rubber infill on sports fields) and fragmentation of macroplastics in the environment. Microplastics in the environment are a concern for human and environmental health. In order to understand the release of microplastics to the environment their material flows from all major sources need to be quantified. A dynamic probabilistic material flow analysis (DPMFA) model [1] was developed for estimating the flow of plastics through the anthroposphere. Micro- and macroplastic emissions to the environment were estimated for the Netherlands and the EU27, for 13 polymers and 7 product categories. The model was used to estimate plastic emissions to soil, air and water compartments with 2019 as reference year. 23 measures to reduce plastic emissions were selected based on insights from literature and experts. The effect of the mitigation measures was estimated for potential for emission reduction in 2030 and 2050, assuming the measures take effect in 2025. The three largest sources of plastic emissions to the environment in the EU27 and the Netherlands are tyre wear, macroplastics and pre-production pellets. The mitigation measures with the largest reduction potential relative to total plastics emission were for the largest sources of plastic emissions, which is to be expected. Furthermore, some of the measures aimed at smaller sources were very effective, but only relative to the plastic emission per source. The results help policy makers prioritize further development of mitigation measures. This model can be extended to other EU countries and the data can be improved. It can support the integrated assessment of micro- and macroplastics mitigation options. [1] Quik JTK, Hids AR, Steenmeijer MA, Mellink Y, van Bruggen A. 2024. Emission of Microplastics to Water, Soil and Air What can we do about it? RIVM report 2024-0106.

1.09.A.T-05 Microplastic-Microbiome Interactions in Aquatic Ecosystems: A Complex Story
*Jessica Song[1], Brittan Scales[2], Katrin Wendt-Potthoff[3], Minh Nguyen[4], Emelie Westberg[4] and **Sonja Oberbeckmann**[1], (1)Federal Institute for Materials Research and Testing, Germany, (2)Leibniz Institute for Baltic Sea Research Warnemunde, Germany, (3)Helmholtz Center for Environmental Research, Germany, (4)Swedish Environmental Research Institute, Sweden*
As pervasive and persistent pollutants, microplastics exist alongside diverse microbial communities in nature. These hardy substrates accumulate rich polymeric matrices from their surroundings that in turn offer nutrition and protection to diverse communities and their theatre of activity, representing a new ecological niche. With our work, we aim to establish a holistic understanding of the interactions between microplastics and microorganisms within aquatic systems, and how these interactions shape their surrounding environment. In our research, we combine field sampling with in situ experiments, and apply high-throughput sequencing technologies to 16S genes and whole bacterial genomes. We demonstrate through our studies that biofilm communities exhibit no specificity to plastic polymer type but appear rather to be opportunistic colonizers more strongly shaped by spatial and temporal factors. While the polymer surface does not appear to elicit a selective effect on associated biofilms, our studies show that microplastics might shape communities in a different way. Based on our detection of carotenoid synthesis pathways and photosynthetic gene clusters among plastic biofilms, we postulate this new niche to shape a specific functional toolkit, adaptive among its members as a product of prolonged exposure to UV radiation at the sea s surface. To fully assess the interactions between microplastics and microorganisms, however, one cannot consider plastics singularly but as a component within a more complex and interconnected system. It is known, for instance, that plastics can sorb significant concentrations of polycyclic aromatic hydrocarbons (PAH) in the environment. We show, in our work, that the PAH sorption patterns of microplastics correlate significantly with the structure of associated biofilm communities. Elevated concentrations of specific PAHs on microplastics coincided with the enrichment of selected taxa reportedly capable of hydrocarbon utilisation as well as a reduced diversity among associated biofilm communities. Here, we present a synthesis of our collective research on microplastic biofilms in the aquatic environment, the factors that shape them, and their interactions with nature. To fully comprehend how microplastics impact ecosystems, the entire substrate must be considered, including all chemicals integrated into the polymeric matrix as well as associated biofilms.

1.09.B Impact of Micro- and Nanoplastics on Environmental and Human Health: Monitoring, Fate, Exposure, Toxicity and Mechanisms of Toxic Action

1.09.B.T-01 The Plastisphere Resistome in Antarctic Collected Microplastic Samples: Impact on Human Health
***Francisca Fernandez-Pinas**[1], Juan Manuel Valenzuela[1], Evelyn Krojmal[2], Barbara De Feo[2], Gissell Lacerot[3], Juan Pablo Lozoya[3], Franco Teixeira de Mello[2], Maria Jesus Martinez Bueno[4], Amadeo Rodriguez Fernandez-Alba[4], Roberto Rosal[5], Francisco Leganes[1] and Miguel Gonzalez-Pleiter[1], (1)Department of Biology, Faculty of Science, Universidad Autonoma de Madrid, Spain, (2)Departamento de Ecolog a y Gestion Ambiental CURE, Universidad de la Republica, Uruguay, (3)Departamento Interdisciplinario de Sistemas Costeros y Marinos, Centro Universitario Regional del Este, Universidad de la Republica, Uruguay, (4)Agrifood Campus of International Excellence (ceiA3), European Union Reference Laboratory for Pesticide Residues in Fruit & Vegetables. Department of Chemistry and Physics, University of Almer a, Spain, (5)Department of Chemical Engineering, Universidad de Alcala, Spain*
Microplastic waste has been found in all environments investigated so far, even reaching remote areas such as Antarctica. Microplastics may serve as reservoir and even help spreading to other environmental compartments the bacterial community growing on them (plastisphere). The plastisphere may have antibiotic resistance bacteria within its members that harbour antibiotic resistance genes (ARGs) contributing to the spread of them, which at present, is a human health concern. ARGs are usually carried within genomes by mobile genetic elements (MGEs). There is a scarcity of studies tackling these issues in microplastic waste from remote sites, particularly in the polar areas. The objective of this study is to characterize for the first time the whole resistome (defined as all the ARGs in communities of both pathogenic and non-pathogenic bacteria) found in the plastisphere of plastic samples collected in Antarctica. In addition, the microbial composition of the antarctic plastisphere is also being characterized to perform correlation analyses between ARGs, MGEs and the underlaying bacterial diversity that may shed light on the potential role of microplastics in environmental dissemination of antibotic resistances and their impact on human health.
Sampling took place in King George Island (Antarctic Peninsula) at three sites: Lake Uruguay (plastic, water and soil samples), Lake Ionosférico (plastic, water and soil samples) and the Ardley peninsula

(plastic and soil samples). Resistome analysis was performed by way of SmartChip Real-Time PCR System (TAKARA), which covers 310 ARGs and 72 MGEs. The diversity of the samples was analyzed through metabarcoding of 16S rRNA. 294 unique ARGs and 52 different MGEs were detected across all samples. Globally, plastic samples presented a 30% of exclusive ARGs/MGEs. ARGs can be classified in 5 categories based on the potential risk they pose to human health. Rank I ARGs are the most dangerous to human health, rank IV the least. Plastic samples always presented rank I ARGs. Plastic waste samples also presented significant correlation otherwise not found in soil and water. Microplastics may be acting as a reservoir and vector of ARGs and MGEs in the Antarctic freshwater ecosystem which may have implications for global human health. The authors acknowledge the financial support by MICINN: PID2020-113769RB-C21/22 and Comunidad de Madrid s government for funding through doctorate grant PIPF-2022/ECO25609 the thesis of JMV. MGP would like to thank the International Association of Antarctica Tour Operators (IAATO) and the Council of Managers of National Antarctic Programs (COMNAP) for the joint IAATO/COMNAP Antarctic Fellowship 2020.

1.09.B.T-02 Toxicity of Aged and Fresh Polylactic Acid Nanoplastics on *Pseudomonas putida*

Virginia Galvez Blanca[1]*, Miguel Tamayo-Belda*[2]*, Miguel Gonzalez-Pleiter*[2]*, Francisca Fernandez-Pinas*[2] *and Roberto Rosal*[1]*, (1)Universidad de Alcala, Spain, (2)Universidad Autonoma, Spain*

Introduced in the mid-20th century, plastics have become ubiquitous in modern society. However, the increase in production around 400 million tonnes per year has led to significant environmental impacts. Biodegradable plastics and biopolymers have emerged as potential alternatives, but the environmental impact of biodegradable nanoparticles (NPs) remains largely unexplored. A suitable model organism to study the effects of biodegradable plastics on soil ecosystems is the bacterium Pseudomonas putida, a common soil-dwelling species. When exposed to a concentration of 5 mg/L of plastic nanoparticles (NPs) and oligomeric nanoplastics (ONPs), both irradiated (I) and non-irradiated (NI), P. putida showed a significant, dose-dependent increase in the production of reactive oxygen species (ROS). In contrast, exposure to ONPs alone induced less pronounced ROS overproduction, especially at the highest concentrations. This difference in ROS overproduction between oligomers alone and the combination of NPs and oligomers may be due to the physical abrasion of the membrane caused by the NPs but not by the oligomeric fraction. Notably, exposure to NPs+ONPs (NI) also resulted in a significant increase in metabolic activity from 5 mg/L, which correlated with increased ROS levels. The association between ROS overproduction and high metabolic activity may partly be explained by P. putida attempt to metabolize PLA through the release of non-specific esterases. When exposed to oligomers alone, non-specific esterase activity is generally similar to controls, except for the 1 and 5 mg/L ONPs (I) and 5-10 mg/L ONPs (NI) concentrations, which show a slight increase in metabolic activity. Furthermore, a paradoxical trend was observed: ROS overproduction increased as metabolic activity decreased towards control levels, suggesting an inhibitory effect of irradiated and non-irradiated ONPs at concentrations above 20 mg/L. This inhibitory effect was further evidenced by a decrease in metabolic activity below control levels for both NPs+ONPs (I) and ONPs (I) at the highest concentrations. The aim of this work is to investigate the biological effects of secondary PLA NPs released from PLA microplastics through abiotic degradation on P. putida under environmentally representative conditions.

1.09.B.T-03 Multi-Level Approach to Evaluate the Toxicity of Weathered Microplastics From Conventional and Bioplastic Polymers on *Daphnia magna*

Beatrice De Felice[1]*, Stefano Gazzotti*[2]*, Eleonora Conterosito*[3]*, Giulia Sauro*[4]*, Lavinia Casati*[4]*, Stefania Marzorati*[1]*, Marco Aldo Ortenzi*[2]*, Valentina Gianotti*[3] *and Marco Parolini*[1]*, (1)Department of Environmental Science and Policy, University of Milan, Italy, (2)Laboratory of Materials and Polymers (LaMPo), Department of Chemistry, University of Milan, Italy, (3)Department of Sustainable Development and Ecological Transition, University of Piemonte Orientale, Italy, (4)Dipartiment of Health Science, University of Milan, Italy*

Similarly to conventional plastics, at end-life bioplastic objects can enter and contaminate ecosystems. Once in the environment, plastic objects made of both conventional or bioplastic polymers, can undergo different weathering processes, which can lead to the production of weathered microplastics (wMPs). These wMPs have variable physical-chemical features compared to the virgin ones and might also represent a threat for organisms. Thus, the aim of this study was to investigate the potential toxicity induced by the exposure to wMPs obtained from objects made of conventional (polystyrene - PS and polyethylene - PE) and bioplastics (polylactic acid - PLA and polybutylene adipate terephthalate - PBAT) towards the cladoceran Daphnia magna. Weathered MPs were obtained following the ISO 4892-2 regulations, by placing previously obtained MPs inside a solar box. Organisms were exposed for 21-days to three concentrations (0.125 µg/mL, 1.25 µg/mL, 12.5 µg/mL) of weathered PS-MPs, PE-MPs, PLA-MPs or PBAT-MPs. A multi-level approach was applied to investigate adverse effects at different levels of the biological hierarchy, from sub-individual (molecular and biochemical) to individual and population level. At molecular level, the modulation of the expression of different genes involved in oxidative stress (cat and sod), physiological and behavioral pathways (flot, SERCA and JHE) was assessed. At biochemical level the onset of oxidative stress (activity of antioxidant and detoxification enzymes, and lipid peroxidation) and changes in energy reserves were explored. Changes in body growth and swimming activity were investigated to assess effects at individual level, while reproductive effort was assessed as endpoint at population level. Our results showed that the exposure to wMPs obtained from both conventional and bioplastic objects induced effects at all considered levels of biological hierarchy. Interestingly, the strongest effects were recorded at population level where all the wMPs lead to a modulation in the reproductive effort. In detail, PS and PLA exposure lead to an increase in the number of offspring, PBAT lead to a reduction in the produced newborns and no effect were highlighted for PE. These results suggest the necessity to study in-depth the toxicity of wMPs.

1.09.B.T-04 Developing the Grouping of Polymers to Streamline Toxicology Testing

***Bibin Sajan*[1]*, Vicki Stone*[1]*, Filipe Vilela*[1] *and Wendel Wohlleben*[2]*, (1)Heriot-Watt University, United Kingdom, (2)BASF, Global Research, Dept. Analytical and Material Science., Germany*

Polymers are used across various industries, in everything from medical devices and packaging to automotive components and electronics. However, their diverse manufacturing processes, chemical structures, interactions with other substances, complex degradation processes, and limited toxicity data, make their hazard assessment complicated. Given the impracticality of individual animal testing for each polymer due to cost, time and animal use, there is a critical need to streamline toxicity assessments to better manage the environmental and health risks. Grouping is an approach that streamlines hazard assessment by providing evidence of similarity between substances so that animal hazard data can be read-across (shared) from one group member to another. This poster introduces a novel strategy integrating the existing grouping framework (from the EU project GRACIOUS) by replacing nano-specific elements with polymer-specific considerations. A polymer grouping hypothesis template has been developed which includes consideration of the purpose of grouping (e.g. regulatory), the lifecycle of polymers (to identify relevant exposure scenarios), and answers the fundamental questions of what they are (physicochemical characteristics), where they go (fate and behaviour in the environment, toxicokinetics), and what they do (hazards). The developed hypothesis template used to determine the dermal exposure to Polyacrylic Acid (PAA) in household detergents with a molecular weight of 4500 Da does not imply skin sensitization. The findings support the acceptance of the hypothesis, showing that PAA exhibits low dermal toxicity, no sensitizing potential, and mild eye irritation in rabbits. These results suggest a minimal human health risk through skin contact. It demonstrates the practical application of the framework and highlights future directions for research and implementation.

1.09.C Impact of Micro- and Nanoplastics on Environmental and Human Health: Monitoring, Fate, Exposure, Toxicity and Mechanisms of Toxic Action

1.09.C.T-01 Nanoplastics Selectively Bind and Unveil Novel Ragweed Pollen Allergens

Jelena Acimovic[1]*, Mirjana Radomirovic*[2]*, Maja Krstic-Ristivojevic*[3]*, Katarina Smiljanic*[2]*, Raquel Portela*[4]*, Tatjana Parac-Vogt*[5]*, Maxim Lox*[5]*, Lea Ann Dailey*[6] *and* ***Tanja Cirkovic Velickovic***[2]*, (1)University of Belgrade - Faculty of Chemsitry, Serbia, (2)University of Belgrade - Faculty of Chemistry, Serbia, (3)University of Belgrade - Faulty of Chemistry, Serbia, (4)CSIC, Spain, (5)KU Leuven, Belgium, (6)University of Vienna, Austria*

The pollen of Ambrosia artemisifolia, ragweed pollen, is widespread cause of respiratory allergic reactions. The aim of the work was to provide evidence of corona formation and its properties on NP particles in simulated lung fluids (SLF), simulating event of pollen and NP co-exposure through respiration. A. artemisifilia pollen is chosen as model system for investigation of NPs interactions with respiratory allergens. Its extract was prepared under mild conditions and short exposure to water, simulating rainfall burst of pollen particles. The binding of Ambrosia pollen allergens to NPs (PP and PET, 100 nm) was monitored in simulated lung fluids (SLF) by corona formation and mass spectrometry, while the effect of NPs on Ambrosia pollen proteins structure was studied by CD spectroscopy. Corona formation was analyzed by glycoproteins staining and immunoblotting with Ambrosia pollen allergic patients sera. Relevant NPs binding proteins of ragweed were also identified by shotgun proteomics in subpollen particles. Ambrosia pollen NPs corona is composed of specific allergenic proteins in SLF conditions showing highly selective binding of ragweed pollen proteins from the extract. Composition of soft and hard coronae is different between nanoPET and nanoPP particles. Hard corona of nanoPP is dominated by a low Mw glycopeptide(s). We have confirmed that 28-32 kDa proteins of hard corona are PCC13-62-like protein and plant basic secretory protein. We have also confirmed their presence in subpollen particles. Specific adsorption of novel ragweed proteins and glycopeptides to NPs hard corona have been shown, allowing us to suggest those IgE-binding proteins and peptides to be major biocorona component of NPs. Our data provide insight into molecular events occurring during co-exposure of NPs and allergens. Selective binding of allergenic proteins to NPs may during co-exposure change the route of allergen exposure to the immune system and modulate allergic reactions. Funding from Horizon 2020, No965173, IMPTOX, by Ministry of Science, Innovation and Technological Development, Republic of Serbia, grant No451-03-66/2024-03/200168 and Serbian Academy of Sciences and Arts, GA F-26.

1.09.C.T-02 Polyvinyl Chloride- and Polypropylene-Model-Micro- and Nanoplastics Exhibit Different Mechanisms of Toxicity in Human Umbilical Vein Endothelial (HUVECs) Cells

Sara Bozzer[1]*, Cristina Tufoni*[1]*, Alessandra Gianoncelli*[2]*, Giacomo Ceccone*[3]*, Rita La Spina*[4]*, Giuseppe Ricci*[1] *and Lorella Pascolo*[1]*, (1)Institute for Maternal and Child Health, IRCCS Burlo Garofolo, Italy, (2)Elettra Sincrotrone Trieste, Italy, (3)European Commission, Joint Research Centre, Italy, (4)European Commission, Joint Research Centre, Belgium*

Plastic pollution, particularly in the form of micro- and nanoplastics (MNPs), has become a significant concern for both environmental and human health. Alarmingly, MNPs have been detected in human placental tissue1, raising serious concerns about potential maternal-fetal exposure and its implications for fetal development. It is expectable that these small particles in the maternal bloodstream can be tranfered to the fetal circulation and influence children's future lives. Since Polyvinyl chloride (PVC) and polypropylene (PP) are dominant plastic types in environmental samples, we used model-MNPs made of these polymers labeled with fluorescent-quantum dots (qDs). To investigate the effects of these potentially circulating polymers at a fetal level, we used Human Umbilical Vein Endothelial Cells (HUVECs) as cell model, as representative of structural and biological barrier. Cytotoxicity assays revealed a concentration- and time-dependent decline in cell viability, with PP exerting a more pronounced effect, particularly at higher concentrations and extended exposure. Flow cytometry and confocal microscopy analyses further uncovered differential cellular responses. PVC-treated cells exhibited significant morphological changes, characterized by increased complexity and granularity, alongside elevated colocalization of MNPs with cellular membranes. In contrast, PP-treated cells demonstrated lesser internalization and predominantly surface-associated interactions. Z-stack fluorescence analysis confirmed the intracellular accumulation of PVC MNPs, with their peak fluorescence intensity outpacing that of PP across cellular layers. These findings suggest that the physicochemical properties of PVC and PP, such as surface charge and hydrophobicity, drive their differential interaction patterns. While both MNP types penetrate cells, PVC exhibits stronger affinity and uptake, potentially posing greater risks to endothelial integrity and vascular health. This study provides critical insights into the cellular effects of common environmental MNPs, emphasizing the need for further investigation into the biological effects and mechanisms of nanoparticle interactions with vascular cells to better assess their risk in maternal and fetal contexts. Ministry of Health, Italy by IRCCS - Burlo Garofolo (RC38/23)

1.09.C.T-03 Distribution of Micro- and Nanoplastics in Perfused Human Placental Tissue

Laura Miranda Zoutendijk[1]*, Britt Juffer*[2]*, Ali Mohammed*[3]*, Verneri Syvanen*[4]*, Hanna Dusza*[2]*, Nikita Korpel*[2]*, Bert Marc Weckhuysen*[1]*, Laurens Dirk Bernardus Mandemaker*[1]*, Markus Forsberg*[5] *and Florian Meirer*[1]*, (1)Chemistry, Utrecht University, Netherlands, (2)Utrecht University, Netherlands, (3)University of Eastern Finland, Finland, (4)University of Estern Finland, Finland, (5)University of Eastern Finland, Finland*

Although micro- and nanoplastics (MNPs) have been found in numerous environmental and human samples, their fate and toxicity is still mostly unknown. As in utero exposure to environmental pollutants may adversely affect fetal health, assessing risks of MNPs to the unborn child is of utmost importance. Ex vivo placental perfusion is a unique system to gain insight into MNP particle size- and type-specific uptake, transport, localization, and quantification. Placentas were attached to a perfusion chamber with both fetal and maternal circulation. The placenta was perfused for a maximum of 6 h with 25 µg/mL of 50 nm, 200 nm, or 1 µm fluorescent polystyrene commercial spheres. Tissue pieces from before and after perfusion were collected, as well as the liquids in the maternal and fetal reservoir before and after perfusion. The perfused tissue was cryo-cut in slices of 30 µm thickness, and the slices were stained using SiR-actin to stain the actin components of the cells. The stained tissue slices were then analyzed with a Confocal Fluorescence Microscope (CFM). The perfusion solutions were measured with a spectrophotometer. Fluorescent polystyrene particles of all three sizes were found to be present in perfused placental tissue. The 50 nm and 200 nm particles seemed to agglomerate around the villi in the placental tissue, where transfer between maternal and fetal sides takes place. The 1 µm particles did not cluster and were found inside the villi. Fluorescence intensity measurements of the perfusion solutions showed limited transfer of all particle sizes to the fetal circulation, but loss of particles on the maternal side, suggesting significant retention in tissue. MNP transport between maternal and fetal side and MNP uptake by placental tissue were studied. All three particle sizes used were found back in the perfused tissue. Smaller particles exhibited a greater tendency to agglomerate around villi compared to larger particles. The perfusion solution on the fetal side showed increased fluorescence after perfusion with 1 µm particles, indicating that a part had crossed to the fetal side, as is also observed with CFM. Smaller particles were retained in the tissue to a greater extent, i.e., 92% and 63% were retained for 50 nm and 200 nm, while only 26% of the 1 µm particles were retained. Next steps include the prevention of clustering of smaller particles during perfusion, as well as perfusions with other MNP polymer types synthesized by our research group. This project has received funding from the European Union s Horizon 2020 research and innovation programme under AURORA grant agreement No 964827.

1.09.C.T-04 Probabilistic Human Risk Assessment of Micro/Nanoplastics: Integrating the Aggregate Exposure Pathway and Adverse Outcome Pathway (AEP-AOP)

***CHAEIN CHONG*[1]*, Jaeseong Jeong*[2] *and Jinhee Choi*[2]*, (1)University of seoul, Korea, Republic of, (2)University of Seoul, Korea, Republic of*

Microplastic particles are ubiquitous in the environment, found in everything from the air we breathe to the food we eat. Despite progress in microplastic research, evaluating the human health risks of micro- and nanoplastics (MNPs) remains challenging due to their varied characteristics and multiple pathways. This study aims to assess the human health risks of MNPs by applying an Aggregate Exposure Pathway and Adverse Outcome Pathway (AEP-AOP) framework integrated with a Bayesian network, taking into account the material properties and multi-media characteristics of MNPs. To enhance the risk assessment of MNPs on human health, several key methodologies were adopted. First, a quality assurance and control (QA/QC) screening process was implemented to ensure data reliability. QA/QC criteria filtered non-standard exposure and toxicity data from the literature, and only datasets meeting these standards were included in the analysis. Next, data alignment methods using parameterized probability density functions (PDFs) were applied to better reflect real-world conditions. Exposure data were standardized by size range, while toxicity data were adjusted to reflect the polydispersity of environmental MNPs and biologically relevant size fractions. Following data alignment, a Cumulative Risk Assessment (CRA) was conducted. An AEP-AOP network was constructed from a comprehensive literature review and the AOP wiki database to integrate the diverse exposure pathways of microplastics. Key event relationships were further assessed using a Bayesian network modeling approach, which improved the network s reliability by analyzing probabilistic relationships. Based on the AEP, total daily exposure to MNPs was calculated, and Margin of Exposure (MoE) values were derived for each key event within the AOP to assess potential risks. This study provides a robust framework for next-generation human risk assessments of MNPs, utilizing an AEP-AOP approach integrated with Bayesian netowrks to address the complex properties of MNPs through various advanced methodologies. Additionally, the NGRA results identified oral ingestion as the primary human exposure route, underscoring potential developmental risks associated with MNP exposure. These findings emphasize the need for further in-depth research to examine the multi-media exposure pathways and developmental toxicity of MNPs. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE)(RS-2023-00215309)

1.09.C.T-05 Biological Evaluation of Binding of Toxins to Microplastics

***Elien Alderweireldt*[1]*, Charlotte Grootaert*[1]*, Bram Jacobs*[1]*, Lukas Wimmer*[2]*, Lea Ann Dailey*[2]*, Tanja Cirkovic Velickovic*[3] *and Andreja Rajkovic*[1]*, (1)Department of Food Technology, Safety and Health, Faculty of Bioscience Engineering, Ghent University, Belgium, (2)Department of Pharmaceutical Sciences, University of Vienna, Austria, (3)Faculty of Chemistry, Center of Excellence for Molecular Food Sciences, University of Belgrade, Serbia*

Micro- and nanoplastics (MNPs) contaminate ecosystems worldwide and enter our food and water via the aquatic environment or plastic food containers. MNPs could serve as carriers of aquatic or food pathogens and/or their toxins, facilitated by their large surface area and hydrophobic nature. However, there is currently no method for qualitative or quantitative evaluation of toxin binding to MPs. This study focuses on cereulide (CER) and fumonisin B1 (FB1) as model toxins, examining their binding to microplastics (MPs) composed of polyethylene terephthalate (PET) and polypropylene (PP) under simulated environmental and biological conditions. It aims to evaluate the binding of toxins to MPs by assessing the subsequent biological effects using advanced cell-based models and analysis techniques. The work is part of the EU-funded IMPTOX project, aiming to unravel the mechanisms of MP-toxin interactions and their implications for human exposure and toxicity. An optimized 3D in vitro cell model assisted in exposing hepatic HepG2 spheroids to the different conditions. The spheroids were chronically exposed to MPs that were pre-incubated for 2 hours with the toxins. Using IncuCyte Sx5 Live Cell Analysis and Agilent Seahorse extracellular flux analysis, the cells' bioenergetic responses were monitored. Shifts in metabolic parameters for bound toxin-MPs versus the MPs or toxins alone indicate that this biological approach could serve as an effective proxy to investigate toxin-MP binding. This research has been funded by IMPTOX European Union s Horizon 2020 research and innovation program (grant number 965173), Research Foundation Flanders research grant 1506419N, Ghent University Special Research Fund grant BOF20/BAS/120, The Federal Public Service (FPS) Health, Food Chain Safety and Environment project RT 21/5 CYANTIR and Research Foundation Flanders/ Slovenian Research and Innovation Agency Weave project with grant number G000123N. M.F.A. received a postdoctoral mandate funded by Ghent University Special Research Fund (BOF) grant number BOF01P03220.

1.09.P Impact of Micro- and Nanoplastics on Environmental and Human Health: Monitoring, Fate, Exposure, Toxicity and Mechanisms of Toxic Action

1.09.P-Mo058 Micro- and Nanoplastics Libraries Reflecting Environmental Physicochemical Properties

Microplastics (MPs), defined as plastic particles smaller than 5 mm, are found widely across the environment, while nanoplastics (NPs) are classified as particles under 1 µm in size. The recent discovery of MPs in human tissues such as the lung, placenta, and blood underscores their human exposure through inhalation or ingestion. MPs and NPs (MNPs) are also prevalent in diverse environments, including air, rivers, and even drinking water. However, their full impact on human health remains largely uncertain. Although MNPs exhibit varied physicochemical properties (e.g., size, shape, and surface oxidation induced by environmental factors like UV radiation), research often overlooks these complexities when evaluating their biological effects. Consequently, particles representing environmentally relevant MPs and NPs are scarce, with most studies relying on plastic particles with limited physicochemical diversity due to availability. To address this gap, we are working on development of MNPs libraries that consider size, shape, surface oxidation of environmental MNPs. We selected polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinyl chloride (PVC) and polyethylene terephthalate (PET) as target polymers based on their high global production. Fragmented particles for each polymer, ranging from NPs to MPs in size, were prepared. In addition, surface-oxidized MPs (oxiMPs) were produced by irradiating them with 172 nm vacuum UV light in air, simulating environmental conditions. For comparison, environmental MPs were collected from a sandy beach along Osaka Bay. Analytical techniques such as ATR-IR revealed hydroxy and carbonyl groups on both the environmental MPs and oxiMPs. To create smaller particles (NPs, under 1 µm in diameter), we employed a previously reported precipitation-based method. Scanning electron microscopy confirmed the successful production of NPs particles. In order to kinetics analysis, we used Nile Red to tag each MNPs, achieving successful labelling, and further adapted the protocol to incorporate Qdot, a bright and photostable fluorescent label, for NP labelling, validated via microscopy. These MNPs libraries, which reflect complex physicochemical properties, enhance the applicability of MNPs research to real-world environmental contexts. They are available for collaborative distribution upon request. This research was performed by the Environment Research and Technology Development Fund (JPMEERF20241003) of the Environmental Restoration and Conservation Agency provided by Ministry of the Environment of Japan and the Sumitomo Foundation for Environmental Research Projects.

1.09.P-Mo059 Detection of Internalized Nanoplastics in Human Cells Using Surface-Enhanced Raman Scattering (SERS)

Barbara Rani-Borges[1]*, Barbara Rothen-Rutishauser*[2]*, Patricia Taladriz-Blanco*[2] *and Alke Petri-Fink*[2]*, (1)Institute of Chemistry, University of S o Paulo (USP), Brazil, (2)Adolphe Merkle Institute, University of Fribourg, Switzerland*

Nanoplastics (< 100 nm) represent one of today's most pressing environmental and health challenges. Compared to larger plastic particles, nanoplastics exhibit increased bioavailability, which can significantly elevate ecological and human health risks. Despite their widespread occurrence, the understanding of how these particles interact with biological systems remains limited. The detection, monitoring, and characterization of nanoplastics in biological contexts, especially in human cells, is a significant challenge due to their size and low environmental concentrations. This study aims to address this gap of imaging and detecting nanoplastics at relevant concentrations within human cells using Surface-Enhanced Raman Spectroscopy (SERS). SERS is an analytical technique capable of providing molecular-level information with high sensitivity and spatial resolution, making it suitable for detecting and visualizing nanoplastics at low concentrations in complex biological environments. To investigate the viability of SERS as a tool for detecting nanoplastics internalized in cells at low concentrations (<100 µg/L), we used macrophages (THP-1 PMA-differentiated) as a cell model. The cells were sequentially exposed to spherical AuNP, followed by exposure to polystyrene (PS) nanoplastics (100 nm) as test nanoplastics. SERS measurements were conducted with a 633 nm laser wavelength in a WiTec Alpha 300 R confocal Raman microscope. Raman mappings collected with enhanced vibrational signals from SERS enabled the identification of AuNP and PS nanoplastics within the cellular environment, confirming the uptake of both particles by the cells. Our findings demonstrate the effectiveness of the SERS technique for detecting and intracellular localization of nanoplastics in human cells and potentially across various cell types. This dual capability for detection and imaging underscores the utility of SERS in studying cellular interactions with nanoplastics. These results contribute to a foundational understanding of nanoplastic behavior, interactions within cells, and their potential health impacts. The authors thank the São Paulo State Research Support Foundation (FAPESP) (Process 2024/07778-1) for financial support to the project.

1.09.P-Mo060 Linear Polyethylene Terephthalate Oligomers Toxicity in Human Primary Cells and Interactions with Biomolecules

Dragana Stanic-Vucinic[1]*, Milica Djapovic*[1]*, Tamara Lujic*[1]*, Vesna Jovanovic*[1]*, Veselin Maslak*[2]*, Tamara Vasovic*[1]*, Jeanette Grundstrom*[3]*, Danijela Apostolovic*[4]*, Lukas Wimmer*[5]*, Lea Ann Dailey*[5]*, Marianne van Hage*[4] *and Tanja Cirkovic Velickovic*[1]*, (1)University of Belgrade - Faculty of Chemistry, Serbia, (2)University of Belgrade - Faculty of Chemistry, Austria, (3)Karolinska institutet, Sweden, (4)Karolinska Institutet, Sweden, (5)University of Vienna, Austria*

Side-products of PET polymerization reactions are cyclic and linear oligomers of PET, recently recognized as novel non-intentionally added substances in food (NIAS) and classified as poor data chemicals. Risk assessment of PET oligomers is challenging due to their size, number, isomerism, complexity in structure, and lack of analytical standards. The great heterogeneity in size and structure of PET oligomers calls for a systematic approach in risk assessment and hazard identification. The aim of our study was to synthesize and characterize physicochemical properties, to investigate solubility in common solvents and food simulants, as well as protein, DNA and cellular interactions of a series of linear methylated and non-methylated PET oligomers (monomer, dimer and trimer). Our results show striking differences in the properties of PET oligomers in relation to size and end-group chemistry (methylated vs. free carboxyl- vs. hydroxyl-). Solubility in food simulants decreases with increase in methylation and the number of aromatic rings. Linear PET oligomers show little to no toxicity in a wide range of concentrations tested in primary cells. All linear PET oligomers tested readily interact with food and serum proteins, and with salmon sperm DNA. Our results point to the importance of size and end-group of PET oligomers in chemical risk assessment: size and methylation of the oligomer strongly contribute to the observed cellular and molecular effects of tested compounds. PET oligomers binding to DNA prompts further research on the toxicological relevance of the observed interactions. This study was supported by the Serbian Academy of Sciences and Arts Project F-26; IMPTOX European Union s Horizon 2020 research and innovation program (grant number 965173); the Ministry of Science, Innovation and technological development of the Republic of Serbia (Contract number: 451-03-68/2024-14/200168). This research was supported by the Science fund of the Republic of Serbia, Grant No. 7275, Exploration of PETase side activity of digestive enzymes of human gastrointestinal tract acting on micro- and nanoplastics: mode of action and products characterization XPACT and Region Stockholm (ALF project FoUI-986234), The Swedish Cancer and Allergy Foundation, The Swedish Asthma and Allergy Association's Research Foundation (Number: F2022-0011); The Swedish Heart-Lung Foundation (Number: 2021042), The Konsul Th C Bergh Foundation, The Magnus Bergvall Foundation and The Karolinska Institutet s Research Foundation Grant.

1.09.P-Mo061 The Toxicity of Microplastics Explorer (ToMEx) 2.0 Database – A Unique Compilation of Microplastics Effect Measurements for Environmental Risk Assessment

Leah Thornton Hampton[1]*,* ***Magdalena M. Mair***[2]*, Stephanie B Kennedy*[3]*, Dana Briggs Wyler*[1]*, Bethanie Carney Almroth*[4]*, Scott Coffin*[5]*, Win Cowger*[6]*, Darragh Doyle*[4]*, Eden Hataley*[7]*, Sara Hutton*[8]*, Ezra L Miller*[9]*, Laura Monclus*[10]*, Emma Sharpe*[11]*, Samreen Siddiqui*[12] *and Alvine C Mehinto*[1]*, (1)Southern California Coastal Water Research Project Authority, United States, (2)Statistical Ecotoxicology,*

The Toxicity of Microplastics Explorer (ToMEx) database is an open-source, open-access database and web application for microplastics toxicity. Its purpose is to provide a valuable easy-to-access tool for data exploration, visualization, and analysis, and a data source for the development of environmentally safe thresholds for micro- and nanoplastic exposure. However, since its release three years ago, the peer-reviewed literature has continued to expand exponentially, rendering ToMEx increasingly obsolete. To guarantee the continued utility of ToMEx, a crowdsourcing approach was employed to establish a global workgroup tasked with updating ToMEx by extracting data from additional studies published after the original release. We here present the results and the experience with this process, which led to ToMEx 2.0 now having doubled in size. Although the aquatic organisms database now encompasses a greater diversity of species and test particle characteristics, both the aquatic and the human health database remain biased towards a few dominant particle characteristics (polystyrene spheres) and particle-only studies (without additional chemicals, not leachates). To investigate, whether the increased amount of can be used to derive more precise regulatory thresholds, a previously developed framework for establishing health-based microplastic thresholds for the state of California was reapplied. We show that thresholds for ToMEx 2.0 are lower and more precise than earlier thresholds based on ToMEx 1.0. Nevertheless, the data suitable for threshold development remained limited with only few proper dose-response experimental designs added to derive No Observed Effect Concentrations (NOECs) and the shift was driven mainly by two new publications. Given the effort required to update the ToMEx database, we believe that future updates should only incorporate studies that meet strict quality criteria to ensure data utility and ensure feasibility. Nevertheless, ToMEx remains a valuable tool for the research community, and this exercise demonstrates that large, coordinated data-mining efforts are feasible. Funding for this project was provided by the Southern California Coastal Water Research Project Authority. B.C.A. is grateful for funding from the Swedish Research Council for Sustainable Development FORMAS 2018 01201. M.M.M. received funding from the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) SFB 1357 391977956.

1.09.P-Mo062 Exploring the Toxic Effects of Microplastics and Heavy Metals on *Enchytraeus crypticus*: A Threat to Soil Ecosystem Integrity

İrem Öztürk Ufuk, *Emel Topuz, Beyza Nur Emanet and Zehra Hazal Kilinc, Gebze Technical University, Turkiye*
Polypropylene (PP), polyethylene (PE), and polystyrene (PS) are among the most produced plastics globally. Once released into the environment, these plastics degrade into microplastics (MPs) that infiltrate water systems, soil, and ecosystems, potentially exerting toxic effects on organisms. Beyond their inherent toxicity, MPs can modify the effects of co-occurring pollutants such as heavy metals by acting as vectors, providing surfaces for metal adsorption. This interaction can significantly influence the bioavailability and toxicity of metals, including cadmium (Cd), chromium (Cr), lead (Pb), nickel (Ni), copper (Cu), and zinc (Zn), to soil organisms. These metals, when present in soil, pose serious risks to ecosystem and human health as they may accumulate in plants and enter the food chain. This study assessed the combined effects of PE, PS, and PP microplastics with Cd, Cr, Pb, Ni, Cu, and Zn on the reproduction of the soil organism Enchytraeus crypticus. Reproductive toxicity was quantified through EC50 values to evaluate individual and combined toxicities. Results revealed that when combined with individual microplastics, all metals exhibited synergistic effects. The EC50 for Cd and MPs was found to be 8.2 mg/kg, representing the most toxic interaction, while Zn and MPs had an EC50 of 97 mg/kg, showing the lowest toxicity among the metals. Notably, when all six metals and all three microplastics were present together, the EC50 was significantly reduced to 2.34 mg/kg, indicating a remarkably strong synergistic effect. These findings highlight the critical role of MPs in enhancing the toxicity of heavy metals through vector effects, particularly in complex mixtures. The observed interactions underscore the importance of considering mixture toxicity in environmental risk assessments. Understanding the combined impacts of priority pollutants such as MPs and heavy metals is essential for evaluating their ecological risks and guiding the development of effective environmental regulations to protect soil ecosystems. This study was supported by the SETAC Europe 2025 Registration Grant - SETAC Europe

Students, which provided a meeting registration fee waiver for the SETAC Europe 35th Annual Meeting, held from 11 15 May 2025 in Vienna, Austria.

1.09.P-Mo063 Breaking Down Recycled LDPE: Nanoplastics, Byproducts and Their Effects on aquatic organisms

Gerardo Pulido-Reyes[1]*, Esther Ortega-Perez*[1]*, Silvia Gomez Kong*[1]*, Miguel Tamayo-Belda*[1]*, Miguel Gonzalez-Pleiter*[1]*, Francisco Leganes*[1]*, Roberto Rosal*[2] *and Francisca Fernandez-Pinas*[3]*, (1)Universidad Autonoma de Madrid, Spain, (2)Universidad de Alcala, Spain, (3)Centro de Investigación en Biodiversidad y Cambio Global (CIBC-UAM), Universidad Autónoma de Madrid, Madrid, Spain*

The increased use of recycled plastics offers a promising approach to mitigate the environmental accumulation of plastic waste. However, it remains unclear whether these plastics, once released into the environment, generate nano-range particles and whether such nanoplastics or the additives they may release pose a potential threat to environmental and human health. This study aims to evaluate the toxicological effects of secondary nanoplastics (NPLs) derived from recycled low-density polyethylene (LDPE) plastics and their byproducts on key aquatic organisms. Three representative species were selected for testing: the green microalga Chlamydomonas reinhardtii, the freshwater plant Spirodela polyrhiza, and the water flea Daphnia magna. Secondary nanoplastics were produced by mechanically fragmenting LDPE microplastics, and their presence was confirmed through extensive physicochemical characterization using dynamic and electrophoretic light scattering, scanning electron microscopy, and Fourier transform infrared spectroscopy. Each organism was exposed to increasing concentrations of secondary nanoplastics and released by-products to assess their biological effects. Acute exposure to both secondary LDPE-NPLs and LDPE-Byproducts had a significant effect on Daphnia magna, with 40% of individuals being immobilized after 48 hours of exposure at 100 mg/l. The ribosomal protein Rpl32 and the one encoding the antioxidant enzyme CuZnSOD have been significantly repressed in the presence of LDPE-NPLs and LDPE-Byproducts. Significant changes have been observed in the expression of glutathione S-transferase, insulin receptor and ecdysone-responsive genes, potentially affecting the molting and other intracellular processes. Acute exposure (96h) to secondary LDPE-NPLs alone had no significant effect on Spirodela polyrhiza in the range of concentration between 1 to 100 mg/l. However, effects were observed with concentration as low as 1 mg/L in various physiological parameters when the duckweed was exposed to LDPE-Byproducts. By examining the effects on these aquatic species, this research highlights the potential environmental risks associated with recycled plastics. It provides critical data on the behaviour and toxicity of secondary nanoplastics, contributing to a deeper understanding of the ecological implications of plastic recycling. This research was supported by 2020-113769RB-C21/22 and RyC2021?034953?I grants from MICINN.

1.09.P-Mo064 Effect of Polyethylene Microbeads on the Growth and Photosynthetic Potential of Freshwater Microalgae, *Scenedesmus quadricauda*

Kanchan Jyoti Nakarmi *and Amit Bhatnagar, Department of Separation Science, LUT University, Finland*

Microalgae are primary producers in food chain and disruption of microalgal population can have cascading effect to every trophic level in the ecosystem. Currently, the background concentration of microplastics in the freshwater systems is increasing which could have potential harmful effect on microalgae. A systematic study is required to investigate the potential toxicological effects of microplastics on microalgae. In this study, the effect of frequently observed microplastics, specifically polyethylene, on a common freshwater microalga, Scenedesmus quadricauda was investigated following the OECD 201 guidelines for the freshwater alga and cyanobacteria growth inhibition test. An incubator shaker equipped with custom-built, bottom-illuminated photobioreactor array is used for the study. Exponentially growing culture of microalgae are exposed to different sizes and concentrations of the commercially available polyethylene microbeads. After every 24 hours, the cell counts, growth rate and photosynthetic efficiency are determined and compared to unexposed control samples. Furthermore, at the end of 72 hours, the microalgae are harvested to study the potential effects on photosynthetic pigment concentration. The microalgae may form biofilm over/with microbeads and size dependent effect could be observed. Larger sized microbeads could provide a surface for microalgae to form biofilm whereas smaller sized microbeads could cover the microalgal surface triggering shade adaptation. Additionally, effect of environmentally relevant and higher concentrations in an isolated system will help determine the effective concentration for growth inhibition for each particle size tested. Lastly, this study aims to utilise the results to draw implications for environmental monitoring studies on microplastics and to provide evidence for future ecotoxicologists and policy makers regarding effect of microplastics on freshwater microalgae. This work is funded by Research council of Finland (Academic project, Decision No. 347690, Awarded to Amit Bhatnagar)

1.09.P-Mo065 Interaction of Aged Filamentous and Fragmented Polypropylene Microplastics in Two Freshwater Zooplankton Species

Matea Marelja[1]*, Simona Cinta Pinzaru*[2]*, Bastiaan Ibelings*[1] *and Vera Slaveykova*[1]*, (1)Department F.-A. Forel for Environmental and Aquatic Sciences, University of Geneva, Switzerland, (2)Biomolecular Physics Department, Babe?-Bolyai University, Romania*

Microplastic (MPs) pollution represents a ubiquitous threat to aquatic ecosystems, with numerous studies highlighting the detrimental effects of pristine MPs on aquatic organisms. Unlike pristine MPs, aged MPs exhibit altered surface properties, chemical composition, and interaction dynamics with organisms, making their study essential to understanding the environmental impacts. Despite their high ecological relevance, experiments using environmentally aged MPs remain limited. This research addresses this critical gap by investigating the interactions between aged filamentous and fragmented polypropylene (PP) MPs and zooplankton, focusing on entanglement, ingestion, and physiological responses, to provide a more comprehensive understanding of the ecological impacts of aged MPs. Aged PP MPs were obtained from 20-year-old fishing gear recovered from the Adriatic Sea, mechanically broken down and processed into filamentous and fragmented forms and characterized. Neonates of two zooplankton species, Daphnia magna and Thamnocephalus platyurus, less than 24 hours old, were selected for their distinct differences in size, morphology, feeding strategies, and ecological roles. The neonates were exposed to increasing concentrations of filamentous (0 50 items per well) and fragmented MPs (0 1000 items/mL) over 24 hours. Endpoints included survival, locomotory dynamics, heart rate, feeding behaviour, ingestion rates, and total copper content, assessed via microscopy, flow cytometry, and ICP-MS. The results demonstrated that filamentous MPs significantly reduced locomotion and promoted entanglement in D. magna across higher concentrations tested (5 50 items/mL), with altered swimming speed and movement trajectories observed in entangled individuals. In contrast, algal ingestion by D. magna was not affected by filamentous MPs. Fragmented MPs exhibited concentration-dependent entanglement in D. magna, with ingestion quantified by copper content. Entanglement with T. platyurus was absent in both MPs shapes. The findings highlight the role of organismal morphology, body size, and MPs characteristics in mediating interactions. These findings underscore the importance of incorporating aged environmental MPs in toxicity studies, to provide ecologically relevant insights. These findings enhance our understanding of the morphological and behavioural impacts of MPs on zooplankton, advancing knowledge of their long-term ecological consequences in aquatic environments.

1.09.P-Mo066 Investigating the Sensitivity of *Daphnia magna* to Natural and Synthetic Microfibers

Andrew Barrick[1]*, Alison Boardwine*[2]*, Safeerul Islam Hashmi*[1]*, Nhung Nguyen*[3]*, Alena Sevcu*[4]*, Jana Novotna*[3] *and* ***Tham C. Hoang***[1]*, (1)Auburn University, United States, (2)Auburn University, Auburn University, United States, (3)Technical University Liberec, Czech Republic, (4)Technical University Liberec, ., Czech Republic*

Microfibers from textiles are one of the most abundant anthropogenic microplastics (MPs) found in environmental samples, with research suggesting most microplastics ingested in situ are microfibers. Microfibers released from clothing can be either from synthetic or natural fibers, which may have different ecotoxicological profiles. Research has suggested that microfibers may be more toxic than fragments or beads due to their capacity to penetrate gut walls and comparatively slow excretion rates. However, there is limited information about hazards from natural and synthetic microfibers with even less information about uptake and depuration. The present study investigated acute toxicity, uptake rates, and depuration rates, of synthetic/semi-synthetic (acrylonitrile, polyester, Kevlar, and nylon) and natural (cotton and silk) microfibers towards Daphnia magna, a water flea. Microfibers were well characterized with microfibers maintained in suspension counted to assess if biological uptake was linked to fiber stability in test media. Species were exposed to the microfibers in a dose-response (10 to 100,000 particles/L) format to identify lethal thresholds and determine if uptake rates were linked to exposure concentrations. Results demonstrated little to no acute toxicity with all microfibers except for nylon which had a lethal concentration where 50% D. magna were expected to die at 0.34 ± 1.26 mg/L. Microfibers used in the study are transparent, making it difficult to identify retention in the body, however results demonstrated that both Kevlar and nylon accumulated at higher rates than other polymer types. Data also suggested that suspension stability was not related to ingestion. This result was supported by the observation of organisms ingested MPs on the bottom of the exposure chamber. Acute toxicity may not be a sensitive endpoint for characterizing the hazards of microfibers. Microfibers which were demonstrated to accumulate in organisms (Kevlar, polyester, and nylon) were investigated for chronic toxicity to characterize alterations to growth rates and reproductive capacity. Results suggested that polymer type influenced ecotoxicity of microfibers. Follow-up research is needed to more appropriately characterize the potential effects of additives and degradation on ecotoxicological potential.

1.09.P-Mo067 Biological Effects of Microcapsules 2

***Norihisa Tatarazako**, Ehime University, Japan*

Microcapsules are the minute particulate matter which encloses various chemical substances inside of the core. The core base for particles are often made by a kind of plastics so it can be regarded as microplastic. They are used in many aspects including drug delivery, stabilizing agricultural chemical effect and to keep fragrancedurability of the aromatic product. The environmental behavior of the chemicals in the capsule changes depending on the properties of the base. It means encapsulation allows any chemical substance to have long-distance mobility and resistance to decomposition results in being equivalent properties of so-called POPs. This may bring the hazard for the environment. On the other hand, this characteristic change of chemicals can be utilized for ecotoxicity testing especially to waterborne animals.
The characteristic of microcapsules provides the change to the behavior of encapsulated chemicals, such effect like easily decomposable chemicals to stable or volatile component to less diffusible. This makes those chemicals difficult to tested can be treated. Also, the exposure process for water animals will be changed from percutaneous to oral intake.
Therefore, with the aim to clarifying the exposure effects of chemicals to organisms mediated by microcapsules, we synthesized microcapsules encapsulating specific chemicals and investigated the changes of the toxicity before and after capsulation. We have synthesized microcapsules with several chemicals and conducted ecotoxicity tests to Daphnia and Medaka. The result will be presented.

1.09.P-Mo068 Evaluating the Role of Sinotaia quadrata (Benson, 1842) as a Bioindicator of Microplastic Pollution in Tuscany's (Italy) Freshwater Ecosystems

***Alice Gabetti**[1], Alessandra Maganza[2], Camilla Mossotto[2], Giuseppe Esposito[1], Annamaria Nocita[3], Monia Renzi[4], Serena Anselmi[5], Tecla Bentivoglio[5], Elena Bozzetta[6], Marino Prearo[1] and Paolo Pastorino[1], (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy, (2)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua); Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (3)The University Museum System, University of Florence, Italy, (4)Department of Life Sciences, University of Trieste, Italy, (5)Bioscience Research Center srl, Italy, (6)The Veterinary Medical Research Institute for Piedmont, Italy*

The Asiatic gastropod Sinotaia quadrata (Benson, 1842), an invasive species in European freshwater ecosystems, may serve as a valuable bioindicator of microplastic (MP) pollution in streams affected by human activity. To assess its potential as a bioindicator of MP contamination, sampling was conducted in Tuscany (Italy) in August 2023. Five sampling sites were selected along three rivers (Arno, Bisenzio, and Ombrone) in areas near urban settlements and subjected to significant anthropogenic pressures (such as the presence of industrial textile factories). Samples were collected from both biotic (S. quadrata) and abiotic (water, sediment) compartments, with S. quadrata specimens categorized into four size classes. Fourier-transform infrared spectroscopy was used to identify and quantify MPs. In total, 84 MP particles were detected, including 56 within S. quadrata, 11 in water, and 17 in sediment samples. The predominant colors of MPs were white (28.74%), blue (34.48%), and black (36.78%), and they were composed of fragments (50%) and filaments (50%), with polymers such as polyethylene (PE) (34.48%), polyethylene terephthalate (PET) (29.89%), and polypropylene (PP) (35.63%) being most common. Among abiotic samples, MPs were more abundant in sediment than in water. No significant differences were observed in MP particle size among different S. quadrata classes. Smaller individuals ingested a higher number of MPs compared to larger individuals, with a significant negative correlation between mollusc size and MP count. Additionally, the generalized linear mixed model revealed that the number of MP items per gram of S. quadrata was predicted solely by mollusc weight. These results could be linked to differences in feeding habits between smaller and larger specimens. These findings indicate that S. quadrata accumulates MPs in its digestive tract, especially during juvenile stages, with ingested MPs reflecting the types present in sediment. Given the potential risks of MP ingestion through local human consumption of S. quadrata, this species offers a useful tool for assessing MP pollution in sediment-rich freshwater ecosystems. Additionally, this study highlights the broader application of invasive species in monitoring and managing anthropogenic impacts on aquatic habitats.

1.09.P-Mo069 Ecotoxicological Impacts of Microplastics on the Freshwater Species *Danio rerio* and *Daphnia magna*

***Ana Rita Correia Fernandes**[1], Diana Isabel Oliveira Carneiro[2], Madalena Vieira[1], Carlos Marques[1] and Roberto Martins[3], (1)University of Aveiro, Portugal, (2)Department of Biology, University of Aveiro, Aveiro, Portugal, (3)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

Human activities have introduced a wide range of contaminants into freshwater and marine ecosystems, including microplastics (MPs), which are persistent and widespread pollutants. MPs pose substantial threats to natural ecosystems, impacting organisms across multiple biological levels. Due to their durability and slow degradation, these particles present ongoing risks to aquatic life. In this study, we accessed the potential effects and environmental hazard of relevant MPs, namely polystyrene (PS), polyvinyl chloride (PVC), polyethylene terephthalate (PET), and high-density polyethylene (HDPE), on two aquatic model species, the crustacean Daphnia magna, and the fish Danio rerio. All four MPs were exposed to both D. magna and D. rerio at the same concentration range (1 to 100 mg/L). Experiments involving D. magna, followed the OECD Test Guideline (TG) 202 for acute immobilization test and, after 48 hours of exposure, immobilization was documented. For D. rerio experiments, the OECD TG 236 was followed, and after 96 hours of exposure period, malformations, hatching delay, and mortality were documented. Regarding D. magna, no immobilization was observed at the end of the 48 hours of exposure for all tested concentrations of each MP. For D. rerio, no mortality, malformations, or hatching delay were observed in embryos/larvae exposed to the different concentrations of the four MPs. These results indicate that, for all measured endpoints in both organisms, the no observed effect concentration (NOEC) is equal to 100 mg/L, demonstrating that the four MPs are no/low toxic for both tested species, The present study provides a better understanding of the interactions between different types of microplastics and various trophic levels as well as biological communities, much needed for a more comprehensive risk assessment. To go further, additional tests are currently being conducted on other model species representative of different aquatic compartments, trophic levels, and life traits to understand if no adverse effects are also recorded on selected species. Thanks are due to the Portuguese Foundation for Science and Technology (FCT) for the financial support to CESAM (UIDP/50017/2020+UIDB/50017/2020+LA/P/0094/2020) and CICECO (LA/P/0006/2020, UIDP/50011/2020, UIDB/50011/2020), to Rita Fernandes (PRT/BD/154317/2023), through a Doctoral grant, to R. Martins (2021.00386.CEECIND; DOI: 10.54499/2021.00386.CEECIND/CP1659/CT0011) and to the NANOGREEN (CIRCNA/BRB/0291/2019; DOI: 10.54499/CIRCNA/BRB/0291/2019) and DigiAqua (10.54499/PTDC/EEI-EEE/0415/2021) projects. 1.09.P-Mo070 Interactive Effects of Polystyrene Nanoplastics and Climate Change Stressors on Zebrafish Embryo Development and Behavior

Monica Torres-Ruiz[1]*, Maria Munoz Palencia*[1]*, Laura Martinez Lopez*[1]*, Antonio De la Vieja*[2]*, Monica Morales Camarzana*[3]*, Raquel Martin Folgar*[3] *and Ana Ca as Portilla*[1]*, (1)Centro Nacional de Sanidad Ambiental, Instituto de Salud Carlos III, Spain, (2)Unidad Funcional de Investigacion en Enfermedades Cronicas, Instituto de Salud Carlos III, Spain, (3)Grupo de Biolog a y Toxicolog a Ambiental, Departamento de F sicaMatematica y de Fluidos, Facultad de Ciencias, UNED, Spain*

Nanoplastic prevalence in all environments is a reality that will only worsen with time as more human plastic waste gets released and degraded. Research on the effects of nanoplastics on aquatic organisms has increased in the past years. However, few studies have taken into consideration the potential interaction between these particles and the effects of climate change stress factors despite its importance regarding environmental risk assessment. The present study aimed at investigating how exposure to polystyrene nanoplastics (PSNP) could potentially interact with two important climate change stressors (pH decrease and temperature increase) to disrupt zebrafish embryo development and behavior. We assessed a variety of endpoints: spontaneous tail coiling activity at 24 hours post fertilization (hpf) as a measure of early neuromuscular activity; morphological characteristics at 72 hpf; and behavioral characteristics at 120 hpf (overall activity, anxiety, and habituative learning). Our findings revealed that there are complex interactions between climate change variables and nanoplastic exposure that affect developmental endpoints differently. PSNP exacerbated the effects of temperature increase and pH decrease for some aspects while for others their effect was independent or negligible, underlying the importance of studying multiple endpoints to fully understand the interactive effects. Our results highlight the importance of addressing the interaction between different environmental stressors to predict cumulative and synergic effects on aquatic ecosystems in a rapidly changing environment. Work funded by the Spanish government Grant PID2023-148109OB-I00.

1.09.P-Mo071 Toxic Effects of PET microfibers on Sheepshead Minnow, *Cyprinodon variegatus*

Jin Soo Choi[1]*, Wan-Seob Cho*[2] *and June-Woo Park*[1]*, (1)korea institute of toxicology (KIT), Korea, Republic of, (2)Dong-A University, Korea, Republic of*

PET fibers in the environment can be degraded into microfibers because of weathering processes such as sunlight, physical wear, and heat. Although recent studies reported adverse effects of PET microfibers on aquatic organisms, the lack of information on their toxicity and mode of action hampers the risk assessment of PET microfibers. Therefore, this study aimed to investigate the biological effects of PET microfibers and their underlying mechanisms in early-staged sheepshead minnows (Cyprinodon variegatus). PET microfibers (about 13 ?m diameter × 106 ?m length) were prepared by cutting PET threads and treated to sheepshead minnow larvae at 10 and 100 mg/L for 10 days. No acute toxicity was found in the minnow, but PET microfibers significantly produced reactive oxygen species and reduced behavioral responses of traveled distance and maximum velocity. The transcriptomic data suggested that Merkel cells (flow sensors) and corpuscles of Stannius (calcium regulator) are putative targets, which were derived from oxidative stress, sensory neuropathy, cognitive impairment, and movement disorders. These findings underscore that although PET microfibers are not directly lethal to sheepshead minnows, they could impact their survival by damaging swimming-related key genes. This study provides new insights into how PET microfibers are toxic to aquatic organisms and disrupt ecosystems beyond survival and pathological changes. This research was supported by Risk assessment to prepare standards for protecting marine ecosystem of Korea institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220383), and by a research project titled "Development of a convergence solution for environmental contamination issues of secondary microplastics" of the National Research Council of Science & Technology (NST) grant by the Ministry of Science and ICT (MSIT), Republic of Korea (No. CAP20024-000).

1.09.P-Mo072 Enhanced Fish Ingestion of Microplastics Due to Colonization and Stimulated Bioluminescence of Luminescent Bacteria on Microplastics

*Jing Yu, **Dali Wang** and Jing You, Jinan University, China (Mainland)*

Microplastics (MPs) are emerging pollutants in marine environments that can interact with various marine organisms, potentially altering their behavior and ecological roles. This study evaluated the effects of polyvinyl chloride (PVC) MPs (~1 mm) on the colonization and bioluminescence of the marine bacterium Photobacterium phosphoreum and investigated the predation behavior of the nocturnal fish Sphaeramia nematoptera towards glowing and non-glowing MPs under dark conditions. Biofilm formation was significantly higher on UV-aged MPs compared to pristine, ethanol-washed MPs, and natural sand particles, suggesting a preference for aged MPs as a colonization substrate. Furthermore, exposure to MPs and their leachates enhanced bacterial bioluminescence, with pristine and UV-aged MPs exhibiting maximum increases of 60% and 70%, respectively. Chemical analysis of MP leachates revealed a time- and concentration-dependent release of dissolved organic matter and metal ions, such as calcium ($Ca^{2?}$) and zinc ($Zn^{2?}$). A maximum concentration of 20 mg $L^{?1}$ $Ca^{2?}$ was observed in leachates from 340 particles $L^{?1}$ of UV-aged MPs after 18-d release. Pearson correlation analysis confirmed that the stimulation of bacterial bioluminescence was primarily associated with the release of $Ca^{2?}$ from MPs. In behavioral assays, S. nematoptera demonstrated a feeding preference for glowing MPs colonized by P. phosphoreum over non-glowing MPs, indicating that the bioluminescent properties of P. phosphoreum increased the visibility and attractiveness of the MPs to the fish. These findings suggest that interactions between MPs and bioluminescent bacteria could facilitate the ingestion of MPs by visually oriented predators, thereby increasing the potential for MP bioaccumulation and trophic transfer within marine food webs.

1.09.P-Mo073 Effects of Environmental Microplastic on Wild Wharf Roach (*Ligia exotica*) as Plastic Detritus Consumer

***Jee hyun Jung**[1], Kwang-Min Choi[1], Seong Hee Mun[1] and Young-Mi Lee[2], (1)Korea Institute of Ocean Science & Technology, Korea, Republic of, (2)Sangmyung University, Korea, Republic of*

Very few studies have clarified the toxic effects and translocation of environmental microplastics (MPs) pollution in marine resident species. To clarify the potential toxicity and gut microbial community variation on coastal resident species, wild wharf roaches (Ligia exotica) collected from Nae-do[as expanded polystyrene (EPS, commonly known as Styrofoam) uncontaminated area] and Maemul-do [as EPS-contaminated area] in south Korea. The MPs (>20 ?m) were detected highly in L. exotica from Maemul-do with average of 50.56 particles/individual. Especially, the concentration of Hexabromocyclododecanes, have been detected highly in L. exotica from Maemul-do (630.86 ±587.21 ng/g l.w.). The results of comparative transcriptomic analysis revealed significant alteration of metabolic processes, mitotic cell cycle regulation, and immune system functions (cutoff: $q<0.05$) in L. exotica from Maemul-do. In addition, the total operational taxonomic units of Ligia gut microbiome were higher in Nae-do than those of Ligia from Maemul-do. Alpha diversity showed a higher richness in Ligia from Nae-do. The relative abundance of phyla, families, and genera were different between Ligia gut microbiome from Nae-do and Maemul-do. These findings suggest that the diversity of the gut microbiome is host-specific, but the different abundances of bacterial groups may depend on diet, including plastic pollution. This work was supported by a grant Risk assessment to prepare standards for protecting marine ecosystem

of Korea institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220383).

1.09.P-Mo074 Effects of Poly(Methyl)Methacrylate (PMMA) Nanoplastics in Shore Crab *Carcinus maenas*: A Behavioural and Biochemical Assessment

*Beatriz Neves[1], **Miguel Oliveira**[2], Ricardo Pinto[3] and Adilia Pires[2], (1)University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal, (3)CICECO - Aveiro Institute of Materials, Department of Chemistry, University of Aveiro, Portugal*

Nanoplastics (NP), plastic particles in the nanoscale, may pose a significant threat to oceans and marine life due to their ability to penetrate biological membranes. These particles may disperse in the water column, eventually reaching sediments where they can interact with benthic organisms. Poly(Methyl)Methacrylate (PMMA), is a polymer with a high commercial importance, with applications in several human activities including biomedicine. Despite its increased use, there is limited knowledge regarding the effects of small particles of this polymer. Thus, this study aimed to assess the effects of PMMA NPs, on behavioural (locomotion), and biochemical endpoints (neurotransmission, antioxidant defenses and oxidative damage) of the epibenthic crab Carcinus maenas, a key species in the benthic community, with important roles in the marine food web and the nutrient cycle. The crabs were individually exposed, via water, to a concentration range (5-320 µg /L) of PMMA NPs (~513 nm), for 10 days. Results showed that crab s locomotion was significantly affected by PMMA NPs exposure, with the crabs from the highest concentrations spending more time moving, but slower than control organisms. Effects on locomotion were associated with a decrease of muscle cholinesterase activity. In gills, an increase of glutathione s-transferase (GSTs) activity was observed for all PMMA NPs tested concentrations whereas superoxide dismutase (SOD) activity only increased for 20 µg PMMA NPs/L. In hepatopancreas, increase of SOD activity was observed after exposure to 5, 20, and 80 µg PMMA NPs/L, whereas GSTs activity decreased at 5 µg PMMA NPs/L. Both tissues revealed oxidative damage, with the increase of protein carbonylation (20, 80 and 320 µg PMMA NPs/L in gills and 5, 20 and 80 µg PMMA NPs/L in hepatopancreas) and lipid peroxidation levels (80 µg PMMA NPs/L in gills and 20, 80 µg PMMA NPs/L in hepatopancreas), with hepatopancreas as the tissue more affected. Overall, suggest that PMMA NPs may have potential impacts not only at individual, but more importantly, at a population level.

1.09.P-Mo075 Microplastics in Sentinel Species (Mussels, Polychaetes and Shrimps): Accumulation, Depuration and Tissue Localization in Experimental Set Ups and in the Environment

*Nagore Blasco, Uxue Uribe, Thomas Maupas, Jennifer Huidobro, Alberto De Diego, Urtzi Izagirre, Nerea Garcia-Velasco and **Manu Soto**, Plentzia Marine Station, University of the Basque Country, Spain*

Microplastics (MPs) in the marine environment have been identified as a growing hazard to marine biota. The aim of this study is to clarify the fate of MPs in different environmental compartments and their interaction with biota through microcosm experiments and a one-year biomonitoring program. MP depuration dynamics and accumulation patterns were assessed in target tissues of different sentinel species Mytilus galloprovincialis mussel, Hediste diversicolor polychaete, and Palaemon serratus shrimp, inhabiting the water column, the sediment and the interface between both. Organisms were exposed to different sized polystyrene MPs (1, 5, 10 ?m) at different concentrations (103-105 particles/mL) up to 5 days, and left depurating 7 and 14 days. The field study was carried out during one year in the Biosphere Reserve of Urdabai (Basque Country) where water, sediment and biota were sampled seasonally. All samples were then subjected to quantitative (alkaline digestion and filtration) and qualitative (cryosectioning) examination under fluorescence microscope, and MPs were analyzed by ?-Raman image spectroscopy. After microcosm experiments, all species accumulated MPs spiked in the water column and sediment irrespective of their habitat, proving the occurrence of MP vertical transference between environmental compartments. The accumulation in tissues was MP dose and size-dependent. Regarding depuration, mussels were able to remove a large amount of MPs, with a significant reduction for small particles. However, in polychaetes the accumulation of MPs increased significantly compared to exposure. For shrimps, no discernible reduction in MPs occurred after depuration. MPs were found mainly in the lumen and epithelia of digestive tract of mussels, in the hindgut lumen of polychaetes, and in the lumen of digestive tract of shrimps. Regarding biomonitoring, mussels and polychaetes did not show seasonal accumulation of MPs neither differences among sites. Transparent PET fibers were the predominant MPs found in both organisms. This study enable to get deeper knowledge on the occurrence and fate of MPs in marine ecosystems. Funded: Basque Government (IT1743-22, IT- 1446-22) and MICINN (PID2020-118685RB-I00).

1.09.P-Mo076 Transcriptomic and Metabolomic Responses of Juvenile Rockfish (*Sebastes schlegeli*) to Fiber-Shaped Polyethylene Terephthalate Microplastics

***Seong Hee Mun**, Kwang-Min Choi and Jee hyun Jung, Korea Institute of Ocean Science & Technology, Korea, Republic of*

Microplastics (MPs) are potentially harmful factors that are widely distributed in the aquatic environment. However, the molecular mechanisms underlying the toxicity of fiber-shaped MPs remain uncertain depending on size and type. Fiber-shaped MPs (Sizes: 200-400 ?m, 3000 ?m) made of polyethylene terephthalate (fPET) were exposed to juvenile rockfish (Sebastes schlegeli) at four concentrations (0.2, 2, 20, and 200 mg/L). And the toxic effects were assessed by cytotoxicity and oxidative stress, and the toxic mechanism were identified using transcriptomic and metabolomics analysis in rockfish exposed to microplastics for 20 days. The growth rate of rockfish decreased but activity of apoptosis and phagocytosis of leukocytes were increased after exposure of fPET. The enzyme activities of glutathione S-transferases and superoxide dismutase increased in the high-concentration MPs exposure group. The liver differential expression genes (DEGs) of rockfish exposed to fiber MPs of size 200-400 ?m were related to lipid metabolic process, cellular component organization, cell differentiation, and response to stress. The DEGs of the liver of rockfish exposed to fiber MPs of size 3000 ?m were related to steroid metabolic process, developmental growth, and cell differentiation. Metabolite analysis showed abundant arachidonic acid metabolism, biosynthesis of unsaturated fatty acids, and linoleic acid metabolism, which belong to lipid metabolic processes. These results might be show the fPET exposure related to process of the antioxidant system and homeostasis maintenance in juvenile rockfish. These results will be helpful in understanding the toxic effects and mechanisms in juvenile fish exposed to fPET.

1.09.P-Mo077 Plastic Debris in Mussels: Molecular Responses and Role in Okadaic Acid Uptake and Toxicity

*Estela Pires[1], **Mario Araujo[2]**, Maria Paula Gomez[2], Mara Kutz[3], Alexandre Campos[2] and Luiz Mafra[3], (1)Parana Federal University, Brazil, (2)CIIMAR, Portugal, (3)Federal University of Parana, Brazil*

Plastic pollution poses a significant threat to marine ecosystems, particularly through the smaller fractions, namely microplastics (MPs) and nanoplastics (NPs). In addition to the toxicity associated with their direct exposure, plastic debris can also adsorb harmful biotoxins produced by microalgae. Microalgal cells can interact with or incorporate smaller plastics, potentially facilitating the transfer of these biotoxins into other marine organisms. Therefore, this study investigates the interactions between plastic debris and marine microalgae, evaluating their harmful effects on bivalve organisms from a trophic transfer perspective. Laboratory experiments were conducted to examine the transfer of NPs (0.1 or 1 ?m) to mussels via microalgae. Additionally, the role of plastic debris (~5 ?m) in adsorbing the lipophilic okadaic acid (OA) toxin and serving as vectors for its transfer was assessed. Using confocal microscopy, flow cytometry, HPLC, and omic approaches, we analyzed the NPs accumulation and alterations induced by its exposure, as well as the accumulation and effects of the adsorbed biotoxin in the digestive glands (DG) and other tissues (OT) of mussels. We anticipate that microalgae will transfer particles of varying sizes differently, leading to significant proteomic changes in mussels. Furthermore, preliminary results indicate that after three days of exposure, significantly higher concentrations of OA were detected in the DG, increasing from 1.81 ± 0.21 ng g?¹ on day 2 to 12.84 ± 4.50 ng g?¹ by day 14 in mussels treated with MPs adsorbed with OA. While alterations in gene expression and differentially expressed proteins (DEPs) are still under analysis, our findings highlight the potential for OA transfer by 5 ?m plastic particles and their associated toxicity. This work emphasizes the risks posed by MPs and NPs to trophic chain stability and safety, not only due to their direct action on aquatic organisms but also by highlighting the role of microalgae in inadvertently facilitating the transfer of harmful particles to higher trophic level organisms. This work was funded by the International Atomic Energy Agency (IAEA) via research contract PHYTOPLASTOX (RC #23548) and by the Coordination of Superior Level Staff Improvement (CAPES, Brazil) via a PhD scholarship granted to E.P. This work was also supported by the Portuguese Foundation for the Science and Technology (FCT) through the project NanoPlanet 2022.02340.PTDC, and UIDB/04423/2020 and UIDP/04423/2020 contracts. M.J.A. and A.C. also acknowledge the FCT funding for the Scientific Employment Stimulus Program (2023.06491.CEECIND and CEECIND/03767/2018, respectively).

1.09.P-Mo078 Harmonizing Data for Dietary Microplastic Exposure: Insights into Seafood and Age-Specific Risks

***Maxime Vankoningsloo[1]**, Andreja Rajkovic[2], Johan Robbens[3], Michael Dekimpe[3], Bavo De Witte[3], Tanja Cirkovic Velickovic[4], Dragana Stanic-Vucinic[4] and Mirjana Andjelkovic[1], (1)Service Risk and Health Impact Assessment, Sciensano, Belgium, (2)Faculty of Bioscience Engineering, Ghent University, Belgium, (3)Flanders Research Institute for Agriculture, Fisheries and Food, Belgium, (4)Faculty of*

Chemistry, University of Belgrade, Serbia
Over recent decades, the rapid increase in plastic production has led to heightened concerns about the pervasive presence of microplastics (MPs) in the environment. Defined as particles smaller than 5 mm, MPs are increasingly detected in various food categories, raising questions about human exposure and associated health risks. This study aims to evaluate dietary exposure to MPs, with a specific focus on seafood, and to assess the contribution of various food groups to total MP exposure. To address this challenge, we reviewed existing data on MP occurrence in bivalves and crustacea and analyzed findings from a previous study involving 218 food items purchased from mainstream food retailers. We employed exposure assessment techniques to estimate daily MP intake across three age groups (children, adolescents and adults), considering realistic and worst-case scenarios. Special attention was given to aligning and comparing data from diverse sources using standardized methodologies. Our results indicate that adults have an average MP exposure of up to 0.37 MP per kilogram of body weight per day under realistic conditions. In contrast, children experience the highest exposure, reaching 4.19 MP per kilogram of body weight per day in worst-case scenarios. These findings highlight significant variability in exposure levels based on age and dietary habits. This study highlights the critical need for harmonized methodologies to synthesize data from diverse sources, particularly in evaluating seafood as a major contributor to dietary microplastic (MP) exposure. MPs in food may act as vectors, potentially transporting contaminants and allergens, making them more significant for secondary risks than nanoplastics (NPs), which are more concerning due to their distinct toxicological profiles. By improving our understanding of MP ingestion through food, this research provides a foundation for future investigations into exposure sources, associated health risks, and strategies for mitigation. The research that yielded MP occurrence results, was funded by the Belgian Federal Public Service Health, Food Chain Safety and Environment through the contract RT 18/05 Plastic_in_Food. The complementary study and the literature review was done in the scope of IMPTOX project which was funded by The EU s H2020 framework program for research and innovation, grant number 965173 entitled An innovative analytical platform to investigate the effect and toxicity of micro and nanoplastics (MNPs) combined with environmental contaminants on the risk of allergic disease in pre-clinical and clinical studies

1.09.P-Mo079 Effects of Micro(nano)plastics on Amphibian Cell Lines
*Carolina Frazao[1], Monica Almeida[1], Miguel Tamayo-Belda[2], Ricardo Pinto[3], Isabel Lopes[1] and **Miguel Oliveira**[1], (1)Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal, (2)Department of Biology, Faculty of Science, Universidad Autonoma de Madrid, Spain, (3)Aveiro Institute of Materials, Department of Chemistry, University of Aveiro, Portugal*
Plastic materials released into the environment undergo abiotic and biotic processes that cause the formation of microplastics (MP 100 nm to 5 mm) and nanoplastics (NP < 100 nm). The increasing reports of the effects of these particles on biota have driven the search for more sustainable alternatives such as bioplastics. However, whether bio-based plastics are more eco-friendly than conventional fossil-based plastics remains uncertain. There is thus the need to increase the knowledge regarding the effects of fossil- and bio-based plastic particles, particularly for organisms under high anthropogenic stress, such as amphibians. Due to ethical constraints, direct testing on these organisms is limited, and in vitro cellular models using established cell lines appear as a potentially valuable approach to assess the risks of MP and NP. This study assessed the effects of MP and NP from two fossil-based polymers polymethylmethacrylate (PMMA) and polystyrene (PS) and one bio-based polymer, polylactic acid (PLA), on two amphibian cell lines: A6 (adult Xenopus laevis kidney epithelial cells) and XTC-2 (tadpole Xenopus laevis carcass fibroblast cells). The cells were exposed to PMMA NPs (0 400 mg/L) and PS and PLA MPs (0 200 mg/L) and cell viability was assessed using the MTT assay (after 72-hour exposure). The ability to generate reactive oxygen species was assessed using the DCFDA assay (after 3-hour exposure), and the ability to cause DNA damage was studied through an alkaline comet assay (after 24-hour exposure).
PMMA NPs had no significant impact on cell viability for both cell lines, despite the ability to increase ROS production. In contrast, PLA MPs significantly affected A6 cell viability in the highest concentration tested whereas PS MPs had no significant effect. The highest concentration of PLA and PS MPs decreased XTC-2 cell viability. Overall, the ability of plastic particles to affect DNA integrity was also shown.
Thanks are due to Portuguese Fundação para a Ciência e a Tecnologia (FCT)/MCTES for the financial support to CESAM (UIDP/50017/ 2020+UIDB/50017/2020+LA/P/0094/2020) and the project Nano Planet (DOI: 10.54499/2022.02340.PTDC) through national funds. Carolina Fraz?o was supported by FCT through a Ph.D. grant (2022.11216.BD).

1.09.P-Mo080 Adsorption and Protection of Environmental DNA (eDNA) on Polymer and Silica Surfaces

*Denise M Mitrano[1], **Roman Schefer**[2] and Celia Paolucci[1], (1)ETH Zurich, Switzerland, (2)Environmental Systems Science, ETH Zurich, Switzerland*
In environmental systems, microplastics (MPs) are found alongside environmental DNA (eDNA). eDNA is genetic material shed by organisms through decayed cells, serving as a valuable tool for non-invasive biodiversity assessments. Adsorbed onto particles, eDNA has been shown to be longer-lived than when in suspension, likely because of protection from enzymatic degradation. Consequently, measuring adsorbed eDNA on MPs could provide insights into plastics origin and environmental transport pathways. The interactions of eDNA with MPs in aquatic ecosystems is influenced by water chemistry and the surface properties of plastics, impacting the fate of genetic material. While MPs fate and transport have been studied extensively, the adsorption of eDNA onto polymer surfaces and its persistence remains less understood. Here we systematically studied eDNA adsorption onto polyethylene terephthalate (PET), polyethylene (PE), and silica (Si) surfaces, where the latter material was used as a proxy for comparison to natural particles. Using Quartz-Crystal Microbalance with Dissipation monitoring (QCM-D), the impact of varying ionic conditions that mimic freshwater and seawater environments was analyzed for adsorption rate and extent. The role of cations, particularly divalent ions such as Ca²?, in promoting eDNA adsorption through cation bridging was particularly important. PET exhibited the highest adsorption rates, followed by PE and Si. Adsorption of eDNA in seawater led to thicker and more rigid adlayers compared to freshwater conditions. However, eDNA adlayers were susceptible to enzymatic degradation and/or replacement by DNase in both freshwater and seawater, suggesting limited protection from decay. Consequently, the longevity and potential for transfer of material over time and distance is brought into question. This study provides insights into the adsorption mechanisms and stability of eDNA on MPs, advancing our understanding of how MPs influence the transport and persistence of genetic material, including antibiotic-resistant genes, in aquatic environments.

1.09.P-Mo081 Bioconcentration and Metabolism of 3H-6PPD quinone in Zebrafish (*Danio rerio*)
***Jung-Hoon Jung**, Jong-Hwan Kim, Ji-Young An and Seong-Hoon Jeong, korea institute of toxicology (KIT), Korea, Republic of*
6PPD is a commonly used antioxidant in the rubber industry. However, its oxidized form, 6PPD quinone, has recently been identified as toxic to fish. A quinone transformation product of 6PPD, known as 6PPD-Q, was isolated from TWP leachates and shown to be a major toxicant to coho salmon, as demonstrated through median lethal concentration (LC50) assays and retrospective analysis. In this study, we quantitatively measured the steady-state bioconcentration factor (BCF_ss) and metabolite concentrations of 6PPD quinone in zebrafish using radiolabeled compounds. Zebrafish were exposed to 1.0 and 10.0 ng/mL of 6PPD quinone for 24 days during the uptake phase, followed by a 7-day depuration period in the elimination phase. Based on total radioactivity residues (TRRs), the BCF_ss values were found to be 243 and 209 for the low- and high-concentration groups, respectively. During the elimination phase, a significant decrease of 85.6% and 94.7% in TRRs was observed after 5 days in the low- and high-concentration groups, respectively. Three metabolites (M-1, M-2, and M-3) were identified via Radio-HPLC. While M-1 and M-2 could not be fully characterized, M-3 was identified as monohydroxy 6PPD-Q through Q-TOF and MS/MS simulation.

1.09.P-Mo082 Histopathological Alterations in Adult Zebrafish Tissues Subchronically Exposed to Microplastics and Fipronil
***Flavio Tominaga**[1], Isis dos Santos[1], Amanda de Azevedo Valle[1], Rafaella da Silva Brito[1], Nuha Dsouki[2], Fabio Kummrow[1] and Bruno Fiorelini Pereira[1], (1)UNIFESP, Brazil, (2)FMABC, Brazil*
Microplastics (MPs; < 5 mm) contamination has emerged as a critical environmental issue due to their ubiquitous presence and negative impact on ecosystems and human health worldwide. MPs also have the capacity of adorption of toxic pollutants in aquatic and soil environments. Fipronil (FP) is a highly effective insecticide widely used to control various arthropod pests, however it can also affect non-target species. Our objective was to evaluate the histopathological alterations in adult zebrafish tissues (gills, liver, and kidney) subchronically exposed (14 days) to a mixture of microplastics and FP. Zebrafish adults were exposed to several mixtures contaning FP (0.01; 0.10; 1.0 µg/L) and a fixed concentration of polythele MP (100 mg/L). No mortality occurred during the whole experiment, nor in the control or in the exposed groups. The histological index of FP individualy indicated significant reduction in circulatory and increase in progressive changens at 1.0 µg/L. However for the mixture histological index (progressive, regressive, circulatory, and total) showed no significant differences among the mixture treatments, indicating the MP presence may reduce FP toxicity. Regarding the liver, vacuolization increased in all fish after MP and FP exposure. Moreover, about 50-100% of the exposed fish presented necrosis in liver tissues. Significant changes in the mean nuclear diameter was shown among all treatments when compared to control. Lastly, for the kidney, no significant alterations were observed in the control groups.

However, after mixture exposure, degeneration of nephron tubules was observed in all organisms. With increased FP concentrations, fish exhibited increased alterations such as a reduction in Bowman's space, increased glomerular volume, and necrosis. The current findings indicate that the mixture of FP and MPs can induce considerable damage on adult zebrafish and may promote histopathological changes in gill, liver, and kidney tissues, demonstrating also that MP can reduce FP toxicity. This research was funded by São Paulo Research Foundation (FAPESP) grant number [2022/03094-5, 2024/10993-1, 2024/01418-3, 2023/09884-0 and 2023/15540-2] and Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) grant number 153725/2024-9.

1.09.P-Mo083 Impacts of Microplastics and Glyphosate on the Microalgae *Arthrospira platensis*
Dercia Santos[1]*, Sandra Mariza Monteiro*[2] *and Ana Luzio*[1]*, (1)Centre for the Research and Technology of Agro-Environmental and Biological Sciences, CITAB, University of Tras-os-Montes and Alto Douro, Portugal, (2)Centre for the Research and Technology of Agro-Environmental and Biological Sciences, CITAB and Inov4Agro, Institute for Innovation, Capacity Building and Sustainability of Agri-Food Production, University of Tras-os-Montes and Alto Douro, Portugal*
Microplastics (MPs, particles < 5 mm) have become a pressing environmental concern with multifaceted implications for aquatic life and ecosystem health. Despite the widespread presence of MPs in aquatic ecosystems is now well-established, the knowledge about the potential toxic effects in lower trophic levels, such as microalgae, is still largely unknown. The present study aims to evaluate the potential toxic effects of polyethylene terephthalate (PET) and polyamide (POLY), isolated or combined with the pesticide glyphosate (GLY), in Arthrospira platensis. For this, A. platensis were cultured in Zarrouks medium and exposed to a control, GLY (3 µg/L), PET (0.5 and 1 mg/L), POLY (0.5 and 1 mg/L) and the respective mixtures of each MPs with GLY (GLY+PET0.5; GLY+PET1; GLY+POLY0.5; GLY+POLY1), during 12 days. The optical density was monitored at 565 nm by UV spectrophotometer. At the end of the exposure, the photosynthetic pigment content (chlorophyll a, chlorophyll b, and carotenoids), phytochemicals (total phenols, flavonoids, and ortho-diphenols), antioxidant (ABTS + and DPPH) and enzymatic (oxidative stress and detoxification biomarkers) activity were determined. Microalgae growth was affected at 4 days of exposure, suffering a significant increase in the group exposed to GLY+POLY1. Nevertheless, no significant effects were observed on the biomass and the photosynthetic pigment contents. These results indicate that MPs or GLY alone seem to have little effect on the growth and chlorophylls of A. platensis. In contrast, it was observed modulation of the detoxification mechanisms, with glutathione-S-transferase being significantly increased in microalgae exposed to POLY0.5, and carboxylesterase activity being inhibited in the PET1 and GLY+PET mixture groups. The glutathione reductase activity and reduced glutathione (GSH) also showed a significant decrease in the PET1 and POLY1 exposed groups, respectively, indicating a higher consumption of GSH. Also, exposure to GLY alone or combined with PET or POLY increased total phenols, while GLY alone decreased flavonoid levels. The present results showed that microalgae interact with MPs, which can have serious consequences for food webs, food security, and ecological health. MPs, single and combined with GLY, affected both the detoxification mechanisms and non-enzymatic defense, including the shikimate pathway, in A. platensis, highlighting that more research in this field is urgently needed. This work is supported by National Funds by FCT - Portuguese Foundation for Science and Technology, under the project UIDB/04033/2020.

1.09.P-Mo084 Visual Evidence of Multigenerational Transfer of Nanoplastics in Pea Plants
***Dokyung Kim** and Youn-Joo An, Konkuk University, Korea, Republic of*
Plants are primary producers in soil ecosystems, and micro- and nanoplastics that entered into plants can be transferred throughout the soil ecosystem. Although studies on the nanoplastic uptake for plants are continuously reported, there are limited studies on generational transfer of nanoplastics. Thus, this study aimed to determine the generational transfer of nanoplastics on pea plants. We exposed nanoplastics (Polystyrene, 200 nm) to the first generation of pea plants (F0) in soil, and the second (F1) and third (F2) generations were replanted to clean soil. We found that nanoplastics were transferred to the grandchildren of peas exposed to nanoplastics, as well as daughter peas. In addition, transmission electron microscope analysis confirmed that nanoplastics entered both the intercellular and intracellular spaces of F2 peas. These findings suggest that once absorbed into plants, nanoplastics can be persistently transferred across generations, highlighting the potential for transfer to animals and humans. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (RS-2024-00355254).

1.09.P-Mo085 Size matters less? Exploring the Cross-species Intricacies of Nanoplastics Toxicity from Zebrafish to Chicken

*Xiaoyu Duan[1], Henrik Holbech[1], Jonathan Brewer[2] and **Elvis Genbo Xu**[1], (1)University of Southern Denmark, Denmark, (2)Department of Biochemistry and Molecular Biology, University of Southern Denmark, Denmark*
Plastic pollution, particularly in the form of microplastics (MPs) and nanoplastics (NPs), is an escalating environmental concern due to their potential toxicity and ability to enter organisms through various pathways. While NPs are typically considered more toxic than MPs due to their ease of tissue penetration, the size-dependent toxicity and mechanisms of NPs across different species remain insufficiently understood. This study investigates the toxicity of polystyrene nanoplastics (PS-NPs) of 50 nm, 200 nm, and 1000 nm in two model species: zebrafish larvae (aquatic) and chicken embryos (terrestrial). The primary challenge addressed by this work is the inconsistent toxic effects and toxicity levels of NPs, which vary based on particle size and species. Understanding these effects at multiple organismal levels is crucial. We hypothesize that NP toxicity varies by both size and species, with distinct mechanisms of action for aquatic and terrestrial organisms, even at similar developmental stages. Zebrafish and chicken embryos were exposed to the same PS-NPs (0, 0.1, 1, and 10 ppm) during comparable developmental windows. Toxicity was comprehensively assessed through behavioral assays, biochemical markers, RNA sequencing, IPA analysis, and 3D imaging. Results revealed species-specific responses: zebrafish exhibited hypoactivity and neurotoxic effects, particularly with smaller NPs (50 nm), while chicken embryos displayed more pronounced morphological effects with larger particles (200 nm and 1000 nm). IPA analysis identified similar hepatic and cardiovascular dysfunctions and diseases across species after PS-NPs exposures. These findings challenge the assumption that smaller particles are always more toxic. We emphasize the need for size- and species-specific considerations in environmental risk assessments, advancing our understanding of nanoplastic toxicity across ecosystems. This study was supported by Danmarks Frie Forskningsfond (0165-00056B) and Novo Nordisk Foundation (NNF18SA0032928).

1.09.P-Mo086 Microplastics Reduce Endocytosis of Earthworm Immune Cells

***JIN IL KWAK**[1], Soi Jeong[2], Lia Kim[1], Young-Min Hyun[2] and Youn-Joo An[1], (1)Konkuk University, Korea, Republic of, (2)Yonsei University, Korea, Republic of*
Although the effects of microplastics (MPs) have been consistently studied, lack of research investigating the response of immune cells in soil invertebrates against MPs has been reported. The purpose of this study is to evaluate the effects of MPs on soil invertebrates at both individual and cellular levels. Earthworm Eisena andrei and polystyrene microplastics (PS MPs) were selected as model organism and MPs, respectively. The in vitro assay for 24 hours and soil bioassay for 14 days were carried out. The in vitro assay revealed an increase in MP internalization by earthworm amoebocytes, followed by inhibited endocytosis in earthworm coelomocytes. Similarly, results from the soil bioassay indicated that MPs soil pollution suppressed coelomocyte endocytic activity and caused mitochondrial damage in the digestive tract. The findings from the present study provide evidence of environmental immunotoxicity of MPs in soil ecosystem. Acknowledgement-This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (2021R1C1C2012628, RS-2023-00207834).

1.09.P-Mo087 Effects of Environmental Microplastics on Soil Microarthropods Survival, Behaviour and Biodiversity

***Marco Scaramelli**[1], Maria Agnese Sabatini[2], Roberto Simonini[2], Daniela Prevedelli[2] and Elisa Bergami[2], (1)Department of Life Sciences, University of Modena and Reggio Emilia; NBFC, National Biodiversity Future Center, Italy, (2)Department of Life Sciences, University of Modena and Reggio Emilia, Italy*
Microplastics (MP, size<1mm) are pervasive in terrestrial ecosystems, found not only in soils affected by various anthropogenic activities, such as urban settings, but also in remote areas due to long-range atmospheric transport and deposition. The widespread presence of MP in soils raises concern as they may negatively impact soil health and functions, as well as impair soil organisms throughout their life cycles. This study focuses on MP released by the weathering of Plastic Pavers for Parking (P3) in urban environments, aiming to: (i) assess the effects of P3-MP on collembolan species (Folsomia candida, Parisotoma notabilis, Mesaphorura macrochaeta); (ii) evaluate differences in springtails behaviour in the presence of MP; (iii) investigate the potential relationship between soil microarthropods community and MP abundance in contaminated sites using the Soil Biological Quality (QBS-ar) index. To reach the first goals, environmentally relevant MP were generated in the lab through abrasion of large HDPE fragments, collected from P3 in an urban area of Northern Italy. MP were analyzed via Scanning electron microscope (SEM) and Raman spectroscopy to ensure lack of microbial colonization and polymer degradation, respectively. Such MP were then used in bench-scale chronic (28 days, MP tested range: 0-10-100-1000mg/kg) and avoidance tests (48hours: MP tested concentration: 0-1000 mg/kg) with springtails, following OECD 232 and ISO 17512-2 protocols. As far as F. candida, a concentration-dependent increase in springtails mortality was observed after 28 days of exposure to MP. Compared to the control

group, which showed an average mortality rate of 17±5% (mean±SD), an increase up to 58±13% in springtails mortality was recorded at 1000mg/kg. MP also altered the behaviour of the collembolans, with an avoidance rate of 34±13% in the treated group, compared to the control group (avoidance rate of 3±4%). Furthermore, a field study was carried out to assess the impact of MP released from the P3 on the soil community. To this aim, soil samples were collected at increasing distances from the MP source and both MP and microarthropods extracted to determine abundance and composition. Preliminary QBS-ar index results suggest a positive correlation between the distance from the contaminated site (i.e., HDPE-P3) and soil microarthropod diversity. Our findings contribute to the understanding of MP levels and impact assessment in urban ecosystems under real exposure scenarios.

1.09.P-Mo088 Unveiling Microplastic and Metal Pollution in Giant Armadillos (*Priodontes maximus*)

Lucas GonCalves Queiroz[1], Lucas M. Barreto[2], Joao Manoel Lima Junior[3], Guilherme Maricato[4], Cassiana Seimi Nomura[1], Marcelo Pompeo[5], R mulo Augusto Ando[1] and ***Barbara Rani-Borges****[1], (1)Institute of Chemistry, University of S o Paulo, Brazil, (2)Federal University of Minas Gerais, Brazil, (3)Institute of Chemistry, University of Sao Paulo), Brazil, (4)Institute of Biology, Rio de Janeiro State University, Brazil, (5)Institute of Biosciences, University of S o Paulo, Brazil*

The Giant Armadillo (Priodontes maximus), the largest armadillo species, is classified as Vulnerable by the IUCN. In Brazil, P. maximus inhabits various ecosystems, including forests, savannas, and grasslands. The Rio Doce basin, located in the Brazilian Atlantic Forest, one of the world s primary biodiversity hotspots, has been recognized as a critical conservation area for this species. However, in 2015, the region experienced Brazil s largest environmental disaster when a mining dam ruptured, releasing approximately 60 million m³ of tailings predominantly composed of iron and containing high levels of toxic metals such as manganese, aluminum, chromium, lead, and arsenic, which have posed a lasting contamination threat to the local ecosystem. Extensive research has documented that tailings from such mining disasters are toxic to biodiversity, affecting various species through bioaccumulation and habitat degradation for example. In parallel, the widespread contamination by microplastics has raised concerns about its impacts on wildlife health, as microplastics can cause a series of negative consequences for the exposed organisms. However, the presence of this pollutant and its effects have been studied only to a limited extent in large mammals. In this study, we investigated the presence of toxic metals and microplastics in feces samples collected from P. maximus within two regions of the Rio Doce basin. Microplastics were found in all analyzed samples, displaying different shapes, sizes, colors, and polymeric compositions, revealing widespread contamination within the habitat of this vulnerable species. Additionally, high concentrations of toxic metals were detected across the samples, suggesting significant exposure of these animals to pollutants from the 2015 disaster. These findings highlight the extent of environmental pollution in critical conservation areas and its impact on vulnerable species such as P. maximus. The consistent detection of both microplastics and toxic metals in samples of the Giant Armadillo underscores the susceptibility of this species to these contaminants. Our study is the first report of the occurrence of microplastic in armadillo feces.

1.09.P-Mo089 Biodistribution of Polystyrene Nanoplastics in Mice: Advancing Analytical Techniques Using Metal-doped Plastics

Theresa Staufer[1], Verena Koptaz[2], Alice Pradel[3], Tess Brodie[4], Robert Kurhwahl[1], Deborah Stroka[4], Julia Wallner[2], Lukas Kenner[2], Verena Pichler[5], Florian Gruner[6] and ***Denise M Mitrano****[7], (1)University of Hamburg, Germany, (2)Medical University of Vienna, Austria, (3)Department of Environmental Systems Science, ETH Zurich, Switzerland, (4)University of Bern, Switzerland, (5)Center for Biomarker Research in Medicine, Austria, (6)University Hamburg, Germany, (7)ETH Zurich, Switzerland*

Contamination of plastic particles in both environmental and biological systems has prompted concerns regarding their potential for negative impacts. As humans are increasingly exposed to microplastics (MPs)- and nanoplastics (NPs), there are potential adverse health effects related to uptake and chronic exposure by such particles, but they remain unclear, in part because of analytical challenges which exist to detect trace concentrations. Various studies have reported that NPs can cross biological barriers and are taken up into cells, where they can cause stress reactions and induce immune responses. To overcome analytical challenges when assessing NPs in biological samples in laboratory settings, we propose a workflow combining three complimentary methods, namely inductively coupled plasma mass spectrometry (ICP-MS), X-ray fluorescence imaging (XFI), and imaging mass cytometry (IMC) for detection of model metal (palladium)-doped NPs (PdNPs). While ICP-MS can quantify metals and metalloids in trace concentrations in different matrices, XFI and IMC provide additional spatial resolution, even down to the cellular level. This workflow was used to quantify the temporal distribution and accumulation of PdNPs in model mouse systems, covering different biological conditions, dosages, and time frames. Short-term exposure to high particle doses showed a clear excretion pathway from the gastrointestinal tract into feces while continuous oral intake over longer time periods led to tissue accumulation of PdNPs, including in distal organs. By assessing plastic particles in complex matrices with these analytical tools, we were able to better quantify and understand uptake and translocation mechanisms of particles down to the nanoscale in mice.

1.09.P-Mo090 Detection of Model Micro And Nano Plastics in Living Cells With Synchrotron Techniques

*Alessandra Gianoncelli[1], Cristina Tufoni[2], **Sara Bozzer**[2], Francesco Guzzi[1], George Kourousias[1], Andrea Sorrentino[3], Giacomo Ceccone[4], Rita La Spina[5], Giuseppe Ricci[2] and Lorella Pascolo[2], (1)Elettra Sincrotrone Trieste, Italy, (2)Institute for Maternal and Child Health, IRCCS Burlo Garofolo, Italy, (3)ALBA SYNCHROTRON, CERDANYOLA DEL VALLES, Spain, (4)European Commission, Joint Research Centre (JRC), Italy, (5)European Commission, Joint Research Centre (JRC), Belgium*

The distribution of nanoplastics (NPs) in the environment is increasingly becoming a cause of concern for human health. The small size of these particles makes them not only prone to accumulate in the tissues of various organs but also enables them to enter cells and act as carriers of external materials and microbes. To allow strategies for investigating cellular interactions and toxicity mechanisms in different in vitro systems, we propose model nano plastics (NPs) made of the two among the most environmentally relevant polymers (polypropylene and polyvinylchloride) and properly labelled with cadmium-selenide quantum dots. The presence of these semiconductor nanocrystals gives them unique properties that enable light fluorescence imaging. Additionally, it allows for the use of synchrotron radiation X-ray imaging combined with X-ray fluorescence micro-spectroscopy (TwinMic at Elettra synchrotron) to detect NPs with high resolution by mapping the distribution of the composing element Se. The human umbilical vein endothelial cell line (HUVECs) was selected for this study as an in-vitro model, providing a relevant and reproducible system for investigating vascular toxicity and the broader effects of MNPs on human health. They were grown in a complete culture medium onto the appropriate substrates for X-ray analyses, finally exposed to relevant concentrations (20- 50 µg/ml) of QDs-PP-, PVC- NPs (50-350 nm sized) Cryo-nano-tomography was used to investigate NPs uptake and internalisation in a three-dimensional visualisation by exploiting the different absorption contrasts of the labelled NPs compared to the cell matrix. Afterwards, the Se QDs component distribution was successfully used to track, by XRF microscopy, the NPs across the cells, while endogenous elements such as Na, Mg, C and O were monitored to investigate potential biochemical changes attributed to NPs toxicity. Together with the 3D reconstruction provided by Crio-nano-tomography, two-dimensional absorption and phase contrast imaging were important to reveal morphological changes, such as the accumulation of vesicles, in response to PP-NPs. PE- and PVC- NPs exposure. In conclusion, when using proper NPs models, high-resolution 3D and 2D imaging, combined with XRF analyses, is a powerful tool for biological studies aimed at deepening our understanding of the toxicological mechanisms of pollutants on human immune response and fertility. Funding: Ministry of Health, Italy by IRCCS-Burlo Garofolo (2022 RC38/23).

1.09.P-Mo091 Effects of Polyethylene (PE) and Polyvinyl Chloride (PVC) Plastic Particles on Isolated Human Erythrocytes

*Liesa Geppner, Verena Braun, Paul Jankowski, Sandro Wariwoda, Lorenz Zoeller and **Maja Henjakovic**, Department of Medicine, Faculty of Medicine and Dentistry, Danube Private University, Austria*

Micro- and nanoplastic particles have been shown to be environmental contaminants with potential health risks. Once plastic particles are ingested or inhaled, nanoplastics and small microplastics can enter the bloodstream and affect human erythrocytes, altering their morphology, aggregation behavior and membrane integrity. It has been previously demonstrated that model particles of polystyrene (PS) can cause a deleterious effect on erythrocytes. The aim of the present study was to produce realistic polyethylene (PE) and polyvinyl chloride (PVC) particles and to investigate their effect in vitro on erythrocytes in concentrations analogous to those found in human blood. For this purpose, PE and PVC particles were initially produced via grinding and subsequent filtration to a diameter between 700 and 400 nm. Subsequently, erythrocytes were isolated from human blood samples and incubated for up to 20 hours with 1, 10 or 50 µg/mL of PE or PVC sub-microplastic particles, as well as with 100 nm and 1 µm PS model particles. Following incubation under cell culture conditions, an analysis was conducted to investigate the impact of alterations in cell number, interaction with plastic particles and resulting changes in cell morphology. The results indicate that the addition of plastic particles did not affect erythrocyte count in low concentrations. However, significant morphological alterations were observed in the erythrocytes exposed to sub-micro PE and PVC particles, as well as to micro- and nano-sized PS model particles. These findings suggest that even at physiological concentrations, plastic particle exposure may impair the ability of erythrocytes to pass through blood vessels efficiently. In future studies, the

incorporation of plasma proteins and the use of a broader range of particle sizes, will provide a more comprehensive understanding of the dynamic interactions between micro- and nanoplastics and erythrocytes under more realistic in vivo conditions.

1.09.P-Mo092 Detection of Microplastics in the Human Penis

Lars Michael Hildebrandt[1], *Jason Codrington*[2], *Alexandra Aponte Varnum*[2], *Daniel Profrock*[3], *Joginder Bidhan*[2], *Kajal Khodamoradi*[2], *Anke-Lisa Hohme*[4], *Martin Held*[4], *Aymara Evans*[2], *David Velasquez*[2], *Christina C. Yarborough*[2], *Bahareh Ghane-Motlagh*[5], *Ashutosh Agarwal*[2], *Justin Achua*[6], *Edoardo Pozzi*[2], *Francesco Mesquita*[2], *Francis Petrella*[2], *David Miller*[2] *and Ranjith Ramasamy*[2], *(1)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Miller School of Medicine, University of Miami, United States, (3)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (4)Helmholtz-Zentrum Hereon, Germany, (5)J.T. Recent investigations have shed light on the prevalence of microplastics (MPs) in human tissues, such as stool samples, lung, placenta, and cardiac tissue, sparking a crucial discourse about their health repercussions [1 6]. For humans, the primary pathways for MP exposure are ingestion, inhalation, and dermal contact. Annual intake estimates range from 39,000 to 52,000 MPs per person, predominantly through ingestion [7, 8]. These particles can penetrate the body directly via the atmosphere, drinking water, and sea salt, or indirectly through the food chain. Inhalation presents another route, with average daily intake estimated at 272 MPs, which can lead to lung inflammation and other respiratory complications [9]. Notably, recent preliminary studies indicate that MPs can impact fertility and sperm quality, thus threatening reproductive success [10]. This can include live sperm count reduction and morphological abnormalities [11]. While direct evidence linking MPs in penile tissue to erectile dysfunction (ED) is lacking, existing research on environmental factors affecting penile health and erectile function offers valuable insights. Studies such as Sorkhi et al. (2022) on microvascular perfusion, Jung et al. (2014) on neurogenic structures, and works by Jaeger & Walker (2016) and Sopko, Hannan, & Bivalacqua (2014), highlight the multifactorial nature of ED, potentially exacerbated by environmental pollutants such as MPs [12 15]. In this study, we employed laser direct infrared (LDIR) analysis to detect the existence of MPs in penile tissue of individuals undergoing inflatable penile prosthesis (IPP) placement for the treatment of ED. The detection of MPs in penile tissue would create a new avenue for the environmental impact on sexual health, prompting inquiries about the sources, pathways, and potential ramifications of MPs exposure on erectile function.

1.09.P-Mo093 Impact of Micro- and Nanoplastics on Human Monocytes: A Focus on Autophagy, Lysosomal Integrity, and Mitochondrial Function

Stefania Pezzana[1], *Claudia Vanetti*[2], *Martina Broggiato*[3], *Fiona Limanaqi*[1], *Silvia Zecchini*[1], *Elena Vezzoli*[4] *and Claudio Fenizia*[1], *(1)University of Milan, Italy, (2)Department of Biomedical and Clinical Sciences, University of Milan, Italy, (3)Department of Pathophysiology and Transplantation, University of Milan, Italy, (4)IRCCS San Raffaele Scientific Institute, Italy*

Micro- and nanoplastics (MNPs) are an emerging environmental concern due to their ubiquity and potential impacts on human health. Humans are exposed to MNPs via ingestion, inhalation, and skin contact. Recent studies have shown that MNPs can induce cellular stress by altering the autophagy-lysosomal system, meanwhile triggering inflammatory and cytotoxic responses, ultimately leading to cell death. Indeed, MNP-induced alterations at the level of the autophagy-lysosomal functions pose significant risks to cellular health by exacerbating chronic inflammation and cellular stress, thus contributing to the development of diseases like neurodegeneration, fibrosis, and metabolic disorders. However, little is known about the mechanisms of MNP internalization and their effects on human cells, especially upon intracellular organelle dynamics and functions. Here, we evaluated the impact of MNPs of different sizes, such as 0.5, 1, 5 µm, on freshly isolated human monocytes, focusing on autophagy, lysosomes, and mitochondrial function. Transmission electron microscopy (TEM) was used to examine ultrastructural MNP localization and organelles. Gene and protein expression related to the autophagy-lysosomal pathway were also analyzed using RT-qPCR and western blot, respectively. Alterations in mitochondrial functions were assessed via oxygraphy. Our results showed that MNPs are internalized by monocytes through endocytosis and accumulate within lysosomes featuring a multilamellar morphology, which went along with massive autophagosome accumulation. TEM imaging also revealed alterations in mitochondrial morphology, while oxygraphy indicated changes in the respiratory chain. Consistent with these observations, genes and proteins associated with autophagy (e.g., LC3) and lysosome formation (e.g., LAMP1) were upregulated. Notably, the evaluation of the autophagy process was performed with MNPs concentrations calculated with IC50 curve. In conclusion, this study provides novel insights into the cellular and molecular mechanisms of MNP internalization in human monocytes and highlights the potential damage caused by MNP exposure to immune cells. These findings contribute to understanding the long-term health risks associated with MNPs and underscore the need for further research on their impact on human health. This research was supported by the PNRR_PRIN23CFENI_01 grant.

1.09.P-Mo094 Investigating the Production, Reproducibility, and Particle Characteristics of Fluorescence-Labeled Micro-Nano-Plastic Reference Material and Their Possible Cell Uptake

My Vanessa Nguyen Hoang *and Lea Ann Dailey, University of Vienna, Austria*

Plastics play a crucial role in many industries due to their numerous advantageous properties, particularly in product packaging. Although designed for durability, overuse and inadequate recycling have led to significant environmental accumulation. When exposed to natural conditions, plastic fragments into smaller particles, including micro- and nanosized fragments, which accumulate in the environment and can re-enter the human system. Despite extensive research, the health effects of nanoplastics remain unclear. As the amount of micro- and nanoplastics (MNPs) in the environment is expected to rise, understanding their potential health impact is crucial. A major challenge in this area is the lack of standardized reference materials. Many studies focus on plastics with varying sizes, chemical structures, and properties, with much research centered around polystyrene (PS), leaving gaps in knowledge about other plastics. Two alternative widely-used plastics, polyethylene terephthalate (PET) and polypropylene (PP), are more interesting for cell interaction studies, due to their differing hydrophobicity and density. From this perspective detectability is an important consideration, and developing fluorescence-labeled materials could significantly improve detection. This project aimed to produce well-characterized PET and PP particles labelled with the fluorescent polymer poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT) to assess their cellular uptake and cytotoxicity in lung cell models. The particles were prepared by co-precipitating PET or PP with varying F8BT concentrations (0.8%, 3%, 5%), their size was measured via laser diffraction, and their fluorescence properties were analyzed. An in-silico model, RiskGone in vitro dosimetry, was used to calculate a theoretical delivered dose, based on which an administered dose was chosen for the uptake experiment conducted with CALU-3 or U937 cells. A desired size distribution (<1 µm) was reproducibly achieved for PET with 5% F8BT and PP with 3% F8BT. The limit of detection (LOD) and limit of quantification (LOQ) improved with higher dye loading. For PET, the LOD was 0.86 µg/mL and the LOQ was 2.61 µg/mL, while for PP, the LOD was 3.40 µg/mL and the LOQ was 10.30 µg/mL. Preliminary uptake experiments showed that PET was taken up by cells to some extent, while PP showed no measurable uptake, possibly due to insufficient sedimentation onto the cell monolayer.

1.09.P-Mo095 In Vitro Effects Of Micro- And Nanoplastics On The Human Immune System

***Martina Broggiato*[1]**, *Stefania Pezzana[2], Claudia Vanetti[3], Silvia Zecchini[2] and Claudio Fenizia[2], (1)Department of Pathophysiology and Transplantation, University of Milan, Italy, (2)University of Milan, Italy, (3)Department of Biomedical and Clinical Sciences, University of Milan, Italy*

The growing prevalence of micro- and nanoplastics (MNPs) in the environment raised concerns regarding their potential impact on human health. Chronic exposure to MNPs has been linked to inflammatory responses and immune system impairment, increasing the risk of chronic and autoimmune diseases. Previous in vitro and in vivo studies have demonstrated that MNPs can alter activity and gene expression immune cells. However, the exact mechanisms by which MNPs and aged MNPs modulate the immune system remain largely unexplored. The aim of this project is to analyze the in vitro effects of MNPs on human immune cells, focusing on the immunological pathways involved. Specifically, we evaluated MNPs cellular alterations in cell proliferation and viability, changes in gene expression and inflammatory responses, and their impact on phagocytosis. The effects of different concentrations and sizes of MNPs were evaluated on primary human monocytes. Monocyte internalization of MNPs was assessed using confocal microscopy and flow cytometry. Flow cytometry was also used to monitor the expression of immune system activation markers, and gene expression was analyzed via qPCR, focusing on genes related to antigen presentation, inflammasome, and inflammation. The same experimental procedures were applied to determine the effects of photoaged MNPs by ultraviolet (UV) exposure. Monocytes rapidly internalized MNPs, causing reduced cell viability and increased apoptosis, showing a size and dose-response relationship with immune activation. We detected increased production of some inflammatory cytokines, such as TNF? and IL8. Additionally, MNPs influenced monocyte differentiation, increasing the expression of activation markers like CD80 and HLA-DRII in classical monocytes. Gene expression analysis revealed a reduction in HLA-A expression, which may influence antigen presentation. Furthermore, levels of NLRP3 and CASP1 were reduced, suggesting decreased inflammasome activation. Notably, preliminary data also indicate that UV-aged MNPs induce a more pronounced inflammatory response compared to untreated MNPs, suggesting that photoaging may amplify the immunotoxic effects of MNPs. The findings suggest that MNPs significantly affect the innate immune response, with detrimental effects on cellular viability, inflammation, and immune function. However, more studies are needed to assess the long-term risks of MNPs exposure, focusing on in vivo models simulating chronic exposure conditions. This research was supported by the PNRR_PRIN23CFENI_01 grant.

1.09.P-Mo096 Impact of Microwave-Treated Polypropylene Microplastics on Caco-2 Cells
Raphaela Oliveira Gama Ferreira[1]*, Aoife Gowen*[2] *and Jun-Li Xu*[3]*, (1)University College Dublin, Dublin, Ireland, (2)School of Biosystems and Food Engineering, University College Dublin, ., Ireland, (3)University College Dublin, Ireland*
Plastics are subject to various forms of deterioration, including photo, mechanical, and chemical degradation. These processes break plastics down into smaller particles known as microplastics. Due to their ubiquitous presence, microplastics can come into contact with human cells, particularly through ingestion. This is especially relevant for food containers made of polypropylene (PP) one of the most widely produced plastics in Europe which is commonly used for food storage and microwave heating. Studies have shown that PP particles can be released from food containers after microwave treatment or prolonged storage. While PP has been detected in the human colon, its potential effects on human health remain unclear. To investigate these effects, the Caco-2 cell line is frequently used in in vitro experiments as a model of the intestinal epithelial barrier. Our study aimed to investigate the impact of PP particles microwave-treated on Caco-2 cells, focusing on cell viability, membrane damage, and oxidative stress. Caco-2 cells were exposed to PP particles at concentration 200µg/ml and subjected to different microwave treatment cycles (3 minutes cycle repeated 1, 5, 10 times - and a 30 minutes continuous at high power (1000 W)), for 24 and 48 hours. Cell viability was assessed using the MTT assay, cytotoxicity/membrane damage were evaluated through LDH assay, and oxidative stress levels were quantified using CellRox. The findings revealed a rise between 13 35% in cell viability across all PP microwave-treated after 24 hours of exposure. However, a subsequent decline was observed after 48 hours in all conditions, with PP Pristine and PP microwave 30 minutes continuous with the most significant decrease rates of 23% and 22%, respectively. No membrane damage was detected in Caco-2 cells following PP microwave-treated exposure. Furthermore, oxidative stress levels surged by a minimum of 74% across all experimental conditions after 24 hours, persisting at elevated levels compared to negative control samples after 48 hours. These findings align with previous studies on other plastics, highlighting oxidative stress as a potential mechanism affecting cell viability and supporting the implications of our research. Our findings contribute to understanding of the biological effects of plastic exposure, urging for continued investigation into the broader health implications of plastic usage.

1.09.P-Mo097 Intracellular Fate of Polymer Nanoparticle Systems Monitored Through mid-Infrared Photothermal Microscopy
Verena Karl[1]*, Naiara Larreina Vicente*[2]*, Mangala Srinivas*[2] *and Markus Brandstetter*[1]*, (1)Research Center for Non-Destructive Testing (RECENDT), IR & Raman Spectroscopy, Austria, (2)Wageningen University and Research, Cell Biology and Immunology, Wageningen, Netherlands, Netherlands*
Perfluorocarbon (PFC)-encapsulating poly(lactic-co-glycolic acid) (PLGA) nanoparticles (NPs) are promising 19F MRI probes, particularly for drug delivery and theranostic applications. In this study they served as model system for investigating the intracellular breakdown processes of polymer-based nanoparticle system. These processes are not yet fully understood, thus it is crucial to observe how cells process, degrade, and metabolize them after endocytosis. This understanding is essential for optimizing safety and efficacy in imaging and therapeutic applications and has implications for other polymer particle types. For investigating the intracellular fate of particle components, Mid-Infrared Photothermal (MIP) Microscopy, also known as Optical Photothermal Infrared (OPTIR) spectroscopy, was utilized. This spectroscopy technique enables precise chemical analysis by delivering component-specific spectral data. This study focused on two particle systems, nanoparticles (NPs) and nanocapsules (NCs), which were incubated with RAW macrophages for 2 and 24 hours. Spectral comparisons of cells, along with NPs, NCs, and their isolated single components, allowed the tracking of particle breakdown. Additionally, chemical maps were generated at specific wavenumbers to quantify particles within a cell. The use of OPTIR spectroscopy setup facilitates precise chemical imaging of intracellular samples by allowing spatial differentiation between particles and cellular components. Based on the results of these chemical images, points of interest inside the cells are selected and full spectral analysis is performed. This analysis revealed a significant reduction in PLGA signals after 24h inside the cells, indicative for PLGA degradation within the cells. This study highlights the potential of OPTIR spectroscopy to provide label-free and detailed insights into intracellular fate mechanisms.

1.09.P-Mo098 Valorizing Fungal Biomass from Microplastic Bioremediation
Ana Sousa[1]*, Virginia Goncalves*[2]*, Jose Carlos Andrade*[2] *and Joao Pinto da Costa*[3]*, (1)Associate*

Microplastics are ubiquitous contaminants and, recently, much focus has been placed on the potential use of bio-based methods for their removal and mitigation within environmental matrices. Among these biotechnological strategies, fungi have played a predominant role, owing to their resilience and ease of use, coupled to reduced or inexistent health risks. While the efficacy of fungal bio remediation in microplastic removal has been demonstrated, the subsequent fate of the fungal biomass remains largely unexplored. Herein, we explore the potential antioxidant and antimicrobial activities of extracts obtained from Penicillium brevicompactum used for biologically mediated removal of low-density polyethylene (LDPE). Bioremediation assays showed that the fungus was able to remove approximately 40% of the LDPE microplastics in 21 days. The generated biomass was then subjected to high-pressure extraction and the obtained extracts were tested for antioxidant and antibacterial activities. Antioxidant and antibacterial tests showed bioactivity of these extracts, and these activities may be further explored and potentiated by the inclusion of bioactive compounds derived from additional types of fungi, as currently under evaluation.
By repurposing the fungal biomass, waste generation may be minimized and reduction of the environmental impact associated with conventional waste disposal methods may be achieved. Furthermore, bioactive compounds extracted from the fungal biomass could serve as valuable raw materials for various industries, such as cosmetics, pharmaceuticals, and food additives.
While the limited bioactivity of the extracts in this study may not immediately translate into commercial applications, it underscores the immense potential of fungal biomass as a valuable resource. Further research and technological advances are needed to fully realize the benefits of this innovative approach.

1.09.P-Mo099 The Power of Electron Microscopy in Plastic Particle-Cell Interaction Studies
*Sara Michelini[1], Ema Kuresepi[1], Andreja Erman[2], Victor Ganin[3], Francesco Tatti[4], Barbara setina Batic[3], **Anita Jemec Kokalj**[5] and Damjana Drobne[5], (1)Department of Biology, University of Ljubljana, Biotechnical Faculty, Slovenia, (2)Institute of Cell Biology, Faculty of Medicine, University of Ljubljana, Slovenia, (3)Institute of Metals and Technology, Slovenia, (4)Thermofisher Scientific MSD Eindhoven Nanopor, Italy, (5)University of Ljubljana, Biotechnical Faculty, Slovenia*
Electron microscopy (EM) provides valuable insights into the interactions between particle and cells and enables detailed visualization of their effects at the cellular and subcellular levels. Scanning electron microscopy (SEM) is essential for studying cell morphology, while transmission electron microscopy (TEM) visualizes intracellular organelles and the potential ultrastructural changes caused by particle uptake. In addition, SEM coupled with focused ion beam (FIB/SEM), where an ion beam mills the sample and an electron beam images it, provides both surface and subcellular analyses in a 3D mode. The aim of our work was to evaluate the suitability and usefulness of EM on plastic particle-cell interaction studies. We used SEM, TEM and FIB-SEM to investigate the interactions between polystyrene nanoparticles and A549 cells (a surfactant-producing alveolar type II cell model). We first grew A549 cells under standard submerged conditions and treated cells with plastic particles at increasing concentrations. We then created a 3D culture model as a more realistic test system combining transwells and an air-liquid interface (ALI) setup. The SEM analysis provided valuable 3D information about the surface of the cell model highlighting the interactions of the particles with the microvilli. TEM examination showed that under standard submerged culture conditions, the particles are mainly localized in the endosomes and occasionally in the few lamellar bodies (LBs) of cells, possibly affecting the endolysosomal compartment. TEM analysis also reveals the presence of enlarged ER cisternae and secretory lysosomes at the cell surface, as well as a reduction in LBs and mitochondria-associated ER membranes (involved in surfactant production) and an increase in the number of endosomes in treated ALI samples. The FIB/SEM study provided an information of the intracellular presence of particles and LBs, while the other structures could not be identified. Here we provide evidence that electron microscopy provides valuable information on the particle-cell interactions, which could be a basis for assessing additional stress related biomarkers. We also point out the significant advantage of FIB/SEM, which makes possible in situ selection of cells to be

milled to inspect their interior. In addition, FIB/SEM on dry, and not in plastic embedded samples, allows to discriminate intracellular components with different physical properties despite similar chemical composition. This work was funded by Horizon 2020 project PlasticsFatE.

1.09.P-Mo100 A Comprehensive Analysis of Plastic Pollution in Greenhouse Agricultural Environments: The Case of Almería (Spain)

*Marina Nunnez-Rubio[1], Carlos Edo[2], Juan Manuel Valenzuela[1], Virginia Galvez Blanca[2], Chloe Wayman[2], **Gerardo Pulido-Reyes**[1], Miguel Gonzalez-Pleiter[1], Luis Fernandez Garc a-del-Rincon[3], Maria Jesus Martinez Bueno[4], Amadeo Rodriguez Fernandez-Alba[4], Roberto Rosal[2], Francisco Leganes[1] and Francisca Fernandez-Pinas[5], (1)Universidad Autonoma de Madrid, Spain, (2)Universidad de Alcala, Spain, (3)Estudios Territoriales Integrados S.L., Spain, (4)Universidad de Almer a, Spain, (5)Centro de Investigación en Biodiversidad y Cambio Global (CIBC-UAM), Universidad Autónoma de Madrid, Madrid, Spain*

The widespread presence of plastic waste in ecosystems has become a critical global concern due to its pervasiveness and associated environmental and health risks. This plastic pollution arises from various economic sectors, including intensive agricultural activities. The Almería region in south-eastern Spain hosts one of the largest areas of plastic greenhouses in the world. This study aimed to trace the fate, distribution and accumulation of mismanaged plastic waste from these greenhouses within the surrounding environment of Almería (Spain), as well as to investigate the potential of these plastics to act as carriers of plant pathogens once they reach the ecosystems. We identified, characterized and quantified plastic waste dispersed across both abiotic and biotic environmental matrices surrounding the greenhouses, extending to coastal marine areas where plastics may potentially end up, including a protected nature reserve. Additionally, we analysed the abundance of plant pathogens associated with the presence of plastics in the biotic matrices. Abiotic matrices included greenhouse and outdoor air, lagoons water, seawater, and coastal marine soils; while biotic matrices involved various wildlife populations including invertebrates, fish, rabbits, hares and foxes, in which we analysed the presence of plant pathogens attached to plastics by examining whole individuals or their faeces. Our findings revealed the presence of plastic waste in all examined environmental compartments, suggesting that a portion of this waste likely originates from the greenhouses. Furthermore, plastics were found across every animal taxon examined. Plastic waste was also present in the nature reserve, exhibiting concentrations that were not consistently lower than those in non-protected areas. This research represents the first comprehensive investigation of plastic pollution linked to greenhouse agriculture in the region of Almería (Spain). The authors acknowledge the Ministry of Science and Innovation of Spain for supporting this research through grant PLEC2021-007693 and RyC2021?034953?I.

1.09.P-Mo101 Trends in Study Quality and Reporting in Microplastics Research

*Stephanie B Kennedy[1], Darragh Doyle[2], **Magdalena M. Mair**[3], Scott Coffin[4], Win Cowger[5], Ezra L Miller[6], Ana Leticia Antonio Vital[7], Andrew Barrick[8], Kazi Towsif Ahmed[9], Andrew Yeh[10], Anna Tuulikki Kukkola[11], Lidwina Bertrand[12] and Yuichi Iwasaki[13], (1)ToxStrategies, Asheville, NC, USA, United States, (2)Department of Biological & Environmental Sciences, University of Gothenburg, Germany, (3)Statistical Ecotoxicology, Bayreuth Center of Ecology and Environmental Research, University of Bayreuth, Germany, (4)Office of Environmental Health Hazard Assessment, Sacramento, United States, (5)Moore Institute for Plastic Pollution Research, United States, (6)San Francsico Estuary Institute, Richmond, CA, USA, United States, (7)Statistical Ecotoxicology, University of Bayreuth, Germany, Germany, (8)School of Fisheries, Aquaculture, and Aquatic Sciences, Auburn University, United States, (9)Department of Fisheries Biology and Genetics, Bangladesh Agricultural University, Bangladesh, (10)Gradient Corporation, Seattle, USA, United States, (11)University of Birmingham, United Kingdom, (12)Laboratorio de Investigaciones en Contaminacion Acuatica y Ecotoxicolog a (LICAE), Centro de Investigaciones en Bioqu mica Cl nica e Inmunolog a - CIBICI, Facultad de Ciencias Qu micas, CONICET, Universidad Nacional de Cordoba, Argentina, (13)National Institute of Advanced Industrial Science and Technology (AIST), Japan*

Interventions through published recommendations or perspective articles are a common practice to advance scientific research and create more reliable output from experimental studies. In 2020, de Ruijter et al. defined quality reporting criteria for microplastic effect studies (with extensions added by Mehinto et al. in 2022). Since then, the number of publications on microplastics effects on organisms and human health-related endpoints has increased exponentially and it is unknown, whether de Ruijter s intervention resulted in effects on study quality in the microplastics community. The Toxicity of Microplastics Explorer (ToMEx) 2.0 database contains quality scores for almost 300 microplastic ecotoxicity studies published through January 2023, including technical quality scores and scores aimed at defining adequacy for use in environmental risk assessments. We used these data to assess whether microplastics study quality has changed over time and how the quality of reporting is associated with the taxonomic group of the test organism and journal impact metrics. We found that most studies reported basic technical aspects like the name of the test species, the polymer type of the particles, particle shape and size and characterstics of the experimental design (e.g., exposure duration, sample size), but information involving more complicated procedures like, for instance, measurements of background contamination, anlytical investigation of the chemical purity of the particles and the verification of exposure were missing more often. In addition, we found that many studies in ToMEx 2.0 did not comply with necessary risk assessment criteria including the testing of aged or biofouled particles or following a proper dose-response design with more than three concentration levels. We show that over the years and by January 2023, study quality according criteria from de Ruijter et al (2020) and Mehinto et al (2022) has not increased. Study quality however correlated slightly with journal impact factors. We further found that research on some taxa achieved higher than average quality scores (Mollusca, Annelida, Crustacea, Hexapoda/Insects) whereas studies on fish received scores lower than average. We emphasize the importance of high quality reporting and test designs and discuss how better reporting practices and knowledge about requirements for risk assessments can contribute to create publications with higher impact on regulation in the future. M.M.M. is grateful for funding from the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) SFB 1357 391977956.

1.09.P-Mo102 Paint: A Ubiquitous Yet Disregarded Piece of the Microplastics Puzzle

***Zoie Taylor Diana**, Yuying Chen and Chelsea M. Rochman, Department of Ecology and Evolutionary Biology, University of Toronto, Canada*

Microplastics are widespread pollutants. Microplastics generated from the wear and tear of paints and coatings have recently been modeled to be a large source of microplastics to the environment. Yet, studies focused on microplastics broadly frequently overlook paint microplastics. In this article, we systematically reviewed the primary literature (turning up 53 relevant articles) on paint microplastic sources, identification methods, environmental concentrations, and toxicity to model organisms. Examples of sources of paint microplastics include paints from buildings and murals, crafts and hobbies, cars and roads, marine boats and structures, and industrial systems like pipes, sewers, and other infrastructure. Paint microplastics have been quantified in several marine samples from Europe and, to a lesser extent, East Asia. Reported concentrations of paint microplastics are up to 290,000 particles per kilogram of sediments, with the greatest concentration reported near a graffiti wall. Out of the toxicity studies testing paint microplastics, there have been 68 tested effects in total across all endpoints and organisms and 17 quantified lethal concentration 50% doses (ranging from 0.001 to 20g/L). Of the tested effects, 45 observed endpoint values in the paint treatment were significantly different from the control (66%) most of which were tests using antifouling paints. Overall, the number of studies on paint microplastics is small, limiting a holistic understanding of microplastics. Based on our synthesis of the state of the science on paint microplastics, we suggest a research agenda moving forward informed by research gaps. We thank Environment and Climate Change Canada (ECCC; Y.C., C.M.R.) and the Liber Ero Postdoctoral Fellowship (Z.T.D.) for supporting this research.

1.09.P-Mo103 Sniping the Hotspots: Identification, Analysis and Elimination of Microplastic by Microflotation from Sedimentation Tanks

***Stefan Grass**, Mike Wenzel and Marina Huber-Gedert, MicroBubbles, Germany*

From the past few years, Micro- and Nanoplastic (MNP) has been identified as one of the most emerging threats to human health and eco systems. After decades of promises for circular economy, we are standing at 9% global recycling rate whilst plastic production didn´t peak, yet. Facing the increased MP pollution issues in an economic way, we developed a combined and scalable approach comprising the three following steps: 1. Identification of the MP hotspot by rapid measurement methods, 2. profound analysis accounting for size and polymer distribution of items and masses, and 3. an eliminating microflotation step, which is adjustable for various aqueous environments and incoming MP concentrations. Hydrophobic interactions between particle and microbubble interfaces are the driving forces for separation. Since these interactions are not highly selective for MP only, there is a strong need for focusing on appropiate hotspots enabling higher removal effiencies and preventing unintended discharge of common biological materials. In this context, tire and road wear particles (TRWP) are considered as the most abundant MP class and, hence, sedimentation tanks are focused as time variant hotspots directly connected to polluting infrastructures. In this study, state-of-the-art analysis techniques are used to qualify MP removal efficiencies for prototype systems under model water and environmental conditions in a semi-technical lab scale and representatively selected sedimentation tanks, accordingly.

1.09.P-Mo104 Development of Methods For Materials and Analytical Techniques of Metal Embedded Nanoplastics and their Application to Environmental Behavior Evaluation

***Hyojung Choi*[1]**, *Kyoung-Woong Kim[1] and Byung-tae Lee[2], (1)Gwangju Institute of Science and Technology, Korea, Republic of, (2)Advanced Institute of Instrumental Analysis, Gwangju Institute of Science and Technology, Korea, Republic of*

Plastics that enter the environment undergo a weathering process through chemical (e.g., photodegradation) or physical (e.g., abrasion) pathways, which promotes fragmentation into smaller particles and the generation of microplastics. In particular, microplastics smaller than 1000 nm are classified as nanoplastics, which are more prevalent in the environment and have high mobility, making them important carriers of other pollutants. Recently, studies have increased showing that nanoplastics can be absorbed by flora and fauna, posing serious threats to ecosystems and human health. This has highlighted the need for research to understand the environmental behavior and characteristics of nanoplastics. Conventional nanomaterial analysis methods (e.g., SEM, TEM, DLS) face limitations in the quantitative analysis of nanoplastics due to difficulties in distinguishing them from background particles and calculating particle number concentrations. This study aims to develop materials for investigating the environmental behavior of nanoplastics and to establish quantitative analysis techniques based on these materials. We synthesized nanoplastic materials embedded with rare metals using general-purpose resins such as polystyrene (PS), polyvinyl chloride (PVC), and the hydrophilic polymer polyvinyl pyrrolidone (PVP). This study proposes methods for characterizing these materials, classifying nanoparticles by size, and calculating particle number concentrations and size distributions of nanoplastics based on the size and concentration of metal ions using single particle inductively coupled plasma mass spectrometry (spICP-MS). The metal-embedded nanoplastic materials offer the advantage of being easily distinguishable from background particles in complex matrices due to the element specificity of spICP-MS, allowing for precise quantification of the behavior of various nanoplastic mixtures under identical experimental conditions. Additionally, this method can be applied to assess and predict the behavior of nanoplastics (e.g., weathering, aggregation, mobility) under various laboratory-based environmental conditions.

1.09.P-Mo105 Detailed Characterization of Polymers and Microplastics by KMD Plots of Complex MS Spectra

***Arnd Ingendoh*[1]**, *Volker Sauerland[1], Toshiji Kudo[2] and Kushal Modi[3], (1)Bruker Daltonics & Co KG, Germany, (2)Bruker Japan, Yokohama, Japan, (3)Bruker Inc, United States*

For the analysis of microplastics, a detailed material characterization can be essential to identify its origin, fate and potential toxicity. Since most of these plastic samples comprise of a complex mixture of ingredients including several types of polymers and co-polymers plus various end groups, the mass spectral analysis can be quite complicated. Here, we introduce MALDI-TOF-MS in combination with Kendrick Mass Defect (KMD) plots as a powerful and convenient tool for assessing information from microplastics. The benefit of the KMD plot is its ability to simplify the interpretation of complex polymer spectra. By plotting polymer signals on a two-dimensional plane based on their KMD values, a clear linear trend emerges with the addition of repeat units, facilitating easier interpretation even for mixed samples. This unique feature makes the KMD plot invaluable for unraveling the composition and structure of intricate mixtures in plastic material. An autoflex maX MALDI-TOF (Bruker) was used in positive reflector mode for data acquisition of model plastic samples. Samples were dissolved in THF at a concentration of 10 mg/ml and mixed with matrix as well as NaTFA for an increased ionization efficiency. The acquired mass spectral data were processed by the flexAnalysis software for peak picking and external calibration with the Bruker fleXstandard polymers, followed by data analysis in Polytools 2.0 (Bruker) for KMD plot display and homopolymer assignment. In addition, Polymerix 3.01 (Sierra Analytics,; Modesto, CA). was used for copolymer spectra interpretation. Data will be shown from various complex plastic and polymer samples. With the extremely high complexity of the spectra, a manual spectrum interpretation becomes very time consuming or even impossible to perform. In the KMD plot, the various polymers show up in horizontal or diagonal lines or grid-like structures revealing the polymer subunit including the presence of co-polymers, possible oxygenation and various end groups. PolyTools generates a resulting table summarizing the information from the KMD plot. For those distributions in the KMD plot which were assigned to copolymers, a further investigation was carried out by Polymerix. E.g., samples revealed propylene glycol, esters of one propylene glycol with phthalic acid (PGPA) as monomer B.

1.09.P-Mo106 Accurate High Throughput Microplastics Characterization on Aluminum-Coated Filter Using the Agilent 8700 Laser Direct Infrared (LDIR) Chemical Imaging System

Wesam Alwan[1] and ***Andreas Kerstan*[2]***, (1)Agilent Technologies, Australia, (2)Hewlett-Packard-Str. 8, Agilent Technologies*

Indeed, microplastic pollution has become a significant environmental concern due to its potential impacts on ecosystems and human health. The Agilent Laser Direct Infrared (LDIR) chemical imaging system represents an innovative approach to imaging and spectral analysis, particularly in the context of microplastic identification and other applications that require chemical characterization of materials. Depending on the level of suspended solids presents, ASTM D8333 describes the steps required for microplastics sample preparation. Regardless of analysis technique used, samples with various levels of microplastics eventually require a filtration step. At present, the Agilent 8700 LDIR microplastics sample introduction can be achieved directly on gold-coated filters. To minimize the cost associated with gold-coated filters while maintaining easy and efficient sample introduction method, accurate microplastics characterization with the 8700 LDIR can be performed on aluminum-coated polyester filters. This study outlines the utilization of the Agilent 8700 LDIR in achieving accurate microplastics characterization on aluminum-coated filters in terms of particles detection, particle count repeatability, particle size accuracy and identification of common microplastics.

1.09.P-Mo107 Micro- and Nanoplastics — A Wish List for Reliable Determination of the Risks for Humans

Dana Kuhnel[1]*, Anita Jemec Kokalj*[2]*, Anja Franziska Ruth Marie Ramsperger*[3]*, Damjana Drobne*[2]*, Anna Undas*[4]*, Annegret Potthoff*[5]*, Korinna Altmann*[6]*, Willie Peijnenburg*[7]*, Nina Jeliazkova*[8]*, Anani K. Afanou*[9]*, Martin G.J. Loder*[10]*, Christian Laforsch*[10]*, Rudolf Reuther*[11] *and Bernd Moritz Giese*[12]*, (1)Helmholtz Center for Environmental Research, Germany, (2)University of Ljubljana, Biotechnical Faculty, Slovenia, (3)University of Bayreuth, Animal Ecology I & BayCEER, Germany, (4)Wageningen Food Safety Research, part of Wageningen University & Research, Netherlands, (5)Fraunhofer Institute for Ceramic Technologies and Systems IKTS, Germany, (6)Bundesanstalt fur Materialforschung und -prufung, Germany, (7)Institute of Environmental Sciences, Leiden University; National Institute of Public Health and the Environment, Centre for the Safety of Substances and Products, Netherlands, (8)Ideaconsult, Sofia, Bulgaria, (9)National Institute of Occupational Health, Norway, (10)University of Bayreuth, Animal Ecology I & BayCEER, Bayreuth, Germany, (11)ENAS Environmental Assessments, Germany, (12)Institute of Safety and Risk Sciences, BOKU University, Austria*

The assessment of risks to human health from micro- and nanoplastics (MNPs) and their associated chemicals is hampered by significant uncertainties and data gaps regarding human exposure, biological fate and potential health effects. There is also a notable lack of validated test MNPs, natural particles to serve as reference controls, and lack of harmonised toxicological assessment methods specifically designed for the unique properties of MNPs. These limitations contribute to data scarcity and further complicate exposure and hazard assessment for MNP and their associated chemicals. The European research cluster CUSP (https://cusp-research.eu/) aims to fill these gaps by providing reliable data and suggests approaches for assessing human exposure and health risks associated with MNPs and their associated chemicals, including contaminants. As part of this initiative, five projects address the health risks of MNPs from different perspectives, focusing on different exposure pathways and health effects. In particular, the PlasticsFatE project (https://www.plasticsfate.eu/) structures the data requirements and developes strategies to overcome both general and material-specific barriers to MNP in hazard and risk assessment. Based on safety research on engineered nanomaterials, which has shown that it is impossible to experimentally test all MNP variants and their chemical mixtures, CUSP emphasises the need for pragmatic approaches. These approaches aim to effectively utilize knowledge from nanomaterial research, emphasize the reuse of generated data on fate and effects of MNPs, as well as identify and address data and knowledge gaps along with uncertainties, while considering the specific properties of MNPs and test approaches. This poster provides a structured overview of the current challenges in the risk assessment of micro- and nanoplastics and introduces the first step of categorising the different types of obstacles. Specific strategies to overcome these different types of challenges will be presented. This work was funded by the European Union s Horizon2020 Research and Innovation Programme, under the Grant Agreement number 965367 (PlasticsFatE).

1.09.P-Mo108 Detection of Microplastics in Amniotic Fluid and Placenta in Preeclampsia and Healthy Full-Term Pregnant Women without Underlying Conditions

DaEun Jeong[1]*, Bo Young Choi*[1]*, Min Jung Lee*[1]*, Juyang Kim*[2]*, Yunjeong Lee*[2]*, Jaehak Jung*[2] *and Hyeon Ji Kim*[1]*, (1)Department of Obstetrics and Gynecology, Seoul National University Bundang Hospital, Seoul National University College of Medicine, Korea, Republic of, (2)Korea Institute of Analytical Science and Technology, Korea, Republic of*

Microplastics (MPs) are now ubiquitous in the environment and can enter the human body through various exposure routes. Concerns have risen around their impact on human health, especially in vulnerable populations such as pregnant women and their fetuses. Preeclampsia (PE), a pregnancy-specific hypertensive disorder, is characterized by high blood pressure and organ dysfunction, often linked to placental vascular abnormalities and inflammatory responses. Although studies have confirmed MPs in placental and amniotic fluid samples, data linking MPs to perinatal complications, such as PE, remain scarce. Given that MPs may induce inflammation and oxidative stress, their presence could exacerbate PE-related placental dysfunction, posing risks to both maternal and fetal health. This study aims to systematically detect and analyze MPs in amniotic fluid and placental samples from pregnancies complicated by PE and compare these findings with MPs detected in samples from healthy, full-term cesarean deliveries in women without PE or other underlying conditions. Under appropriate IRB approval, informed consent was obtained from pregnant women scheduled for cesarean delivery at Seoul National University Bundang Hospital. During the procedure, amniotic fluid and placental samples were collected, adhering to stringent protocols to prevent plastic contamination. Cotton, glass, and metal instruments were exclusively used for sample handling and storage. MPs were detected using ?-Raman spectroscopy following extensive pre-processing to eliminate organic materials. Blank control tests were conducted to ensure that air, collection instruments, and pre-processing reagents were free of plastic contamination. We analyzed MP particle size, type, and concentration, comparing findings between PE and healthy, full-term control groups. Additionally, inflammatory markers in amniotic fluid (e.g., CRP, interleukins, MMPs) were measured via ELISA to assess differences in inflammatory responses between the two groups.

1.10.A Exploring the Complex Dynamics and Ecotoxicological Impacts of Micro- and Nanoplastics in Aquatic Systems

1.10.A.T-01 Exploring Vegetation Complexity as a Driver of Microplastic Accumulation in Coastal Marshes

Hayley McIlwraith[1]*, Penelope Lindeque*[2]*, Trevor Tolhurst*[3] *and Matthew Cole*[2]*, (1)Plymouth Marine Laboratory and University of East Anglia, United Kingdom, (2)Plymouth Marine Laboratory, United Kingdom, (3)University of East Anglia, United Kingdom*

Coastal vegetated wetlands, such as mangrove forests, seagrasses, and saltmarshes, are thought to act as traps for both macro- and microplastic pollution. While microplastics occurrence in coastal vegetated sediments is well documented, there is conflicting evidence on whether the presence of vegetation enhances microplastics trapping relative to unvegetated sites. There are many potential underlying drivers of microplastic entrapment that have yet to be explored. Through a combination of laboratory flume experiments and field observations, we investigated three factors influencing microplastic trapping in vegetated wetlands: vegetation structure, species diversity, and microplastic type. In a controlled flume experiment we tested the effects of grassy and branched forms of vegetation structure and microplastics that differed in shape, size, and polymer type on microplastic trapping efficiency. Following this, we collected sediment samples from four levels of species diversity across a saltmarsh (Blakeney National Nature Reserve, United Kingdom) to explore how microplastic accumulation patterns change from the laboratory to the field. Quadrats (N = 20; n = 5) were randomly stratified in areas with no vegetation, monospecific grass (Spartina anglica), monospecific branched (Atriplex portucaloides), and diverse (>3 species) sites. From the laboratory experiment we observed that the presence of vegetation did not affect the number of microplastics trapped but did affect location of deposition. Microplastic shape, rather than polymer, was the dominant factor in determining whether microplastics were retained in the sediment or adhered to the vegetation canopy. We predict that our field observations will reveal similar patterns to the flume experiment in addition to highlighting interacting effects from both biological and physical processes. The outcome of this work will enrich our understanding of coastal vegetation as a microplastics sink and inform where hotspots of microplastic accumulation are most likely to occur within a biogenic canopy. By increasing our understanding of microplastics pollution within highly valued coastal habitats, we can aid protection, restoration, and potential clean-up efforts.

1.10.A.T-02 Leaching Potential of Weathered Ocean Plastics: Insights from Cross Sectional Metals Analysis and Mapping

Lyndsey Hendriks[1]*, Denise M Mitrano*[2] *and Matthias Egger*[3]*, (1)University of Vienna, Austria, (2)Department of Environmental Systems Science, ETH Zurich, Switzerland, (3)Ocean Cleanup, Netherlands*

Plastic pollution poses an environmental threat, with millions of tons of waste entering the oceans annually. Once in the ocean, plastics undergo various aging processes due to their prolonged exposure to harsh marine environments including UV radiation from sunlight, wave and wind stress, mechanical abrasion, thermal oxidation, and biodegradation. Through these weathering processes, their chemical and physical properties are altered and hazardous metals natively in the plastics can be released. Alternatively, inorganic substances in the water can sorb onto the plastic surface. While analytical techniques such as

FT-IR and Raman spectroscopy are commonly used to assess polymer composition, they do not allow for the detection of inorganic substances, such as metals, within the plastic matrix. This study aims to address metal distribution within pristine and ocean-weathered plastic items recovered from marine environment to better understand potential pollutant uptake and release. Laser Ablation Inductively Coupled Plasma Time-of-Flight Mass Spectrometry (LA-ICP-TOFMS) allows to perform elemental mapping with high spatial resolution. By sectioning plastic samples and scanning their cross-sections, it provides a deeper understanding of metal distributions, patterns of accumulation, and leaching tendencies. Our analysis identified distinct metal distribution patterns, including: (1) surface enrichment of biofilm-associated elements such as Na and Mg, (2) uniform distribution of some metals such as Al, Cu, and Zn, potentially used during manufacturing, (3) gradual surface-to-core increases in elements like Mg, Ca, I, suggesting adsorption, and (4) leaching of manufacturing-related elements like Sb. Correlation analyses further distinguished elements likely acquired during marine exposure from those originally incorporated into the plastic during manufacturing. This study demonstrates the potential of LA-ICP-TOFMS mapping for detailed profiling of weathered plastics, providing critical insights into pollutant dynamics in marine environments. These findings enhance our understanding of metal uptake and leaching in weathered plastics, contributing to the assessment of ecological risks and informing strategies for managing plastic pollution in marine ecosystems.

1.10.A.T-03 A High-Resolution Spatial Model to Predict the Distribution of Microplastics in European River Basins: ePLAS

***Yichen Sun*[1]*, Jikke van Wijnen*[2] *and Ad Ragas*[3]*, (1)Radboud university, Netherlands, (2)Open univeristy, Netherlands, (3)Radboud univeristy, Netherlands*

Microplastic pollution has emerged as a pressing environmental concern, particularly in aquatic ecosystems where rivers act as key conduits transporting these pollutants. While models for microplastic transport in river systems do exist, they are typically limited to smaller-scale environments or single catchments, and comprehensive, high-resolution models for extensive geographic regions like entire countries or continents remain scarce. This study utilizes the existing ePiE (Exposure to Pharmaceuticals in the Environment) framework, integrating it with multimedia box modeling to assess the fate of microplastics within the lacustrine and riverine systems at a high spatial resolution (~1x1 km). Our approach combines per capita emissions of microplastics with spatially detailed data on wastewater treatment plant (WWTP) locations and characteristics across Europe. This integration allows for precise predictions of microplastic concentrations at specific coordinates downstream of emission points. The model considers distinct physical properties of microplastics (size, shape, and density) and incorporates various fate processes such as advective transport, heteroaggregation, sedimentation-resuspension, burial, and bed load transport, thereby providing a comprehensive analysis of microplastic dynamics in water and sediment layers. Initial observations from a case study conducted in the Elbe River Basin suggest that the model can identify potential hotspots of microplastic accumulation, demonstrating its potential as a promising tool for developing strategies to mitigate the environmental impact of these contaminants.

1.10.A.T-04 Investigations of Fragmentation, Aggregation and Settling of Microplastic in Complex Riverine Environments

***Lucas Kurzweg*[1]*, Oliver Kretschmar*[1]*, Martin Socher*[1]*, Andreas Fery*[2] *and Kathrin Harre*[1]*, (1)Dresden University of Applied Sciences, Germany, (2)IPF Dresden, Germany*

Polymeric materials (PM), including microplastics (MP) and nanoplastics (NP), undergo complex transformation processes in riverine systems, altering their size, shape, density, and surface chemistry. These transformations, driven by factors like flow conditions, polymer properties, and environmental factors, are crucial for understanding MP behaviour and their ecotoxicological impacts. A holistic approach including fragmentation, aggregation and settling on PM is presented to improve the understanding of MP in complex aquatic environments. Fragmentation experiments using a Taber Abraser demonstrated that MP release rates vary by polymer type, with polystyrene exhibiting the highest rates and polyamide the lowest. Despite differences in release rates, particle size distributions were consistently bimodal, suggesting overlaying fragmentation mechanisms and a mechanical fragmentation threshold. Shore D hardness was identified as a key predictor of MP release, with insights to support the development of models that estimate MP release during bed load transport using sediment transport data. Aggregation and sedimentation experiments focused on low-density polyethylene (LDPE) particles modified by UV irradiation and biofouling. Surface modifications reduced hydrophobicity, increasing water affinity and enhancing particle aggregation and settling. Laboratory and environmental experiments, including field exposure studies in the Elbe River, revealed that modified LDPE particles are more likely to settle under specific conditions, despite their low density. These findings provide a framework to evaluate how laboratory results translate to real-world riverine processes. This research highlights the importance of considering polymer-specific behaviours in MP monitoring strategies and transport models. By incorporating dynamic changes in particle size and shape, the study offers practical tools for assessing MP release and transformations in aquatic systems. Ultimately, the findings enhance the understanding of MP ecotoxicological impacts, supporting effective river management and pollution mitigation strategies.

1.10.A.T-05 Microplastic Fate and Transport in Rivers: A Flume Experiment

David Mennekes[1], *Francesco Parrella*[2], *Viola Dully*[2] *and Denise M Mitrano*[2], *(1)Environmental Systems Science, ETH Zurich, Switzerland, (2)ETH Zurich, Switzerland*

Microplastic (MPs) pollution in aquatic environments has become a growing concern and understanding their fate in rivers is important to predict particle exposure as part of an environmental risk assessment. To date, a growing number of studies have focused on the interactions between MPs and sediments, while the sedimentation of MPs in such systems has hardly been investigated. Here we constructed an experimental flume setup designed to capture MPs dynamics in flowing water and predict their sedimentation probability based on tracked particle trajectories. We developed a low-cost, reproducible setup using a GoPro Hero12 Black camera and developed Python code in-house to analyze videos. Using 3D printed sediment beds of varying grain sizes (plane, sand-sized, and gravel-sized), MPs fragments of five different polymer chemistries (PET, PA, PS, PE, PP) with densities ranging from 0.90 to 1.4 g/cm^3 in three discrete size classes (ranging from 100 µm to 1000 µm) were assessed. Water flow velocities reached up to 0.2 m/s with a slope of up to of 1%. MPs sedimentation velocities varied with polymer type, particle size and flow conditions, in agreement with established sedimentation theories. However, small particles, particularly under highly turbulent flow conditions with rougher sediment beds, remained in suspension regardless of polymer density. Finally, we found that the cavity traps observed were not sufficient to settle larger MPs with densities lower than water (e.g., PP) despite turbulences introduced from the sediment bed. In summary, our findings could be used in existing MPs fate and transport models to predict large-scale exposures in water bodies, which can improve environmental risk assessments.

1.10.B Exploring the Complex Dynamics and Ecotoxicological Impacts of Micro- and Nanoplastics in Aquatic Systems

1.10.B.T-01 New versus Naturally Aged Greenhouse Cover Films: Degradation and Micro-Nanoplastics Characterization under Sunlight Exposure

Carmen Sorasan[1], ***Patricia Taladriz-Blanco***[2], *Laura Rodriguez-Lorenzo*[3], *Begoña Espina*[3] *and Roberto Rosal*[1], *(1)Department of Analytical Chemistry, Physical Chemistry and Chemical Engineering, University of Alcala, Spain, (2)Adolphe Merkle Institute, University of Fribourg, Switzerland, (3)International Iberian Nanotechnology Laboratory, Portugal*

Micro- and nanoplastics generated by the degradation of plastic products can persist in the environment for prolonged periods, contributing to pollution and posing risks to wildlife and human health. Their presence has been documented across various ecosystems, including soil, and in food and beverages. Compared to macro- and mesoplastics, micro- and nanoplastics (MPLs and NPLs) exhibit distinct behaviors and physicochemical properties. The formation of smaller MPLs and NPLs via photodegradation has been demonstrated in earlier research, including studies quantifying NPLs derived from MPLs of polystyrene (PS), polypropylene (PP), and low-density polyethylene (LDPE) under UV exposure, as well as investigations into MPL formation from LDPE films with varying crystallinity. Additionally, Sorasan et al. identified NPLs emerging during the photoaging of LDPE in water and from marine plastic debris containing PE, PP, and PS, while Song et al. reported MPLs and NPLs in weathered expanded PS containers. Other studies have examined the release of MPLs and NPLs from diverse plastic items, such as tea bags, clothing during laundering, and disposable coffee cups. However, many of these investigations overlook the varying effects of aging on naturally aged (used) plastics compared to new ones. To gain an in-depth understanding of particle quantity and size distribution resulting from the photodegradation of greenhouse LDPE cover films, we analyzed both new and used LDPE films over six months using advanced nanotechnology methods. These cover films, originating from Almeria, Spain, where more than 30,000 hectares are devoted to greenhouses, underscore the importance of our work due to the typical six-month planting and harvesting cycle of most vegetables in this area. Raman spectroscopy, electron microscopy, and nanoparticle tracking analysis were utilized to characterize the chemical signatures, size and shape distributions, and concentrations of the plastic particles released following simulated sunlight exposure over this period. Our study showed that new and naturally aged greenhouse cover films release nanoplastics and exhibit different micro- and nanoplastic release behaviors. Importantly, our data highlight the importance of using multiple techniques to analyze the release of nanoplastics from the degradation of plastic products.

1.10.B.T-02 Unveiling the Leaching Dynamics of Hydrophobic Additives from UV-Weathered Plastics Using a Cosolvent Approach

Jiejie Ma[1], *Deedar Nabi*[1], *Aaron Beck*[1], *Annika Jahnke*[2] *and Eric P. Achterberg*[1], *(1)GEOMAR, Germany, (2)UFZ, Germany*

Plastics exposed to UV radiation undergo surface weathering, leading to physical degradation and chemical transformations that affect their environmental behaviour. This study focuses on the leaching dynamics of hydrophobic additives from UV-weathered custom-made polyethylene (PE) and polyvinyl chloride (PVC) materials with known polymer chemistry and additive compositions. While most studies simulate aquatic environments by submerging plastics during UV weathering, this work uniquely explores surface (dry) UV weathering followed by immersion in a cosolvent system to mimic environmental leaching scenarios. Custom plastics were exposed to UV light for up to 48 hours, during which significant visual changes were observed. PE materials exhibited varying degrees of discoloration, influenced by the type and concentration of additives such as UV stabilizers, antioxidants, and flame retardants. PVC samples showed pronounced degradation in the absence of stabilizers but remained visually stable when additives like Tinuvin P were present. These results highlight the protective roles of specific additives against UV-induced surface weathering. To study leaching behaviour of hydrophobic additives, a cosolvent system of acetonitrile and water was used, addressing challenges posed by extremely low solubility and slow leaching kinetics in pure water. Results indicated that leaching rates increased with higher acetonitrile concentrations. However, UV exposure effects on leaching were inconsistent, with lower additive concentrations observed in UV-exposed samples compared to dark controls. This discrepancy suggests formation of transformation products, or redistribution of surface additives, as supported by the US EPA s Chemical Transformation Simulator. By employing a cosolvent approach, this study condensed environmental leaching timescales into laboratory experiments, enabling accurate quantification of hydrophobic additives in pure water. These findings provide insights into the environmental fate of hydrophobic additives and highlight the complexity of additive leaching dynamics under UV exposure. Future research should focus on understanding transformation products and surface additive interactions to better predict environmental impacts.

1.10.B.T-03 Unveiling the Multi-Tier Effects of Commercial PVA-based Dishwasher Pods on Danio rerio Embryos: Insights on the Role of Additives

Giada Caorsi[1], *Cristina Cremonesi*[1], *Lara Nigro*[2], *Marco Aldo Ortenzi*[3], *Stefano Gazzotti*[3], *Silvia Giorgia Signorini*[2], *Riccardo Sbarberi*[2], *Stefano Magni*[4], *Camilla Della Torre*[2] *and Andrea Binelli*[2], *(1)University of Milan, Italy, (2)Biosciences, University of Milan, Italy, (3)Chemistry, University of Milan, Italy, (4)Biosciences, University of Milan, Milan, Italy*

Water-soluble polymers (WSPs) are synthetic polymers widely applied in industrial, medical, and consumer products. Despite their prevalence, WSPs are not regulated as plastics or chemical contaminants, leading to the lack of monitoring, production estimation, and circular economy action plans. This regulatory gap allows their uncontrolled release into aquatic ecosystems, raising considerable concerns about their potential risks to organisms and human health. Therefore, this study aims to evaluate the potential effects of polyvinyl alcohol (PVA), one of the most common WSPs, comparing the standard powder, and PVA-based dishwasher pods in both powder and liquid form, on the freshwater biological model Danio rerio embryos exposed for 120 hours post-fertilization (hpf) to the estimated concentration (0.1 mg/L) for the civil wastewater treatment plant of Milan-Nosedo (N. Italy). Detection of additives in the two types of dishwater pods was performed using Proton Nuclear Magnetic Resonance (1H-NMR), while a multi-tier approach was employed to evaluate the effects across molecular, cellular, physiological, and organism levels, including proteomics and metabolomics analyses, genotoxicity (micronuclei formation, apoptosis and necrosis), reactive oxygen species (ROS) levels, acetylcholinesterase (AChE) activity, as well as mitochondrial respiration and glycolysis. Additionally, heart rate was measured as physiological endpoint, while at the organismic level various endpoints (e.g. distance moved, turn angle, and thigmotaxis) were assessed to evaluate the swimming behaviour of D. rerio embryos. The 1H-NMR spectrum of PVA standard compared to powder pods revealed only few differences, while many for liquid pods, suggesting the presence of several additives. Although the measurement and processing of some endpoints are still in progress, we observed a significant alteration ($p<0.05$) for ROS, AChE, and heart rate of embryos exposed to powder pods compared to controls, contrary to those exposed to the PVA standard. These findings suggest that the additives present in commercial PVA-based products could be responsible for the observed toxicity, aligning with our previous studies. Further analyses are ongoing to better understand the ecotoxicological impact of these everyday PVA-based products on aquatic organisms.

1.10.B.T-04 In Vitro Toxicity of an Environmental Micro and Nanoplastic Mix Representative of Plastics Collected at Five Beaches of the Bay of Biscay

Nagore Gonzalez Soto[1]*, Christelle Clerandeau*[2]*, Benedicte Morin*[2]*, Jer me Cachot*[2] *and Miren P Cajaraville*[3]*, (1)CBET+ Research Group, Department of Zoology and Animal Cell Biology, Faculty of Science and Technology and Research Centre for Experimental Marine Biology and Biotechnology PiE, University of the Basque Country UPV/EHU,& EPOC UMR 5805, University of Bord, Spain, (2)EPOC UMR 5805, University of Bordeaux, CNRS, Bordeaux INP, France, (3)CBET Research Group, Department of Zoology and Animal Cell Biology, Faculty of Science and Technology, Research Centre for Experimental Marine Biology and Biotechnology PIE, University of the Basque Country UPV/EHU, Spain*
Despite increasing micro and nanoplastic (MNP) research, limited information on toxicity of realistic environmental MNPs exists. This study aims to assess the toxicity of an environmental MNP mix representative of plastics collected in beaches of the southwest part of the Bay of Biscay (BoB) on RTL-W1 cells. Plastics were collected following the OSPAR guideline once per season in 5 beaches of the Basque Country: 4 in Spain from January to October 2023 and 1 in France from July 2023 to April 2024. Polymer composition of each item was identified by FTIR and then items were micronized to <250 µm by polymer. MNPs were mixed keeping the polymer composition by weight to produce MNPs representative of each beach and season (winter, spring) and of the overall mix of all beaches and seasons (BoB-eMNPs). For toxicity assessment leachates (lch) and extracts (ext) were made by adding filtered distilled water, DMSO or methanol to MNPs at 10 g/L and agitating them (24h, 190 rpm, 18°C, darkness). The liquid phase was recovered by filtration (0.8 µm). In methanol ext, DMSO was added postfiltration (1:1) and methanol was evaporated with N2. Cells were exposed to lch (0.01-100%) and ext (0.01-1%) for 24h for cytotoxicity evaluation. Then, cell were exposed to 20% (per beach and season) or 10% (BoB-eMNPs) and 1% lch and exts for 4h or 24h to assess ROS production and EROD activity, respectively. 11 polymers were identified in the items collected in the beaches. On a weight basis, a representative mix of plastics beached at the Bay of Biscay consists mainly of PE, PVC, PP and smaller amounts of PA, PS, PET and PUR. Per beach and season, all lch caused cytotoxicity at ?40% dilutions and almost all ext at ?1%. ROS increased significantly in cells exposed to all lch at 20%, while different responses were observed for 1% dilution of lch, DMSO and methanol ext. EROD activity was induced in cells exposed to almost all lch, but not to all ext. The lch of BoB-eMNPs showed the highest cytotoxicity, with less than 50% of cells surviving at 40% dilution and no cells surviving at 100% lch. Cytotoxicity of DMSO and methanol ext was similar in BoB-eMNPs as in beach and season MNP samples. ROS increased in cells exposed to 10% lch of BoB-eMNPs, while EROD activity was induced for all lch and ext of BoB-eMNPs. These results highlight the complexity of analyzing toxicity of environmental MNPs due to differences in polymer types and proportions, additives, sorbed pollutants and aging degree. Funded by Spanish MICIU (project FIERA), Basque Government (grant to consolidated group IT1743-22 and postdoctoral fellowship to NGS), and Euskampus (LTC AquEus).

1.10.B.T-05 Predicting Microplastic Toxicity for Aquatic Organisms Using Machine Learning
Ana Leticia Antonio Vital[1]*, Scott Coffin*[2]*, Luan de Souza Leite*[3]*, Win Cowger*[4]*, Maaike Vercauteren*[5]*, Andrea Bonisoli Alquati*[6] *and Magdalena M. Mair*[1]*, (1)Statistical Ecotoxicology, University of Bayreuth, Germany, (2)California Office of Environmental Health Hazard Assessment, United States, (3)State University of Campinas (UNICAMP), Brazil, (4)Moore Institute for Plastic Pollution Research, United States, (5)Blue Growth Research lab, Ghent University, Ghent, Belgium, (6)California State Polytechnic University Pomona, United States*
Similar to Quantitative Structure-Activity Relationship (QSAR) models, which link the molecular structures of chemicals to toxic outcomes, models are needed to link MNP traits to their toxicities. We used the Toxicity of Microplastics Explorer (ToMEx) 2.0 database, which compiles data on MNP effects on aquatic species from the published literature. Two datasets were prepared: (i) a high quality dataset with data points filtered according to the quality criteria outlined by de Ruijter et al. 2020 (2,264 data points); (ii) a full dataset from which only data points with missing values (NAs) were removed (4,768 data points). We applied a 5-fold cross-validation scheme to train boosted regression trees on tasks to predict the toxicity. We compared the predictive performance of the two models and used Average Marginal Effects to gain insights into the relationships between toxic outcomes and MNP traits, experimental parameters, and species traits. Despite the high heterogeneity of our data, our models are able to predict the presence/absence of effects with almost 80% accuracy. This performance was the same for both datasets, suggesting that concentrating on high quality publications for data mining might be a valid measure to reduce data mining efforts. Based on averaged marginal effects, we found that for both models, increasing concentration and particle surface-area-to-volume ratio were associated with a higher likelihood of observing a toxic effect. In contrast, measures linked to increased particle size (particle surface area, length and volume) were associated with a lower likelihood of observing a toxic effect. Based on current data availability from published studies, it is unfortunately impossible to link toxic outcomes to specific MNP properties (i.e., beyond shape, density, and dimensions). The reason for this is

that MNP properties are often not measured and largely lack reporting (e.g., zeta potentials/surface charges are only rarely reported). We argue that standardized experimental setups could help increase comparability of results. Also, a stronger focus on characterizing MNP traits is needed to disentangle the specific effects of different MNP properties. By identifying key toxicological MNP properties, models similar to the ones we present here will be able to recognize less toxic combinations of microplastic traits, which can support reliable hazard and risk assessments, as well as the development of new, environmentally safer materials. This study was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) SFB 1357 391977956.

1.10.P Exploring the Complex Dynamics and Ecotoxicological Impacts of Micro- and Nanoplastics in Aquatic Systems

1.10.P-Tu058 Assessing the Plastic Removal Efficiency of Riverine Litter Collection and Prevention Solutions

***Mariana N. Miranda**[1], Juliette Grandjean[1], Luca Muth[2], Stephan Wagner[2], George Triantaphyllidis[3], Liesbeth De Keukelaere[4], Tim H.M. van Emmerik[5], Arno Doggen[6], Rok Pucnik[7], Annamaria Vujanovic[7], Abdusalam Uheida[8], Joydeep Dutta[8], Daniel Gonzalez-Fernandez[9], Dimitris Deligiannakis[10], Rinze de Vries[11], Ana I Catarino[1] and Gert Everaert[1], (1)VLIZ - Flanders Marine Institute, Research Department, Ocean and Human Health Division, Belgium, (2)Hochschulen Fresenius gemeinnutzige Tragergesellschaft mbH, Germany, (3)MINDS Technologies & Environmental Sciences PC, Greece, (4)VITO - Vlaamse Instelling voor Technologisch Onderzoek, Belgium, (5)Wageningen University, Hydrology & Environment Hydraulics Group, Netherlands, (6)River Cleanup, Belgium, (7)University of Maribor, Faculty of Chemistry and Chemical Engineering, Slovenia, (8)KTH Royal Institute of Technology, School of Engineering Sciences, Sweden, (9)University of Cadiz, Department of Biology, University Marine Research Institute INMAR, Spain, (10)DELVEC, Greece, (11)Noria Sustainable Innovators, Netherlands*

Rivers play a key role in the global plastic pollution crisis, by connecting sources of plastic litter from anthropogenic to natural environments. However, efforts to mitigate plastics in rivers have been scarce. In this work, we focus on solutions to reduce the current levels of pollution, which include technologies and actions designed to collect plastics already polluting rivers or to prevent them from entering waterways. Estimating the plastic removal efficiency of each solution is essential for evaluating its costs and benefits, enabling policymakers and stakeholders to advance with informed decision-making. Furthermore, it supports the development of customized and sustainable strategies to reduce plastic pollution. The assessment method should account for the diversity of solutions developed so far, but also the range of locations where they can be deployed (e.g., urban/rural river section, ports, water treatment facilities), and the spatial and temporal variability of the plastic pollution in rivers (e.g., due to tides, seasonality, hydroclimatic changes, and irregular pollution inputs). Due to this complexity, no harmonised method has been adopted to evaluate the efficiency and effectiveness of the solutions, hampering their comparison. In the INSPIRE project, we developed a new harmonized method to assess the efficiency of plastic removal solutions in the field. With it, we cover manual cleanups and ten technologies that are being deployed and tested in different river, urban water, and wastewater treatment plant locations in Europe (Danube, Douro, Kamni ka Bistrica, Rhine, Po, Scheldt). To do so, we revised existing methodologies and organised the assessment method in a modular approach that combines versatile protocols with pre-defined and qualified test materials that mimic the environmental plastics target by the solution. This combination enables us to carry out release-catch experiments to determine the percentage of plastic litter removed by the technology or action and its characteristics (e.g., plastic size range). This approach resulted from an effort between academia and industry to create improved guidelines for quantifying plastic removal efficiencies in a way that is both comparable and unbiased. It also ensures flexibility and adaptability to accommodate a wide range of solutions with diverse characteristics, that target different plastic sizes, and under distinct conditions. Innovative Solutions for Plastic Free European Rivers (INSPIRE) is funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or the European Climate, Infrastructure and Environment Executive Agency (CINEA). Neither the European Union nor the granting authority can be held responsible for them. This project has received funding under grant agreement No 101112879 (INSPIRE).

1.10.P-Tu059 Evaluation of the Effectiveness of Flocculants in the Removal of Plastics in Wastewater Treatment Plants and Related Ecotoxicological Impacts

***Cristina Cremonesi**[1], Giada Caorsi[1], Stefano Magni[2], Riccardo Sbarberi[3], Lara Nigro[3], Camilla Della Torre[3] and Andrea Binelli[3], (1)University of Milan, Italy, (2)Biosciences, University of Milan, Milan, Italy, (3)Biosciences, University of Milan, Italy*

The pervasive presence of plastics in the environment and their increasing release into natural ecosystems represent a significant concern for both human and environmental health. Wastewater treatment plants (WWTPs) are identified as a primary source for plastics to enter water courses. Although various studies have demonstrated the efficiency of certain polymer-based flocculants in removing plastics from wastewater in laboratory tests, their potential application in WWTPs remains underexplored, and numerous commercial polymer-based flocculants have not yet been tested. To address this gap, the aim of this study is the evaluation of the effectiveness of different commercial polymer-based flocculants, synthetic and natural, to decrease the plastic concentration in wastewaters. To ensure the applicability of these flocculants in real-world scenarios, wastewater samples will be collected from two distinct type of WWTPs (civil and industrial) to assess their effectiveness across different matrices and mixtures of plastics. The outcome will provide insights into the practical applications and potential environmental advantages of using these flocculants in WWTPs, contributing to the development of better strategies for plastic mitigation and promoting more sustainable treatment processes. To achieve this goal, given that flocculation is one of the final depuration processes in wastewater treatment, it is imperative to also evaluate the effects that flocculants could be in aquatic ecosystems, their interaction with plastics and the potential decrease of plastics ecotoxicity by using the freshwater crustacean Daphnia magna, one of the most used aquatic biological models. Specifically, the study will investigate the exposure of this model-organism to the most effective concentrations identified for each of the flocculants and plastics observed in the removal efficiency experiments. The investigation will span various levels of biological organization, from molecular to organismal. It will assess potential alterations in the proteome, as well as changes in behavior, reproduction, and feeding patterns. This comprehensive approach aims to provide a detailed understanding of how these treatments may influence aquatic organisms and ecosystem health.

1.10.P-Tu060 Modelling the Environmental Fate of Microplastics with UTOPIA, An Evaluative Unit World Model for Microplastics

***Maria del Prado Domercq**[1], Antonia Praetorius[2], Sam Harrison[3] and Matthew MacLeod[1], (1)Stockholm University, Sweden, (2)University of Amsterdam, Netherlands, (3)UK Centre for Ecology & Hydrology, United Kingdom*

Plastic pollution is pervasive in the environment as a complex footprint of particles of different sizes, shapes, compositions and properties. Despite the efforts made over the last decades to understand microplastics' fate in the environment, uncertainties about their sources, transport, transformation processes, and microplastics properties are still prevalent. To advance our understanding of plastic pollution and its associated risks, knowledge integration and extrapolation is urgently needed. In this context, process-based mass-balance models offer a useful platform for synthesising knowledge about sources, processes and pathways, and estimate exposure concentrations of plastic pollution in all forms. Here we present UTOPIA, an open-source process-based mass-balance model, that addresses the plastic footprint challenge by simulating the fate of plastic particles across 17 environmental compartments, accounting for five size classes and four aggregation states. By solving a system of coupled mass-balance equations, UTOPIA estimates steady-state concentrations, persistence, and transport metrics such as travel distance for the five size classes and four aggregation states globally and per compartment. Integrated sensitivity and uncertainty analyses allow exploration of key factors influencing plastic fate. Accessible via a web-based interface, UTOPIA enables users to define emission scenarios, identify dominant reservoirs, and explore transport and transformation processes. The model serves as a reference framework for screening-level risk assessments, hypothesis generation, and identifying knowledge gaps in understanding microplastic pollution. The authors thank Cefic Long Range Research Initiative for their funding support of the project LRI ECO56 (UTOPIA).The authors acknowledge support from InfraVis for providing application expertise for visualization and web-interface development through the Swedish Research Council grant 2021-00181.

1.10.P-Tu061 Untangling the Influencing Factors Governing the Interaction Between Plastics and Metals: A Focus on Conventional and Compostable Plastics

***Ludovica Botta**[1], Gilberto Binda[2], Stefano Carnati[1], Andrea Pozzi[1] and Davide Spanu[1], (1)Department of Science and High Technology, University of Insubria, Italy, (2)Norwegian Institute for Water Research, Norway*

Plastics, the most pervasive pollutants in ecosystems, pose a significant environmental threat by serving as vectors of waterborne chemicals. These materials seem capable of adsorbing and releasing (trace) metals. Their adsorption onto plastics may result in concerning environmental impacts, posing interest in the alteration of their environmental fate. The sorption capacity of plastics is influenced by various factors, many of which remain poorly understood. To address this critical knowledge gap, clarifying how polymer type, additive content, and ultraviolet (UV) degradation affect this phenomenon is essential. Our study aims to investigate the adsorption likelihood of copper (Cu) and lead (Pb) on plastics in aquatic environments. We selected two polymers, namely a conventional polymer (low density polyethylene) and a compostable polymer (polybutylene adipate terephthalate, since this type is commonly used as environmentally friendly alternative). For both types, pristine pellets - ideally without any additive - and end-use plastic materials were considered. All these samples were both analyzed as they were (i.e., pristine) and after a degradation process induced by UV radiation. These samples were compared regarding their physicochemical properties (i.e., surface morphology, functional groups) and their sorption affinity towards Cu and Pb (after adsorption kinetics experiments). The adsorption process was also validated by assessing the metal content before and after the sorption experiments. The results of adsorption experiments highlight the key role of additives in plastics as a primary factor influencing adsorption capacity. In fact, end-use plastics show significant metal adsorption, unlike pristine pellets, which show none. Regardless of the other factors, the UV degradation can increase the adsorption capacity, as well as the presence of the compostable polymer. The nature of the interaction was also assessed through kinetic models. Both pseudo-first order and pseudo-second order models explained adsorption, suggesting a complex, multi-step process. Our study provides valuable insights into the behavior of plastics with heavy metals, emphasizing the roles of UV degradation and chemical composition. These results highlight the critical influence of chemical composition on plastic behavior in the environment, as well as the uncertain behavior of compostable polymers.

1.10.P-Tu062 Bridging Laboratory and Nature: Exploring the Adsorption Behaviours on True-to-Life Microplastics

Mario Rigo[1]*, Serena Ducoli*[1]*, Ula Putar*[2]*, Fabjola Bilo*[1]*, Eva Margui*[3]*, Gabriela Kalcikova*[4]*, Laura Borgese*[1]*, Laura Eleonora Depero*[1] *and Stefania Federici*[1]*, (1)University of Brescia, Italy, (2)University of Ljubljana, Slovenia, (3)University of Girona, Spain, (4)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia*

Although microplastics are widely recognised as a modern environmental threat, current studies predominantly employ polymeric models, i.e., pristine spherical microplastic particles (microbeads). These model materials enable the unraveling of modes of action, mechanisms, and other insights, but they share little to no analogies with microplastics found in nature. Therefore, there is an urgent need to create a material that better reflects the real characteristics of naturally formed microplastics, bridging the boundaries between laboratory parameters and the rules of nature. To address this problem, we investigated the broad-spectrum of adsorption capabilities of a novel, true-to-life type of test microplastics obtained by employing different fragmentation techniques, namely ultracentrifugal milling and mixer milling, using commercially available plastic products. In particular, we investigated the adsorbome profile through the biofilm formation with various biotic components, the absorption of metal cations, i.e., Ni²? and Pb²?, and also the exposure to other organic pollutants such as perfluoroalkyl substances. Biofilm formation on these microplastics alters their physicochemical properties, potentially enhancing pollutant uptake. These results suggest that true-to-life microplastics provide more reliable assessments of environmental risks associated with microplastics. Furthermore, our preliminary findings demonstrate that true-to-life microplastic exhibit different adsorption behaviours depending on the polymer type, metal cation, and/or organic pollutant investigated. The study underscores the importance of employing environmentally relevant microplastic test materials to better understand their interactions with pollutants and biota, thereby improving the consistency of environmental risk assessments and informing mitigation strategies. This contribution is based upon work from COST Action CA20101 Plastics monitoring detectiOn RemedIaTion recovery PRIORITY, supported by COST (European Cooperation in Science and Technology, www.cost.eu). S.F. acknowledges the Italian Ministry of University and Research (Research program Research Projects of National Relevance, PRIN 2022) and the project PLASTACTS 202293AX2L, CUP D53D23009050001.

1.10.P-Tu063 Factors Impacting Resuspension of Microplastics from Rivers: Analysis of Burial and Shielding Effects of Sediment Beds

Francesco Parrella[1]*, David Mennekes*[2] *and Denise M Mitrano*[1]*, (1)ETH Zurich, Switzerland, (2)Environmental Systems Science, ETH Zurich, Switzerland*

Riverine systems can retain considerable amounts microplastics (MPs) through sedimentation, but their resuspension depends on multiple factors. These include particle characteristics (size, morphology, density) and hydrodynamic conditions (flow velocity, sediment bed structure). The resuspension of natural particles has been studied using various models for bed load transport, such as Shield theory, where the critical shear stress (function of flow velocity, viscosity, particle density and size) describes the hydrodynamic conditions at which a particle could be resuspended. However, little is known on if MPs behavior can also be predicted by these standard models due to significant differences in the properties between natural particles and MPs. How specific river morphologies such as bed thickness and grain size impact resuspension is also unexplored, both in the context of 1) shielding/exposure effects exerted by grains on MPs deposited on the sediment surface and 2) MPs resuspension potential when buried within the sediment bed. Here we investigated MPs resuspension using a flume setup across various sediment grain sizes and bed thicknesses under different flow rates. The shielding effect was anticipated to be dependent by the grain size, with larger ones expected to have higher shielding potential than smaller ones. We found that larger grains limited MPs resuspension by changing the bed porosity instead. Large grains allowed MPs to deposit between the pores and cavities, limiting their resuspension. This effect was more pronounced with thicker bed where particles could deposit more in depth and be lost. Smaller grains lead to a more compact bed where MPs deposited on the surface were more exposed to the flow shear stress and more easily resuspended. When MPs were buried within the sediment bed, the main factor influencing their resuspension was the bed thickness, with thin layers allowing more MPs to resuspend than thicker ones. For both the scenarios tested, higher flow rates resuspended more particles than lower ones due to increased shear stress. Collectively, these results provide a better understanding of MPs transport in rivers by assessing the conditions which facilitate particle resuspension in various scenarios where bed load transport models do not directly apply. With the data collected we supported future modeling efforts to predict MPs fate, accumulation and transport in rivers.

1.10.P-Tu064 The Role of Flooding in the Distribution of Microplastics in an Arid Zone Stream
Michael J Barry[1]*, Fatema Al Maqbali*[2] *and Hassan Al Reasi*[3]*, (1)Biology, Sultan Qaboos University, Oman, (2)Sultan Qaboos University, Oman, (3)Sohar University, Oman*
Plastic waste has been detected on every continent and in every biome, from the deepest ocean trenches to deserts and mountains. Freshwater ecosystems are particularly at risk as sinks for microplastics (MPs). Factors that affect the distribution of microplastics in temperate areas are well studied, however, relatively little is known of processes in arid zones. The aim of this study was to investigate the effects human activities and flooding on the distribution of MPs in an arid zone stream, in the Sultanate of Oman. Sediment samples were collected from nine sites along the stream and two sites in the coastal floodplain. All sites had slow moving water, except Site 9, which was dry. Site 9 was in front of a flood retention dam designed to slow the flow of water to the sea. Samples were taken during the dry season and again shortly after flooding. Each site was categorized based on physico-chemical features and local human activities. Microplastics were separated from the sediments using a density gradient and were classified based on size, shape and colour. Polymers were identified using micro-Fourier Transform Infrared Spectroscopy (μ-FTIR). In both seasons, the most common shapes were fragments, followed by fibers, while most MPs were between 10-50 μm. MPs abundance was positively correlated with total organic carbon, silt, and clay, and negatively correlated with sand content. Before flooding, most microplastics were associated with residential and agricultural zones, and lowest densities were in the middle reaches that were remote and hard to reach. The average concentration of MPs increased at most sites after the rain, suggesting that MPs in the surrounding watershed were washed into the stream. The most dramatic increase was at Site 9, the flood retention dam, where numbers increased from 927.7±205.5 MP/Kg to13166.7±433.3 MP/Kg after rain, indicating that many particles accumulated at the dam base. As this site was dry, and predominantly consisted of fine clay, the MPs would eventually be distributed by wind, potentially creating a hazard to surrounding areas. Overall, we demonstrated that MP abundance is highly sensitive to local activities. The flood retention dam reduced the number of MPs reaching the sea, but also created a potential hazard by concentrating them in a dry basin where they will be distributed aerially. This study was funded by The Research Council Oman (RC/GRG-SCI/BIOL/23/01)

1.10.P-Tu065 Testing Single and Combined Environmental Stresses on their Potential to Induce Microplastic Fragmentation and Dissolution: Results on Abiotic Hydrolysis
Patrizia Pfohl[1]*, Omar Tantawi*[2]*, Katherine Santizo*[3]*, Joana Marie Sipe*[4]*, Mark Wiesner*[4]*, Sam Harrison*[5]*, Claus Svendsen*[5]*, Desiree Plata*[2] *and Wendel Wohlleben,*[1]*, (1)BASF SE, Germany, (2)Massachusetts Institute of Technology, MIT, United States, (3)Cefic, Belgium, (4)Duke University, United States, (5)UKCEH, United Kingdom*
To optimally assess the fate of microplastics in the environment, it is essential to understand the mechanisms behind their degradation and fragmentation over time. Depending on the environmental compartment, microplastics encounter various environmental stressors (e.g., UV radiation, humidity, temperature, enzymatic activity) that can lead to polymer aging and subsequent fragmentation. Several decades of polymer aging research can serve as a basis to understand these complex environmental aging mechanisms. For microplastic fate assessment this knowledge needs to be expanded by investigating the fragmentation and release of secondary species, correlating them to the detectable changes in polymer properties. Abiotic hydrolytic reactions can be one potential environmental degradation pathway but the

impact of hydrolysis on polymer properties and fragmentation are rarely investigated. Determining the release rates of secondary micro- and nanoplastics, as well as dissolved organic carbon (DOC) under abiotic hydrolytic conditions, is essential for a better understanding of the issue. Here we conducted systematic comparative studies by testing the OECD TG111 and 3 more hydrolysis protocols on 7 types of microplastics (HIPS, LDPE, PP, PA-6, TPU, PLA, PET).We varied the temperature of artificial seawater (4, 22, 65 °C) and the pH (4, 7, 9) of ultrapure water. Various analytical methods were employed to quantify the time-dependent and size-selective release of DOC, as well as micro- and nanoplastic fragments up to 100 days and even 1 year aging. The chemical composition of the microplastic particles had the most significant effect on the type and quantity of species released, with only a few polymer types being affected by the treatments at room temperature. It was found that increased temperature had the most substantial influence on microplastic degradation and fragmentation. This study also revealed distinct polymer-derived DOC dynamics of PA-6 and PLA at 65°C. PA-6 exhibited stable DOC pool over 100 days, while PLA showed a dramatic increase. Liquid chromatography high resolution mass spectrometry (LC-HRMS) non-target analysis identified 561 unique features for PA-6, with minimal changes in chemical profiles, while PLA showed a dynamic chemical and kinetic evolution of degradation products.
The data obtained from these experiments are currently being utilized to enhance the parameterization of the mechanistic fragmentation model FRAGMENT-MNP.

1.10.P-Tu066 Microplastic Contamination at Various Early Developmental Stages of Marine Fish from Coastal Waters in Taiwan

***Ming-Yih Leu**[1], Sun-Hon Lin[2], Te-Yu Chen[2] and Fung-Chi Ko[3], (1)Department of Biology, National Museum of Marine Biology and Aquarium, Taiwan (Greater China), (2)Graduate Institute of Marine Biology, National Dong Hwa University, Taiwan (Greater China), (3)National Museum of Marine Biology and Aquarium, Taiwan (Greater China)*

Microplastics (MPs) are widespread in coastal seas, posing risks to marine life. Planktonic fish larvae and juveniles, essential for fish population sustainability, are particularly susceptible to MPs, environmental stress, and predation. However, the effects of MP ingestion on larval fish remain poorly understood. This study investigated MP ingestion in 173 larval and juvenile fish from the coastal waters of Qieding, Taiwan. Gastrointestinal tracts were analyzed using alkali digestion, microscopy, and FT-IR analysis, revealing MPs in 21.39% of samples at an average of 0.35 ± 0.78 MPs individual-1. A total of 59 MPs were identified across 20 fish species, with whipfin silver-biddy (Gerres filamentosus) showing the highest count (14 items; range: 0 3 MPs individual-1). Polyethylene terephthalate (PET) was the most common polymer (44.07%), while fibers constituted the majority of particles (89.83%), primarily transparent (54.24%). Nearly half of all MPs measured between 1 and 5 mm. MPs were positively correlated with fish size ($R^2 = 0.038$, $p = 0.009$), and more advanced developmental stages, such as juveniles, showed a significantly higher incidence of MPs ($p < 0.001$). This trend indicates that MPs are more frequently ingested by juvenile or larger fish larvae. These findings provide essential insights into MP contamination in Taiwanese waters, highlighting potential impacts on the health of planktivorous larval fish and marine ecosystems. This study was financially supported by Grants from the National Science and Technology Council (NSTC 111-2611-M-291-001, NSTC 112-2611-M-291-003, and NSTC 113-2611-M-291-005) of the Republic of China to Ming-Yih Leu.

1.10.P-Tu067 Identification and Characterization of Microplastics in Mussels from the Bay of Biscay

*Isabella Gutierrez-Zabala[1], Nagore Gonzalez Soto[1], Eider Bilbao[1], Amaia Orbea PhD[1], Jer me Cachot[2], Sophie Lecomte[3] and **Miren P Cajaraville**[1], (1)CBET Research Group, Department of Zoology and Animal Cell Biology, Faculty of Science and Technology and Research Centre for Experimental Marine Biology and Biotechnology PiE, University of the Basque Country UPV/EHU, Spain, (2)EPOC UMR 5805, University of Bordeaux, CNRS, Bordeaux INP, France, (3)CBMN, UMR 5248, University of Bordeaux, CNRS, Bordeaux INP, France*

Recent studies classified the Bay of Biscay (BoB) as a marine litter accumulation zone, but knowledge about the characteristics of microplastics (MPs, 1 µm to 5 mm) in the region is scarce. Mounting evidence suggests that MPs are ingested by marine organisms, harming aquatic life and ecosystems. Furthermore, bivalves can be sources of MP exposure to humans since they are usually consumed as whole. While many studies focus solely on MPs, other anthropogenic particles (APs) such as cellulose, also exhibit persistence and potential hazards to marine environments. In this study, the presence and characteristics of APs including MPs were investigated in the whole flesh of marine mussels (Mytilus sp.) from the BoB, coming from the field and aquaculture. Field samples were collected in the Butroi-Plentzia estuary and in the Arriluze harbor (Basque Country-BC, Spain) in summer 2023 and in the Arcachon Bay, outside the harbor (France) in spring 2023. Aquaculture mussels were obtained from Galicia (Spain) in autumn 2023 and in Mendexa (BC, Spain) in winter 2022. The whole tissue of 10 mussels per site was analyzed. Samples were digested with 10% KOH and sorted particles were characterized by visual analysis under a stereomicroscope followed by polymer identification by ATR-FTIR spectroscopy. APs were found in all individuals analyzed. APs mean concentration per individual ranged from 1.40 (±1.20) to 7.60 (±7.23) APs/ind, and APs mean concentration per fresh weight ranged from 0.20 (± 0.13) to 0.75 (± 0.60) APs/g fw. APs found were classified as fibers (97.9%) and fragments (2.08%). The length of fibers ranged from 342.40 (±159.38) to 76.97 (±390.67) µm and width ranged from 8.20 (±3.46) to 19.46 (±10.57) µm. The most prevalent colours detected were black and transparent. The most abundant polymer found was cellulose (60%). Six plastic polymers were detected: polyethylene terephthalate (PET), polyethylene (PE), polyamide (PA), polystyrene (PS), polyvinyl chloride (PVC) and polyisobutylene (PIB), of which PA fibers were the most common. In farmed mussels only PET and PA MPs were found, while a higher polymer diversity was observed in wild individuals. No significant differences were found in AP concentration and polymer composition among studied samples. These results can contribute to the definition of baseline levels of MP occurrence in mussels from the BoB. Work funded by the Spanish MICIU (project FIERA, ref PID2021-128600OB-I00, MCIN/AEI/ 10.13039/501100011033 and ERDF A way of making Europe), the Basque Government (grant to the consolidated research group IT1743-22 and a postdoctoral fellowship to NGS), the University of Bordeaux (internship grant to IG), and Euskampus Foundation (Laboratory for Transborder Cooperation LTC AquEus)

1.10.P-Tu068 The Role of Organismal Traits in Understanding Variability & Uncertainty in Reported Biota Microplastic Concentrations

Davide Asnicar[1], *Benjamin Patrick de Jourdan*[1], *Danielle Philibert*[2] *and Craig Warren Davis*[3], *(1)Huntsman Marine Science Centre, Canada, (2)Huntsman Marine Science Centre, St. Andrews, NB, Canada, (3)ExxonMobil Biomedical Scienc,, United States*

A significant body of ecotoxicological data has been developed for microplastics (MPs). However, there remain challenges in synthesizing and interpreting these data within the context of ecological risk assessment. While many of these challenges are being addressed, particularly those around study design, QA/QC, and reliability, one significant challenge remains - identification of relevant species for use in the development of ecological protection criteria (i.e., PNECs, HC5). Previous studies have attempted to derive these values, but without unanimity. This results in significantly different PNEC values as a function of the selected particle characteristics (size, shape, polymer), and uncertainty as to the relative sensitivities of different aquatic species to different MPs. This work summarizes the results of a systematic quality review of over 400 MPs biomonitoring studies using criteria previously developed by Hermsen et al., with minor modifications to integrate relevance and reliability more clearly for risk assessment & prioritization of potential future environmental monitoring programs. For studies that met the criteria, trait-based descriptors and particle characteristics and distributions were compiled for all species to provide guidance on species selection and environmentally relevant exposure profiles for informing future biomonitoring and risk assessment studies, highlighting knowledge gaps. The long-term objectives of this work are three-fold first, to systematically compile and evaluate species-specific traits (e.g. feeding guild, habitat, size, ingestion rate) data for a wide range of freshwater and marine species into a searchable database for use in identification of sentinel species for ecosystem health & quality monitoring, and ecological risk assessment. Second, this work is intended to provide a biologically-relevant framework against which the relevance of existing (and developing) MPs reference materials may be evaluated and additional studies prioritized. This can provide a systematic basis for the inclusion or exclusion of species or materials for the purpose of quantitative risk assessment in various environmental compartments. Third, available information on functional traits can inform the selection of relevant and efficient species for integrated biomonitoring programs in sea surface, subsurface, estuarine, and sediment environments.

1.10.P-Tu069 A New Active Device for Sampling Microplastics in Lakes: Development of a Floating Sampling Station

Isabella Gambino[1], *Benedetta Villa*[2], *Gloria Martegani*[2], *Edoardo Luciani*[2], *Gaia Bolla*[2], *Elisa Terzaghi*[2], *Roberta Bettinetti*[3] *and Antonio Di Guardo*[2], *(1)DiSAT, University of Insubria, Varese, Italy, (2)Environmental Modelling Group, Department of Science and High Technology, University of Insubria, Italy, (3)Department of Human Sciences, Innovation and Territory, University of Insubria, Italy*

The largest production of plastics lead to a significant increase of volume of plastic entering natural environment. More than 80% of the plastics entering into aquatic ecosystems derived from terrestrial ecosystem through rivers. Among freshwater ecosystems, lakes can be considered relatively closed ecosystems compared to other aquatic environments and therefore a potential long term reservoirs for microplastics (MPs). Recently there has been an increase in studies of freshwater water bodies as key sources of drinking water and other paramount ecosystems services. Como basin in Lake Como (Northern Italy) is characterized by a relatively low water exchange, receiving water from two streams with wastewater treatment plants located along their course, which process domestic and industrial water, in part of textile origin. Within LIFE CASCADE project a number of activities are aimed at reducing the contribution of MPs and PFAS from the textile sector to surface water. For this reasons, in order to determine MP in water, it is important to be capable to sample large amount of water in specific geographic locations within the lake to study the fate of MPs. The aim of this study is to evaluate MP levels in Como town basin of Lake Como and the contribution of river output. In order to reach this goal a new MP sampling device was set up to collect larger volume samples at specific areas in the lake, rather than large transects obtained with a manta trawl. Several lake water samples were collected in Summer 2024 from the Como basin and from the main inflow rivers, Cosia and Breggia. Samples were analyzed with Py-GC-MS. Sediments were also collected. Overall, results were qualitatively in line with those found in literature although only few studies reported polymer concentrations (µg/m3). The main polymers found were polyethylene (PE), polypropylene (PP), nylon (N66) and polyethylene terephthalate (PET). MP concentration was higher in littoral areas presumably affected by sediment re-suspension and the presence of largest particles than in open water areas. However, the low concentration of MPs in pelagic area could be also related to phytoplankton development and consequent suspended solid deposition which scavenges MPs from the epilimnion. River Cosia and Breggia concentrations and water flows allowed to estimate MP riverine contribution. Work is in progress and new monitoring campaigns are needed to evaluate MP fate and their temporal evolution in Lake Como.

1.10.P-Tu070 Qualitative and Quantitative Assessment of Microplastics Derived from Antifouling Paint in Effluent from Ship Hull Hydroblasting and Their Emission into the Marine Environment

Taekhyun Kim, *Soeun Eo, Wonjoon Shim and Moonkoo Kim, Korea Institute of Ocean Science & Technology (KIOST), Korea, Republic of*

Microplastic (MP) pollution is a growing environmental concern, and ship paints have been identified as a significant source of MPs entering the marine environment. Hydroblasting, a common ship hull cleaning method, contributes to MP emissions, but its impact remains poorly understood. Understanding the characteristics and scale of MP emissions from hydroblasting operations is critical for assessing their contribution to global marine pollution. This study evaluated MPs generated during the hydroblasting of an ocean-going vessel, focusing on particle number, size distribution, polymer type, and mass. Additionally, an MP emission factor was calculated and extrapolated to estimate global emissions. Paint particles released from hydroblasting were analyzed for their physical and chemical characteristics. The emission factor (g/m²) was derived by dividing the total emissions by the vessel's wetted surface area (WSA) (m²). This factor was then used to estimate global MP emissions based on the WSA of ships worldwide and their cleaning frequency. Hydroblasting a vessel produced 4.3 × 10¹? particles, with 99.9% smaller than 5 mm, predominantly comprising acrylic-based particles. Of the 44.1 kg of antifouling (AF) paint particles generated, 36.5 kg were smaller than 5 mm, including 18.2 kg of plastic emissions. The MP emission factor was determined to be 8.43 g/m². Using this factor, annual global MP emissions were preliminarily estimated at 665.6 tons, with 550.2 tons consisting of MPs. This study demonstrates the significant contribution of hydroblasting to marine MP pollution and emphasizes the urgent need for stricter regulations on hydroblasting operations and waste disposal practices to mitigate environmental impacts. These findings provide critical data for policymakers to develop effective measures to reduce MP pollution from ship maintenance activities, advancing efforts to protect marine ecosystems. This research was supported by the Korea Institute of Marine Science & Technology Promotion (KIMST), funded by the Ministry of Oceans and Fisheries, through the following projects: Land/sea-based input and fate of microplastics in the marine environment (RS-2022-KS221604) and Techniques development for management and evaluation of biofouling on ship hulls (RS-2021-KS211530) .

1.10.P-Tu071 Integrating Metals in the Complex Array of (Micro)Plastic Additives: A Preliminary Screening in Conventional and Biodegradable Polymers

Gilberto Binda[1]*, Stefano Carnati*[2]*, Gabriela Kalcikova*[3]*, Rachel Hurley*[4]*, Luca Nizzetto*[4]*, Davide Spanu*[2] *and Andrea Pozzi*[2]*, (1)Norwegian Institute for Water Research, Norway, (2)Department of Science and High Technology, University of Insubria, Italy, (3)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia, (4)Norwegian Institute for Water Research, Norway*

Plastic pollution is a well-known environmental issue, yet the ecotoxicological implications, particularly concerning the chemical additives in plastics, are still underexplored. Attention has in fact increased for the characterization of chemical additives in plastics and their potential risks. The variety of additives (e.g., plasticizers, catalysts, fillers) is vast, and understanding their abundance is essential for developing effective safe designs of plastic materials. While significant research has been done on organic chemicals and their leaching process, the data on inorganic additives (i.e., metallic and organometallic compounds) remain limited. In this study we analyzed the metal content in different types of plastics, focusing on their sources of enrichment and the associated risks. Specifically, we investigated pristine plastic pellets, recycled plastic pellets, and single-use plastic products made from both conventional and biodegradable polymers found in environmental compartments. Our goal is to better understand the presence of inorganic additives in these materials, their distribution across different polymer types, and their potential impacts. Our analysis revealed notable enrichment of metals particularly Ti, Al, Fe, and Zn across a range of plastic types, especially when comparing pre-production pellets to final consumer products. Polymers such as polyethylene (PE), polystyrene (PS), polybutylene adipate terephthalate (PBAT), polylactic acid (PLA), and polypropylene (PP) showed significant metal concentrations in the end-use products only, suggesting that these additives are incorporated during the final stages of production. PET samples also displayed elevated levels of antimony, while biodegradable plastics like PBAT and PLA exhibited specific trends related to tin and indium (the latter for PLA only): these elements resulted enriched already in the pellets, since they are used as catalysts in polymer production. This study provides the first comprehensive comparison of metal additives in both biodegradable and conventional plastics across different production phases. It highlights the need for caution when using plastic pellets for environmental risk assessments, as some may already contain additives not present in the final products. Additionally, the findings underscore the role of biodegradable plastics as potential carriers of metals in terrestrial and aquatic environments, raising concerns about their degradation and impact. This work was funded by the Research Council of Norway for the project PATTERN- PlAsTic effecTs on the Exchanges of nutRienTs and biological information in aquatic ecosystems (project number 345077).

1.10.P-Tu072 Physical and Chemical Stability of Recycled Plastic Aggregates as Natural Aggregate Replacement in a Cementitious Matrix

Hasanthi Kosgahakumbura[1], *Ivan Kourtchev*[1], *Sue Charlesworth*[1], *Damien Callahan*[2] *and Will Gates*[3], *(1)Centre for Agroecology, Water and Resilience, Coventry University, United Kingdom, (2)School of Life and Environmental Sciences, Deakin University, Australia, (3)Institute for Frontier Materials, Deakin University, Australia*

The shortage of construction materials and the overflow of plastic waste have driven an increase in research aimed at substituting traditional aggregates with recycled plastic aggregates (rPA) in cementitious structures. However, the physicochemical stability of rPA may be impacted by the high alkalinity of cements, and thus pose questions on durability of such structures. The deterioration rate of two widely researched recycled plastics used as substitutes for aggregates, namely polyethylene terephthalate (rPET) and high-density polyethylene (rHDPE) was studied and the leachability of new emerging pollutants (NEP), such as per and polyfluoroalkyl substances (PFAS) and phthalates (PAE), from these rPA were measured in an aqueous cementitious matrix. Plastics were used in two particle size ranges: m=2.36 0.6 mm and μ=0.6-0.15 mm. Approximately 3 g of each polymer in the m-rPA and ?-rPA sizes were immersed in 30 mL of simulated concrete pore solution (SCPS) (13<pH) for 75 days. The deterioration rate of rPA during the alkali exposure was assessed through weight loss analysis, and the potential PAE leachability was examined using a gas chromatography mass spectrometer (GC-MS). The results revealed a significantly higher weight loss for μ-rPA with a higher deterioration rate in rPET than rHDPE. This suggested that ester groups in rPET underwent rapid cleavage due to alkaline hydrolysis and dissolved in SCPS. Moreover, a clear trend was observed in plastic degradation with prolonged alkali exposure; after 75 days, the weight loss of m-rPET, μ-rPET, m-rHDPE and μ-rHDPE were 9.8%, 39.0%, 1.1% and 7.9% respectively. GC-MS analysis revealed rHDPE contributed mostly to PAE release when exposed to SCPS, while μ-rPA released more PAE than m-rPA. Additionally, all rPA showed higher leachabilities of targeted PAE with increased time of exposure, most significantly being diethyl phthalate (leaching of up to 3.8±1.1 ng mL-1). Subsequent research will include leachability of short-, medium- and long-chain PFAS from rPA in alkaline-SCPS using liquid chromatography mass spectrometry. The findings offer important knowledge regarding the potential for polymer contamination upon degradation and NEP leachability from different plastic types under alkaline conditions. These results can be used to assess the environmental impact and sustainability of plastics when incorporated into a highly alkaline cementitious matrix.

1.10.P-Tu073 Conventional and Biodegradable Microplastics Influence Nutrient Cycling in the Aquatic Environment

Ula Putar[1], *Anita Jemec Kokalj*[2] *and Gabriela Kalcikova*[1], *(1)University of Ljubljana, Faculty of Chemistry and Chemical Technology, Slovenia, (2)University of Ljubljana, Biotechnical Faculty, Slovenia*

While significant progress has been made in understanding the direct effects of microplastics, knowledge of their indirect effects, particularly on biogeochemical cycles, is still limited. Most studies have focused on nutrient uptake in soils, while relatively little attention has been paid to the aquatic environment. In this context, the aim of our study was to investigate the adsorption of phosphorus (in the form of orthophosphates) and nitrogen (in the form of ammonium, nitrite, and nitrate) on polyethylene (PE) and polybutylene adipate terephthalate (PBAT) microplastics prior and after biotic aging (i.e. with a developed biofilm). Biotic aging of microplastics was performed in freshwater from a local stream under controlled laboratory conditions. After 9 weeks, the percentage of biofilm was 33 ± 3% and 23 ± 3% for PE and PBAT microplastics, respectively. The maximum adsorption capacity of nutrients was reached after 24 h regardless of the type of microplastic and the results showed that the presence of biofilm significantly affected nutrient levels in the medium due to the adsorption by microplastics and utilization by microorganisms within the biofilm. For PE microplastics with biofilm, the adsorption capacity for ammonium nitrogen and nitrite was 10% and 13% lower, respectively, compared to pristine microplastics while no changes were observed for nitrate. For PBAT microplastics with biofilm, the adsorption of ammonium nitrogen was 20% lower than in untreated PBAT microplastics, while no changes were observed in the adsorption of nitrite or nitrate. The phosphorus concentration in the aquatic medium decreased by 18% and 13% when pristine PE and PBAT microplastics were present, respectively, indicating phosphorous removal by adsorption. On the other hand, the concentration of phosphorous decreased by 57% and 46% when PE and PBAT microplastics with biofilm were present, respectively, which was most likely due to adsorption and utilization by microorganisms. The results indicate complex interactions between microplastics and nutrients that vary with the presence of biofilm. Therefore, further studies are essential to elucidate the impact of these interactions on nutrient cycling in the aquatic environment, as they may also influence global biogeochemical cycles and greenhouse gas emissions.

1.10.P-Tu074 Effects of Plastics and Tire Rubber Leachates on Free-Living Freshwater Bacteria

Marius Schubert[1]*, Fazel Abdolahpur Monikh*[2]*, Yuyi Yang*[3] *and Hans-Peter Grossart*[4]*, (1)UBA, Germany, (2)University of Padua, Technical University of Liberec, IGB, Finland, (3)University of Chinese Academy of Sciences, China (Mainland), (4)IGB, Germany*

Plastic pollution poses a significant threat to aquatic ecosystems, e.g. as plastic leachates are contaminating water and posing toxicity risks for aquatic organisms. Plastic leachates, however, can also stimulate microbial growth, impacting carbon and nutrient cycles in aquatic ecosystems. Different synthetic polymer types have varying chemical make-ups, which result in variable leachate composition and thus effects on microorganisms. This study aims to assess i) how different synthetic polymer leachates affect free-living aquatic bacteria, and ii) how these effects vary at high and low nutrient conditions. To address these questions, leachates were extracted from five synthetic polymers, i.e. low-density polyethylene (LDPE), polypropylene (PP), polyvinyl chloride (PVC), starch-polylactic acid (starch-PLA), and tire rubber by incubation in ultrapure water under UV radiation. Free-living (<5.0 µm) microbial communities of Lake Stechlin, Germany, were exposed to leachates, and the resulting communities were analyzed for changes in total microbial growth (TMG) using flow cytometry and for community shifts using 16S rRNA gene amplicon sequencing. To establish dose-response models, microbial communities from the lake were also exposed to a concentration series of PP, PVC, and tire rubber leachates, for which effects on TMG rates were observed. Synthetic polymers revealed differing effects on TMG and community composition depending on nutrient availability. For instance, at high nutrient concentrations, PP leachates didn t reveal any significant effects but led to significant community shifts and changes in TMG rates at low nutrient concentrations. In contrast, PVC leachates stimulated TMG of free-living communities at both nutrient conditions, though significant community shifts were only observed at low nutrient conditions. Starch-PLA leachates caused community shifts at both nutrient conditions despite having no effect on TMG, whilst tire rubber leachates showed inhibitory effects on TMG only at low nutrient conditions. These results highlight the importance of leachate quality and nutrient availability for our understanding of the effects of leachates on microbial growth and community composition. Our findings have important implications for understanding the impact of synthetic polymer pollution on microbial loop functioning and hence the biochemistry of various aquatic ecosystems, e.g. differing in trophic status. This work received funding from the European Union's Horizon 2020 Research and Innovation programme, under the Grant Agreement number 965367 (PlasticFate). The author(s) declare that there are no conflicts of interest regarding the publication of this paper. The research was conducted independently, without any influence from personal, financial, or organizational interests that could affect the study's outcomes.

1.10.P-Tu075 Identification of Metabolism and Degradation Patterns of 6PPD-quinone in Aerobic Soil Using Liquid Chromatography-Tandem Mass Spectrometry

Seong-Hoon Jeong[1]*, Ji-Young An*[2]*, Jung-Hoon Jung*[2] *and Jong-Hwan Kim*[2]*, (1)Korea Institute of Toxicology, Korea, Republic of, (2)korea institute of toxicology, Korea, Republic of*

6PPD (N-1,3-dimethylbutyl-N-phenyl-p-phenylenediamine), a commonly used antioxidant in rubber, is primarily incorporated into tires to prevent oxidative degradation and enhance durability. However, it is released into the environment through tire and road wear particles. Upon exposure to sunlight, 6PPD undergoes photo-degradation to form its toxic metabolite, 6PPD-quinone, which has recently been identified as highly toxic to coho salmon, raising concerns about its environmental impact. In this study, we investigated the distribution and degradation mechanisms of 6PPD-quinone in aerobic soils. The research was conducted across three distinct soil types under controlled temperature conditions (20 ± 2°C) in the dark for 120 days. 6PPD-quinone was dissolved in acetonitrile and introduced into a flow-through system containing 80 g (dry weight) of soil. Throughout the experiment, each soil sample was collected in duplicate, extracted, purified, and concentrated before analysis by LC-MS/MS. The limit of detection (LOD) and limit of quantification (LOQ) for the target compounds were 0.02 ?g/kg and 0.05 ?g/kg, respectively, with a calibration curve yielding a coefficient of determination (r^2) ? 0.99. Recovery was evaluated at three concentration levels (LOQ, 2×LOQ, and 10×LOQ), and the results indicated recoveries ranging from 97.7% to 113.9%, with relative standard deviations (RSD) below 20%. Soil samples were taken at multiple time points (0, 3, 7, 14, 30, 60, 90, and 120 days) for LC-MS/MS analysis after extraction, purification, and concentration. The average half-lives of 6PPD-quinone in the three soils were determined to be 43.0 to 94.9 days. Furthermore, a major metabolite was identified in each of the three soil types. The observed degradation pathways, degradation rates, and metabolites identified in this study contribute critical data for understanding the environmental behavior of 6PPD-quinone and its potential ecological risks in aerobic soils.

1.10.P-Tu076 Impact of UV Weathered Polystyrene and Polyethylene Microplastics on Microbially Mediated Nitrate Reduction in Floating Treatment Wetlands

Meredith Keleigh Sutton[1]*, Daniel Miller*[2]*, Tiffany Messer*[3] *and Shannon Bartelt-Hunt*[4]*, (1)Civil and Environmental Engineering, University of Nebraska Lincoln , United States, (2)USDA-ARS, United States, (3)University of Kentucky, Lexington, United States, (4)University of Nebraska Lincoln, United States*

Floating treatment wetlands are a remediation option for waterbodies that receive nutrient pollution from agricultural and urban sources. Microplastics, a contaminant of emerging concern, are also prevalent in these sources and have the potential to alter microbially mediated nitrogen transformation, thus impacting the effectiveness of floating treatment wetlands. Previous experiments using virgin polyethylene and polystyrene microplastics to look at the influence of added microplastics on potential denitrification in floating wetland systems found a change in the potential denitrification rate dependent on microplastic size. This research indicates the potential for microplastic influence in floating wetland systems, but further exploration is needed to consider the impacts of altered surface characteristics due to environmental weathering of microplastics and the mechanisms causing the observed changes in potential denitrification. To create more environmentally relevant microplastics, the surface of polyethylene (200 µm) and polystyrene (200 µm and 30 µm) microspheres were weathered with simulated sunlight via xenon arc lamp over a spectral range of 300 800 nm at an irradiance of 650 W/m2 and a 65 oC BST for 30 days (720 hrs). Weathered microplastics were evaluated for changes in surface characteristics after the full weathering period. Rate of nitrate reduction was assessed for both weathered and virgin microplastics over two concentrations (1 mg/L and 100 mg/L). Microplastics were incorporated into microcosms with aggregated root samples collected from floating treatment wetland mats and monitored over five days to observe changes in nitrate concentration in the microcosm. Results from this research will help inform function and denitrification potential of floating treatment wetlands placed to provide remediation in contaminated waterbodies as well as contribute to potential trends on the impact of microplastic presence in environments that host similar denitrifying microbial communities such as natural wetlands and wastewater treatment plants.

1.10.P-Tu077 Unity Is Strength: Contrasting Responses in Group Formation Between the Green-algae *Tetradesmus obliquus* and the Cyanobacteria *Dolichospermum flos-aquae* When Exposed to Nanoplastics

Franca Stabile[1]*, Mikael T. Ekvall*[2]*, Johanna Sjostedt*[1] *and Edith Hammer*[1]*, (1)Functional Ecology, Department of Biology, Lund University, Sweden, (2)Biochemistry and Structural Biology, Department of Chemistry, Lund University, Sweden*

Plastic pollution is a complex, global environmental problem, and its impact on freshwater ecosystems is not yet fully understood. Changes in freshwater phytoplankton community composition can be expected under nanoplastic pollution scenarios, due to the differential effects they pose upon the different phytoplankton groups. However, despite the efforts to synthesize the knowledge regarding nanoplastics effects on phytoplankton, a clear consensus has not been reached yet. This study shows contrasting effects on growth and morphology induced by nanoplastics (gold-doped polystyrene (PS) nanoplastics, 93 ± 9 nm in diameter) exposure on two different representatives of phytoplankton: the green-algae Tetradesmus obliquus and the cyanobacteria Dolichospermum flos-aquae. Moreover, it explores how nanoplastics interact with these organisms at the cellular level, using transmission electron microscopy (TEM). We found that the species are affected differently: while the green algae was negatively affected by nanoplastics during its exponential growth phase, the cyanobacteria was negatively affected in the stationary phase and entered the decline phase earlier. Moreover, we observed that the proportion of cells in groups (coenobia or colonies) was different between treatments. When cyanobacteria were exposed to the highest concentration of nanoplastics in our experimental setup (45 mg PS/L), there was a higher proportion of cells in groups. Interestingly, this was the opposite for the green algae where the formation of groups followed a dose-response pattern and was lower in the presence of nanoplastics. When exploring possible mechanisms under TEM, we found that nanoplastics were attached to the cell wall of the green algae, which showed indications of damage. However, when analysing the cyanobacteria, although it was possible to observe nanoplastics in the close surroundings of the cells, we did not find nanoplastics directly attaching to them. Our study contributes to the understanding of the responses of phytoplankton species to nanoplastics exposure and the mechanisms behind those responses, to produce more accurate predictions of the impact of plastic pollution on freshwater phytoplankton communities. We acknowledge financial support by Kungliga Fysiografiska Sällskapet i Lund (Royal Physiographic Society).

1.10.P-Tu078 Evaluation of Photosynthetic Parameters of *Raphidocelis subcapitata* Exposed to Polystyrene Micro- and Nanoplastics

Giseli Swertes Rocha[1], *Renan Castelhano Gebara*[2], *Cinthia Bruno de Abreu*[2], *Elson Longo*[2], *Ana Lombardi*[2], *Maria Melao*[3], *Jordi Sierra*[4] *and Marta Schuhmacher*[5], *(1)Universitat Rovira i Virgili, Spain, (2)Universidade Federal de S o Carlos, Brazil, (3)Universidade Federal de Sao Carlos, Brazil, (4)Faculty of Pharmacy and Food Sciences, Universitat de Barcelona, Spain, (5)Chemical Engineering, Universitat Rovira i Virgili, Spain*

Plastic pollution has been gaining attention in the last decades, especially regarding the effects of micro- and nanoplastics (MNPs) on biota and ecosystems. However, the impacts of MNPs on primary producers are less well understood, with the expectation that the lower the size of the plastic, the higher the risks of damage to organisms. In the present study, cells of the freshwater microalga Raphidocelis subcapitata (Chlorophyceae) in exponential growth phase were exposed to two concentrations of fluorescent polystyrene nanoplastics (50 nm NP 50 and 100 nm NP100) and microplastic (1 µm; MP): 0.1 (low) and 100 mg L-1 (high). The photosynthetic activity of microalgae (maximum and effective quantum yields, photochemical and non-photochemical quenching, and rapid light curves) was assessed using a pulse amplitude modulated fluorometer (Phyto-PAM), and parameters were measured after 72 h exposure. Our results indicate that some parameters were not affected by the presence of microplastic, regardless of size and evaluated concentration. This was the case with the non-photochemical quenching NPQ and the parameter related to the activation of photoprotection mechanisms. Regarding the maximum quantum yield, both concentrations decreased the values in MP1, while only the high concentration affected the NP50 and NP100 treatments. The effective quantum yield was not affected by NP50 and MP1, and a lower value was observed at 100 mg L-1 in NP 100. A slightly higher loss of heat and fluorescence by non-regulated non-photochemical energy loss was observed at the low concentration in MP1, with no difference at the high MP1 or in NP50 and NP100 treatments. The photochemical quenching was slightly affected at the high concentration in NP100 and MP1, with no differences at the low or NP50. Non-photochemical quenching was only affected at high concentrations in NP100. The rapid light curve parameters were not affected by NP50. On the other hand, high concentrations of NP100 decreased all the parameters (maximum electron transport rate rETRmax, light use efficiency, and saturation irradiance Ek), while high MP1 increased rETRmax and Ek. Even though some differences were observed, considering the different sizes and concentrations evaluated, a severe impact of MNPs in photosynthetic parameters was not observed, suggesting that photosynthetic machinery was not damaged by polystyrene MNPs. This project has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No 801370 and the Beatriu de Pinós postdoctoral programme funded by the Secretariat of Universities and Research (Government of Catalonia), project 2021BP00102 granted to the first author.

1.10.P-Tu079 Analysis of High Mass Polycyclic Aromatic Hydrocarbons (PAHs) Extracted from Microplastics Spilled in the Marine Environment

Douglas Michael Stevens[1], *Bryan D. James*[2], *Christopher Reddy*[2], *Robert K Nelson*[2], *Frank Dorman*[1], ***Michael andrew McCullagh***[3] *and David Gould*[4], *(1)Waters Corporation, United States, (2)Woods Hole Oceanographic Institution, United States, (3)Waters Corporation, (4)Waters Corporation, United Kingdom*

In 2021, the container ship M/V X-Press Pearl caught fire and later sank off the coast of Sri Lanka. Over 1,600 tons of polyethylene pellets, also known as nurdles, were aboard the ship along with 25 tons of nitric acid, which began to leak and is suspected to be the cause of the fire that led to the sinking. To exacerbate the problem this fire included fertilizers and explosives being transported as well as the flame retardants deployed. When combined with abundant, naturally occurring compounds found in the marine environment, the need arises to characterize the composition of intact, burned, and broken pieces of the spilled plastic later collected from kilometers of Sri Lankan beaches. Samples of relatively intact, burnt, and aggregated combustion remnants of microplastics were extracted using a microextraction method involving sonication in DCM and the addition of multiple surrogates. Extracts were analyzed on a Xevo TQ Absolute (Waters Corporation) tandem quadrupole system using N? CID gas and fitted with the Atmospheric Pressure Gas Chromatography (APGC) source in positive ion mode using charge exchange ionization and dry N? reagent gas. The focus of this work was on high mass PAHs (314 - 424 Da, 6 - 11 rings). However, an overlapping range of PAHs (228 302 Da, 4 6 rings) was included to facilitate comparison across techniques and with other published results. NIST Coal Tar SRM 1597 was used to perform method development as it was anticipated to include representative analytes. The final method using a high temperature (400°C) stable column resulted in all analytes being eluted in <23 minutes while still providing satisfactory chromatographic resolution for the majority of high mass analytes. Development of MRM transitions was based on extracting prospective high mass PAH molecular weights from multiple sources and using NIST 1597 to optimize response for the most prominent peaks in each RT range. Subsequent quantification of the overlap region analytes found in 1597 were within 10.2% of the reference values for 8 of 9 analytes, with coronene being an outlier (+58.9%) due to coelution. Combustion remnant and burnt samples contained >500x and >250x, respectively, of the levels of high mass PAHs found in white nurdles. Quantification of high mass PAHs shows that white samples have <1%, burnt have 18.2%, and CR has 40.7% by mass when comparing the cumulative response for all analytes detected in 1597.

1.10.P-Tu080 Investigating the Complex Impacts of Plastic Pollution in Aquatic Ecosystems: Insights from a Laboratory Experiment

***Gilberto Binda**[1], Margarida Costa[2], Xiaxia Di[1], Sunniva Tangen Haldorsen[1], Eva Leu[3], Luca Nizzetto[2], Birger Skjelbred[1] and Luka supraha[2], (1)Norwegian Institute for Water Research, Norway, (2)Norwegian Institute for Water Research., Norway, (3)Akvaplan-niva, Norway*

The presence of plastic litter in freshwaters has raised concern about its long-term implications for water ecosystem functioning. However, while increasing knowledge is collected regarding ecotoxicological implications, wider direct and indirect environmental consequences of plastic pollution are still poorly understood. In this study, we investigated the role of plastic as a new, anthropogenic substrate for microorganisms affecting the microalgal community composition and functioning in a lab-based experiment. We crafted plastic fragments of different polymer types and incubated them with water collected in an urban pond, in order to have them colonised by a microbial community. Then, we transferred these fragments into experimental batches containing environmental samples of a microbial community from a pristine lake to simulate the potential longitudinal transport of plastic in unpolluted water bodies. Plastic fragments were added at 2 different concentration levels in the experimental batches. The experiment lasted 21 days in total, and we sampled water and plastic weekly to assess major and minor trace metals, the growth of photosynthetic microorganisms, extracellular polysaccharides and the microbial community composition. We observed changes in the algal community composition and marked chemical alterations driven by the presence of plastics. This is due to the dispersal of algal species from the biofilm and the specific colonisation of plastic fragments by some of the organisms in the natural pelagic community, favouring specific traits. We observed a lower abundance of microalgae in the pelagic phase, a faster depletion of nitrates and a significant change in the extracellular polymeric substances available in the dissolved phase at increasing plastic concentrations. We also observed the leaching of some trace metals (e.g., lead) from plastic. We also observed endpoints that were not affected by the concentration of plastic, such as some minor nutrients (e.g., sodium, magnesium and sulphates) and the enzymatic activity of the microbial community. This experiment highlights the complex array of mechanisms by which plastic can alter the ecosystem functioning and warns the community about the broader environmental risks that should be taken into account when considering plastic pollution in aquatic ecosystems. This work was funded by the Research Council of Norway for the project PATTERN-PlAsTic effecTs on the Exchanges of nutRienTs and biological information in aquatic ecosystems (project number 345077).

1.10.P-Tu081 Ecotoxicological Assessment (*Daphnia magna*) of Safe, Sustainable and Recyclable by Design SURPASS Polymeric Alternatives for Food, Building, and Transport Applications

Ruben Martínez[1], *Patricia Solorzano*[2], *Ana Candalija*[1], *Thierry Douki*[3], *Niels Leijten*[4], *Yvonne Staal*[4] *and Socorro Vazquez-Campos*[1], *(1)Leitat Technological Center, Spain, (2)Hehs, Leitat Technological Center, Barcelona, Spain, (3)Universite Grenoble Alpes, CEA, CNRS, IRIG, SyMMES, France, (4)Dutch National Institute for Public Health and the Environment (RIVM), Netherlands*
Plastics have become indispensable across many sectors due to their durability and versatility. However, their persistence in the environment poses severe health and ecological risks, as they degrade over centuries, fragmenting into micro- and nano-plastics (MNPs), and leaching toxic additives that pollute ecosystems and potentially disrupt human health. Currently, 70% of plastic waste in Europe is landfilled or incinerated, underscoring the need for safer and more recyclable alternatives. The SURPASS project addresses this challenge by developing Safe, Sustainable, and Recyclable by Design (SSRbD) polymeric materials. Following the European SSbD framework, the new developed materials focus in three high-demand sectors: a) building (replacing PVC in windows frames by bio-sourced polyurethane resins); b) transport (using lightweight epoxy-vitrimers to replace train metal components); and c) packaging (replacing non-recyclable films by recyclable multinano layered films). These alternatives are intended to reduce environmental impact while meeting industry performance standards. To assess the environmental safety of these new developed SSRbD materials, Daphnia magna was selected as model organism for acute aquatic toxicity, measuring EC50 immobilization values (following OECD202 guideline). 3 hardeners, 5 different combinations of resins + flame retardant, and leachates extracted from 4 different final composites were tested in the transport sector. In the case of building sector, 5 different bio-based polyols and 3 catalysts were studied, along with other 5 non-replaceable components. In the case of packaging sector, toxicity of the leachates of 4 multilayered films were tested. Safer materials were selected (regarding acute aquatic toxicity) for each of the component s types. The obtained values shall be integrated with other hazard endpoints as cytotoxicity, oxidative stress, epigenetic modifications, genotoxicity, and endocrine disruption to generate a final hazard score of each material, allowing the selection of the materials that offer more comprehensive environmental and human safety. This study is crucial in driving safer and greener innovations in the plastics industry. By rigorously evaluating and advancing less hazardous polymers, the project sets a benchmark for sustainable design, fostering broader adoption of SSRbD principles and supporting a circular economy transition. This project has received the funding from the European Union s Horizon Europe research and innovation program under grant no. 101057901 Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union. Neither the European Union nor the granting authority can be held responsible for them.

1.10.P-Tu082 Combined Toxicity of Antibiotic Ciprofloxacin and Polylactic Acid Microplastics to *Daphnia magna*: Role of Dissolved Humic Acid

Hanseong Kim[1], *Joorim Na*[2], *Gersan An*[1], *Gunay Karimova*[1] *and jinho jung*[1], *(1)Division of Environmental Science and Ecological Engineering, Korea University, Korea, Republic of, (2)OJeong Resilience Institute, Korea University, Korea, Republic of*
Biodegradable microplastics (BMPs) can exhibit toxic effects on aquatic organisms, similar to conventional plastics, through pollutant adsorption and ingestion. This study investigates the adsorption of humic acid (HA) and ciprofloxacin (CIP) onto BMPs (polylactic acid, PLA) and their combined toxicity to Daphnia magna during a 17-day chronic exposure. CIP, a fluoroquinolone antibiotic, is known to induce mitochondrial genotoxicity in Daphnia magna, affecting growth and reproduction. We hypothesized that antibiotics adsorbed onto BMPs would amplify toxicity in the gut of Daphnia magna and that HA-BMP interactions would increase CIP adsorption sites, further enhancing toxicity. The results provide insights into the interactions between aquatic organic matter, BMPs, and antibiotics, highlighting the combined toxic mechanisms and implications for environmental risk assessment. This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-RS202400335682).

1.10.P-Tu083 Ecotoxicity of Microplastics from Biodegradable Mulch Films: Metabolomic Analysis on *Daphnia magna*

Zhihan Cao[1], *Nik Nurhidayu Nik Mut*[2] *and jinho jung*[3], *(1)Korea University, China (Mainland), (2)Korea University, Malaysia, (3)Korea University, Korea, Republic of*
Biodegradable mulch films have been introduced in agriculture as a sustainable alternative to conventional plastic mulches to reduce waste and improve soil health. However, concerns have emerged regarding the environmental impact of these materials on nearby freshwater ecosystems. As these films degrade, they may release various organic compounds and microplastics, potentially becoming bioavailable to aquatic organisms such as Daphnia magna, leading to unforeseen ecological interactions. Metabolomics has proven to be one of the most powerful tools for identifying mechanisms of toxicity. Therefore, the

application of metabolomics is expected to reveal the mechanisms of the toxic effects of biodegradable microplastics (BMPs) derived from biodegradable mulch films on metabolite expression in D. magna. This study investigated the chronic toxicity of BMPs considering relevant scenarios (5 mg/L, <60 ?m, using pristine and original particles), using the water flea D. magna as model organisms, respectively, due to their ecological relevance in freshwater environments. Adults (5 d old) daphnids were exposed for 21 days to identify the impact of BMPs on metabolites of D. magna. Growth (mother's body length), consumption (ingestion rate, energy reservation) parameters, and metabolomics were measured to evaluate the effects of BMPs and additives. This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-RS202400335682).

1.10.P-Tu084 Effect of Conventional and Biodegradable Microplastics on *Daphnia magna* Population

***Changhae Kim**, Jungmin Kim, In-Geol Choi and jinho jung, Korea University, Korea, Republic of*
Biodegradable plastics (BPs) have been raising concerns lately regarding the generation of biodegradable microplastics (MPs) from incomplete biodegradation in the natural environment. Thus, evaluating the ecological effect of biodegradable MPs in aquatic ecosystems is essential for understanding the environmental effect of BPs. The present study investigates the population-scale effect of conventional (polyethylene terephthalate, PET) and biodegradable (polyhydroxybutyrate, PHB) MPs to Daphnia magna population. PET MPs significantly lowered population biomass compared to control, while PHB MPs did not. Gut microbial community analysis showed that PHB MP changed community structure compared to control and PET. This implies that biodegradable MPs may have a different mode of action than conventional MPs by altering the gut microbial community of zooplanktons, possibly acting as an additional carbon source or as an additional symbiotic relationship. This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-RS202400335682).

1.10.P-Tu085 Role of Humic Acid in the Combined Toxicity of Biodegradable Polylactic Acid Microplastics and the Pesticide Diflubenzuron to *Daphnia magna*

***Joorim Na**[1], Gunay Karimova[2], Hanseong Kim[3] and jinho jung[3], (1)OJeong Resilience Institute, Korea University, Korea, Republic of, (2)Korea University, Azerbaijan, (3)Korea University, Korea, Republic of*
The increasing need to address plastic pollution has led to the growing production and use of biodegradable polymer-based plastics. Although biodegradable plastics are known to completely decompose into water, carbon dioxide, and biomass under specific conditions, they may persist in the environment as microplastics under various environmental conditions, similar to conventional plastics. Recent studies have shown that biodegradable microplastics may exert comparable or even greater ecological toxicity effects on animals and plants than non-biodegradable microplastics. They can also act as carriers for environmental pollutants in a similar manner. Organic matter can interact with microplastics and pollutants in aquatic environments, influencing their adsorption behavior. Several studies have demonstrated that the interactions between organic matter, microplastics, and various pollutants can either mitigate or exacerbate toxicity to aquatic organisms. However, the role of organic matter in relation to biodegradable microplastics and pollutants remains insufficiently explored. Diflubenzuron (DFB) is an insecticide with a toxic mechanism that interferes with exoskeleton formation in insects. It has been reported to cause mortality, reproduction inhibition, and growth impairment in the aquatic crustacean Daphnia magna. In this study, we evaluated the role of humic acid, a representative organic matter, in the combined toxicity of the biodegradable plastic polylactic acid (PLA) and DFB. Adsorption test were conducted to examine the interactions between biodegradable microplastics and diflubenzuron in the presence of humic acid. Additionally, acute toxicity test performed using D. magna. After 48 hours of exposure, we recorded toxicity results (immobilization and mortality) and collected organisms to analyze oxidative stress, and chitin content related to the toxic mechanism of DFB. The findings of this study provide valuable insights into the interactions between organic matter and biodegradable microplastics and their ecotoxicological risks. Furthermore, they contribute to a better understanding of the role of biodegradable microplastics as vectors for pollutant transport in the environment. This research was supported through the National Research Foundation of Korea (NRF) funded by Basic Science Research Program from Ministry of Science and ICT of Korean government (NRF-2022R1C1C2009130).

1.10.P-Tu086 Egestion Rates of Microplastics in *Daphnia magna* Depending on Food Uptake

***Haemi Kim** and Youn-Joo An, Department of Environmental Health Science, Konkuk University, Korea, Republic of*
Micro-sized plastics have been concerned about potential effects on aquatic organisms. Microplastics can be ingested by aquatic organisms, both filter feeders and non-filter feeders. Waterflea is one of the filter

feeders, and previous studies have shown waterflea can ingest various types of microplastics. Most research have been reported ingestion and egestion of microplastics on waterflea using microscopy images. Since gut fullness images cannot be quantified the amount of microplastics, this study aimed to quantify the ingestion and egestion amounts of microplastics using fluorescence microplastics. Egestion rates of microplastics were observed under presence and absence of food conditions. Daphnia magna was exposed to 1 mg/L of 1 5 ?m sized green fluorescent polymer microspheres for 24 hours then, they were transferred to clean media for 24 hours under presence or absence of food conditions. Egested microplastics were detected using fluorescent intensity. As a result, microplastics were egested from D. magna faster under the presence of food than the absence of food. D. magna can be egested the microplastics under food supplied conditions. This method can be easily quantifying the amount of ingested and egested microplastics than using the gut fullness of image. Food co-exposure system also need to consider the microplastic effects on aquatic organisms. This research was supported by Korea institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220383).

1.10.P-Tu087 The Long-Term Effects of Plastics in Semi-Natural Population of Zooplankton

*Maiju Lehtiniemi[1], Pinja Nakki[1], **Jyri Tirroniemi**[1], Anna Kangas[1], Dieter Ebert[2] and Outi Setala[1], (1)The Finnish Environment Institute, Finland, (2)University of Basel, Switzerland*

Multiple studies on the ingestion and effects of primary and secondary plastic fragments on zooplankton have been performed in laboratory conditions. However, the knowledge on the effects of naturally fragmenting microplastics (MP) in situ is still scarce and impacts over generations are rarely assessed. In this experiment effects of plastics on the fitness of cladoceran communities, based on the production of resting eggs, were studied in a mesocosm study spanning over two summer periods. The experiment was carried out with local, field-collected cladocerans (Daphnia magna) on an outer archipelago island (Furuskär, SW coast of Finland) with multi-generational exposure of macro- and microplastics. Altogether 42 experimental units (glass containers) were prepared: 14 control units with only cladocerans (40 ind. D. magna), 14 units with D. magna and weathered MP originating from a polyethylene (PE) tarp and 14 units with D. magna and a piece of the same tarp. At the end of the first summer adult cladocerans and the resting eggs were collected and counted. The resting eggs were stored in glass vials over winter in natural conditions. The experiment was repeated in the following summer with a similar set up, with the exception that instead of using field-collected cladocerans, the ephippia from the previous year were used to initiate the cladoceran communities in the units. At the end of the experiment D. magna and ephippia were counted, water and sedimented organic matter samples collected for the additives (UV-stabilizers) and microplastic analyses. Ephippia were kept in cold (+5 C) and dark over winter, and a hatching rate experiment carried out in the following spring. Preliminary results indicate that both MP and leachates from larger plastics have a negative impact on the resting egg production. These findings increase knowledge on the role of different exposure pathways of plastic litter in aquatic invertebrate communities' generations.

1.10.P-Tu088 Ingestion and Depuration Rates of Metal-Doped Nanoplastics (Pd-PS NPs) in Pelagic and Benthic Copepods: Implications for Trophic Transfer

***Kevin Ugwu Hernandez**[1], Denise M Mitrano[2], Annemette Palmqvist[1] and Kristian Syberg[1], (1)Department of Science and Environment, Roskilde University, Denmark, (2)Department of Environmental Systems Science, ETH Zurich, Switzerland*

The fragmentation of environmental plastics into nanoplastics (NPs, <1000 nm) and shedding of nanoplastics from plastic surfaces has raised concerns regarding their distribution and impacts in marine ecosystems. Many studies have reported NPs ingestion and effects on marine invertebrates, often utilizing fluorescently labeled NPs. However, the reliability of these methods has been questioned due to the potential leaching of fluorescent dyes into tissues. Moreover, most research has been conducted individually in a few model species like zebrafish, sea urchins, or mussels, which do not reflect the diversity of the species in marine communities. Copepods, the most abundant marine animal group, play a key role in energy transfer within food webs. However, to the best of our knowledge, no studies have investigated NPs accumulation across different copepod species. This study aimed to quantify NPs ingestion and depuration in various pelagic and benthic copepods with distinct feeding behaviors: ambush feeding, cruising, current feeding, and benthic grazing. For this, we exposed the copepods Temora longicornis, Centropages hamatus, Apocyclops royi, and Tisbe battagliai, that represent the major copepod groups (calanoids, cyclopoids, harpacticoids) to 150 nm metal-doped polystyrene NPs (Pd-PS NPs). Following foodborne exposure, copepods were transferred to clean seawater for depuration. NPs content was quantified at multiple time points during the exposure and depuration period using Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Our preliminary results show species specific rates for

NPs accumulation and depuration. We hypothesize that species such as A. royi (ambush feeders) and T. battagliali (benthic grazers) will retain NPs longer due to their feeding behaviors and slower gut transit times, compared to calanoids like T. longicornis and C. hamatus. These findings highlight the importance of species-specific traits in NPs accumulation and emphasize the need to consider biological and physiological factors when designing experiments of trophic transfer of NPs.

1.10.P-Tu089 Distinct Chronic Toxic Effects of Fragmented and Fibrous Polyethylene Terephthalate Microplastics on Marine Amphipod *Monocorophium uenoi*

***Jinyoung Song**, Jin Soo Choi, Hyeonji Nam, Asna Ali and June-Woo Park, korea institute of toxicology, Korea, Republic of*

Microplastic (MP; 1 5000 µm) pollution has emerged as a critical environmental concern, with fragments and fibers being the most abundant shapes of MPs in marine ecosystems. Despite their prevalence, toxicological studies on benthic organisms remain poorly understood. Therefore, this study aimed to distinguish the chronic toxicity of fragmented and fibrous polyethylene terephthalate (PET) MP to Monocorophium uenoi. Chronic toxicity tests (n = 3) were conducted with 34 M. uenoi (size: 300-500 µm) in 1 L glass beakers containing 200 g of sediments and 800 mL of artificial seawater (salinity 30 psu). M. uenoi were exposed to fragmented (small, medium, and large size) and fibrous (short and long length) MPs for 35 days. At the end of the experiment, mortality, MPs accumulation, behavioral activities (distance, velocity, energy distribution (carbohydrate, protein, lipid), and oxidative stress (lipid peroxidation (LPO) and total antioxidant capacity (TAC)) were evaluated. All concentrations (0.0005 and 10 mg L-1) of Fragment M induced significant mortality with MP accumulation at 10 mg L-1, while no accumulation of fibrous MPs was observed in M. uenoi. For behavioral activities, all concentrations of Fiber S showed significant decreases compared to the control, while fragmented MPs decreased behavior only in dark conditions or at high concentrations (10 mg L-1). Regarding energy distribution, fragmented MPs induced significantly greater changes than fibrous MPs, with energy being utilized for immediate energy source, growth, and immunity. Furthermore, fragmented MPs significantly increased both LPO and TAC, indicating activation of antioxidant defense mechanisms in response to fragmented MP-induced oxidative stress. In contrast, fibrous MPs only induced significantly low TAC without changes in LPO, suggesting different stress mechanism. These findings highlight the distinct toxic effects and mechanisms between fragmented and fibrous PET MPs in marine organisms. This understanding provides crucial insights for environmental risk assessment of differently shaped microplastics and supports the development of more targeted management strategies for marine plastic pollution. This work was supported by Risk assessment to prepare standards for protecting marine ecosystem of Korea Institute of Marine Science & Technology Promotion (KIMST), funded by the Ministry of Oceans and Fisheries (KIMST-20220383).

1.10.P-Tu090 Biological Response and Molting Regulation of Whiteleg Shrimp to Microplastic Fibers

***Lia Kim**, Haemi Kim, Yubeen Song and Youn-Joo An, Konkuk University, Korea, Republic of*

With the continuous release of plastic particles, the marine ecosystems are under threat from the microplastic contamination and these microplastics eventually reach to the ecological receptors consumed as food sources. Penaeus vannamei (whiteleg shrimp), one of the valuable food sources in the ocean, were exposed to polyethylene terephthalate based microplastic fibers (PET MFs) for 21 d, and the biological responses were observed. We revealed that PET MFs induced growth inhibition and altered molting cycle with the changes of exoskeletal chromatophores and hepatopancreas. By analysing the transcriptomes and metabolomes, the alterations of biosynthesis in chitin and molting hormone related molecules affected to the molting cycle and exoskeletal impacts. These results improve our understanding of biological responses and metabolic regulation of P. vannamei to PET MFs, ultimately suggesting the need to protect ecological receptors from the microplastic contamination for the environmental sustainability and economic value as food sources. This research was supported by Risk assessment to prepare standards for protecting marine ecosystem of Korea institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220383).

1.10.P-Tu091 Comparative Toxicity of Dialyzed Nanoplastic and Leachates in Zebrafish Larvae

***Mohamed Helal**[1], Xiaoyu Duan[2], Elvis Genbo Xu[2] and Henrik Holbech[2], (1)Biology, University of Southern Denmark, Odense, Denmark, (2)Department of Biology, University of Southern Denmark, Denmark*

Amid growing concerns over the ecological and health impacts of plastic pollution, nanoplastics have emerged as a significant environmental hazard. A key debate centers on whether the observed toxicity is due to the plastic particles themselves or their leachates. In this study, we address this issue by comparatively analyzing the toxic effects of small-sized (15 nm) dialyzed nanoplastics and their leachates on the development of zebrafish (Danio rerio) larvae up to five days post-fertilization. We also investigated the impacts of plain polystyrene particles versus those with an anionic carboxyl (COOH) surface charge. Extensive morphometric analyses of sixteen endpoints revealed that both nanoplastics and their leachates adversely affect organ development in zebrafish larvae. Notably, dialyzed polystyrene (DPS) and carboxylated polystyrene (DPSCOOH) induced significantly higher mortality rates compared to their leachate counterparts. DPS had a more pronounced effect on body curvature and length than its leachate. Furthermore, significant differential impacts between nanoparticles and their leachates were observed in neurodevelopment (eye, head, otolith, and neuronal areas), digestive system development (stomach area, intestine length, and yolk area), and muscular development (muscle area). Behavioral abnormalities in larvae from both the dialyzed and leachate exposure groups accompanied these morphological defects. Future chemical characterization of leachate constituents will aid in identifying specific chemicals responsible for the observed toxic effects. This study was funded by the Sapere Aude Research Leader program from the Danish Council for Independent Research (No.0165-00056B).

1.10.P-Tu092 Effects of Field-Collected Microplastic Particles on Zebrafish (*Danio rerio*) Embryos: Importance of Particle Size

Lisa Bauer[1]*, Laura Franzen*[1]*, Silas Muller*[1]*, Ria Mauch*[1]*, Patrick Heinrich*[1] *and Thomas Braunbeck*[2]*, (1)Heidelberg University, Centre for Organismal Studies, Germany, (2)University Heidelberg, Centre for Organismal Studies, Germany*

Due to the global surge in plastic production, the evaluation of the environmental impact of plastic waste has emerged as a central focus in ecotoxicology. Notably, smaller plastic fragments, termed microplastics (MPs), have been identified across diverse aquatic ecosystems. Due to their small size and low biodegradability, MPs can easily be ingested by organisms and transferred along food webs. Ingestion may not only bear physical risks, but could also implicate chemical hazards, as MPs can convey man-made environmental contaminants, including pharmaceuticals and pesticides. Consequently, MP ingestion has frequently been linked to adverse effects on mortality, growth, feeding behavior, endocrine functions, and immune responses. Given that many mechanisms driving MP toxicity remain poorly understood, additional research is essential to evaluate the risks MPs pose to aquatic life. To study the biological effects of organic extracts from MPs, wild-type zebrafish (Danio rerio) embryos were used as a non-protected vertebrate model. The MP samples, collected as part of the JPI Oceans project RESPONSE (https://www.response-jpioceans.eu/), consisted of three different size fractions: 20 - 50 µm, 100 - 200 µm, and 500 - 1000 µm. These samples were sourced from European coastal waters including the Tyrrhenian and Adriatic Seas as well as the Bay of Biscay. Organic contaminants adsorbed to MPs were extracted using n-hexane. Toxicological endpoints included (1) acute toxicity; (2) induction of ethoxyresorufin-O-deethylase (EROD) activity through the aryl hydrocarbon receptor-mediated activation of cytochrome P450-dependent monooxygenases (CYP1A); (3) acetylcholinesterase activity; and (4) changes in the optokinetic response, with a focus on differences in effects related to particle size. Effects proved particle size-related and include symptoms of acute toxicity, a reduction of body length and induction of EROD activity, as well as changes in swimming activity. Together, these experiments provide insights into the toxic mechanisms and effects induced by MP extracts in zebrafish embryos, potentially enhancing the environmental hazard and risk assessment of MPs. This study has received financial support within the JPI-Oceans-associated project RESPONSE from the German Ministry for Education and Science (BMBF) under contract no. 03F0853A.

1.10.P-Tu093 Nanoplastic Alleviates Neurotoxicity of Mercury in Zebrafish through Regulating the Metabolic Pathways of Brain-Gut-Microbiota Axis

Liqiang Chen*, Yifan Bu, Zihao Fu and Ruiyuan Gaoli, Institute of International Rivers and Eco-security, Yunnan Key Laboratory of International Rivers and Trans-Boundary Eco-security, Yunnan University, China (Mainland)*

Mercury is a high neurotoxic environmental pollutant that affects human health. However, the impact of emerging environmental pollutants such as micro-and nano-plastics on the neurotoxicity of mercury remains unclear. In this study, the ' brain-gut-microorganism ' axis of zebrafish was used as the object to explore how nanoplastics affect the neurotoxicity of mercury on zebrafish by integrating metabolomics and microbiomes. The results showed that single mercury exposure significantly increased the anxiety behavior of zebrafish and slowed zebrafish swimming capacity, but the co-exposure of nanoplastics alleviated the anxiety behavior and exercise injury of zebrafish caused by mercury exposure. Moreover, the co-exposure of nanoplastics and mercury also significantly reduced the accumulation of mercury in the brain and intestine of zebrafish. Microbial and metabolomics analysis showed that nanoplastics could not only alleviate the disorder of intestinal microflora in zebrafish caused by mercury exposure, but also significantly reduce the intestine microbial diversity. Compare with single mercy exposure, the co-exposure of nanoplastics can also improve the brain metabolic disorders and slow down the neurotoxicity of mercury by regulating glycerophospholipid metabolism, arachidonic acid metabolism and ?-linolenic acid metabolism in the ' brain-gut-microorganism ' axis. In summary, nanoplastics alleviate the neurotoxicity of mercury exposure to zebrafish by regulating the key metabolic pathways of the ' brain-gut-microbiota' axis. Our results provide a new understanding of how nanoplastics interfere with the neurotoxicity of mercury in zebrafish. The work was supported by the National Natural Science Foundation of China (No.22066026), the Applied Basic Research Foundation of Yunnan Province (No.202401AS070144).

1.10.P-Tu094 Polyvinyl Chloride Microplastics Modulate Fipronil Accumulation and Toxicity in Zebrafish

*Long Fu, **Dali Wang** and Jing You, Jinan University, China (Mainland)*

Microplastics (MPs) can transport and facilitate the transformation of co-existing contaminants, altering their bioaccumulation and toxic effects in organisms. This study examined the adsorption and transformation of fipronil in the presence of polyvinyl chloride (PVC) MPs (150 530 ?m) and assessed their individual and combined effects on zebrafish. PVC MPs were found to adsorb fipronil with a maximum capacity of 7393 ng g?¹ and facilitated its transformation into fipronil-sulfone and fipronil-desulfinyl. Zebrafish exposed to dietary fipronil alone (70 ng g?¹) for 14 days accumulated fipronil and fipronil-sulfone at total levels of 0.17 and 0.30 ng g?¹, respectively. In contrast, combined exposure with MPs (1% w/w) increased the bioaccumulation of fipronil and fipronil-sulfone to 0.53 and 3.25 ng g?¹, respectively, and additionally led to the accumulation of fipronil-desulfinyl at 0.77 ng g?¹. Both single and combined exposures enhanced zebrafish swimming behavior, with synergistic effects observed initially (days 1 and 3). The impact on antioxidant enzyme activities (CAT and SOD) was more pronounced in the groups exposed to MPs and the combined treatments, highlighting the dominant role of MPs in inducing oxidative stress. Principal coordinate analysis of behavioral and enzyme activity outcomes revealed distinct separations among the control, single MPs, single fipronil, and combined exposure groups. Overall, our findings demonstrated that PVC MPs significantly enhanced bioavailability and altered the metabolic profile of fipronil in aquatic organisms, leading to notable physiological and biochemical changes.

1.10.P-Tu095 Multi-omics Insights into the Combined Ecotoxicity of Antibiotics and Microplastics in Zebrafish under Acute and Chronic Exposure

***Mingcan Li**[1] and Sungwoo Bae[2], (1)Department of Civil and Environmental Engineering, National University of Singapore, Singapore, (2)Department of Environmental System Engineering, Korea University, Korea, Republic of*

Emerging contaminants pose growing environmental concerns due to their inadequate regulation and unclear ecotoxicity. Among these emerging contaminants, microplastics and antibiotics have obtained increasing scientific attention. Given the ubiquity and sorption ability of microplastics, investigating the ecotoxicity of their co-occurrence is both realistic and crucial. However, our current understanding on their combined ecotoxicity remains limited. This study aims to perform comprehensive ecotoxicity assessment on antibiotics, microplastics and their co-occurrence, by multi-omics approach, using adult zebrafish (Danio rerio) as a model organism under both acute and chronic exposure. In this study, Oxytetracycline (OTC) and Polyethylene (PE) fragments (<500 μm) were selected as representative antibiotics and microplastics, due to their wide application and environmental prevalence. Adult zebrafish was exposed to OTC alone, PE alone, or their combination for 4 days (acute exposure) or 30 days (chronic exposure). Subsequently, DNA, RNA, and metabolites were extracted accordingly and processed by sequencing or Ultra Performance Liquid Chromatography-Tandem Mass Spectrometry (UPLC-MS/MS) to retrieve gut microbiome, transcriptomics, and metabolomics data. OTC and PE microplastics exhibited a significant synergistic effect on the transcriptomic profile of adult zebrafish under acute exposure, highlighting combined toxicity related to cell death, genotoxicity, and reproductive toxicity. This synergism was less evident in the gut microbiome and metabolomic profiles. However, all three omics layers consistently revealed the distinct ecotoxicity of co-occurring OTC and PE. Greater within-group variation was observed in gut microbiome of co-occurrence group, indicating potential gut microbiome dysbiosis. Metabolomics indicated distinct combined impacts, including dysregulated arachidonic acid and carbohydrate metabolism. The observed synergistic effect raises the environmental concerns of co-occurring antibiotics and microplastics, but was limited to acute exposure. Similarly, toxicological impacts under chronic exposure were generally lower, indicating the potential adaptation. However, chronic OTC exposure induced additional toxicity on reproduction and cell development, which was not identified under acute exposure. Further research is recommended to explore the mechanisms underlying the synergystic effect and biological response to external exposure.

1.10.P-Tu096 Application of Probabilistic Species Sensitivity Distribution Modelling to Characterize Microplastic Risk for Marine and Freshwater Environments

*Scott Coffin[1], Andrew Barrick[2], Andrew Yeh[3], Anna Tuulikki Kukkola[4], Bethanie Carney Almroth[5], Ezra L Miller[6], Kazi Towsif Ahmed[7], Lidwina Bertrand[8], Mariella Sina[9], Luan de Sourz Leite[10], Magdalena M. Mair[11], Stephanie B Kennedy[12], **Tham C. Hoang**[13] and Win Cowger[14], (1)California Office of Environmental Health Hazard Assessment, United States, (2)Auburn University, United States, (3)Graident, United States, (4)University of Birmingham, United Kingdom, (5)University of Gothenburg, Sweden, (6)San Francisco Estuary Institute, Richmond, United States, (7)Bangladesh Agricultural University, Bangladesh, (8)The National Scientific and Technical Research Council, Argentina, (9)National Taiwan University, Taiwan (Greater China), (10)University of Campinas, Brazil, (11)University of Bayreuth, Germany, (12)ToxStrategies, United States, (13)Auburn University, (14)Moore Institute, United States*

Reliable accounting for the diversity of microplastics (MPs) in hazard assessments involves the use of ecologically relevant metric (ERM) alignments requiring distribution data of physical particle attributes and organism bio-accessibilities. While eco-toxicological thresholds have been developed using this approach, uncertainties associated with the alignments have not been fully quantified. The present study utilized a probabilistic species sensitivity distribution (pSSD) model based on the updated Toxicity of Microplastics Explorer (ToMEx 2.0) database to derive hazard thresholds for MPs, while accounting for uncertainties due to alignments. Aligned No Observed Effect -concentrations (NOECs) were used to populate pSSDs to derive thresholds in a four-tier management framework based on the food dilution and tissue translocation-mediated effects ERMs. pSSDs differ from traditional SSDs by avoiding the use of predefined distributions to model species sensitivities, instead utilizing empirical calculations with the complete data set therefore more accurately representing underlying data. The ToMEx 2.0 dataset comprises 12,878 data points from 289 studies covering species across marine (n = 101) and freshwater (n = 67) environments. The dataset was filtered using pre-defined quality criteria, resulting in a total of 398 data points from 58 studies, with 25 marine and 19 freshwater species. Thresholds for marine and freshwater environments were derived separately using previously defined four-tier-management criteria. The resulting ERM-aligned hazard thresholds ranged from 1x10-4 to 4 particles/L, and 1 to 4,000 particles/L for marine environments, and 8 to 1,000 particles/L, and 500 to 20,000 particles/L for freshwater environments for food dilution and tissue translocation-mediated effects, respectively. Threshold uncertainties based on alignment of Monte Carlo simulations were lower for freshwater than marine environments, with percent relative standard deviations ranging from 24% to 270% for marine thresholds, and 21% to 130% for freshwater. This study is the first application of fully probabilistic methods to derive ERM-based MP hazard thresholds. We further explore the variability, uncertainty, and limitations of these thresholds through quantitative global and local sensitivity analyses, as well as qualitative discussions regarding study quality and data availability.

1.10.P-Tu097 Horizontal Gene Transfer Antibiotic Resistance Gene in Presence of Bio-Plastics: PLA and PHBV

*Yousuf Dar Jaffer[1], Fazel Abdolahpur Monikh[2], **Nhung Nguyen**[3], Alena Sevcu[3] and Hans-Peter Grossart[4], (1)leibniz Institute for Freshwater Ecology and Inland Fisheries, Germany, (2)Leibniz-Institute of Freshwater Ecology and Inland Fisheries, Germany, (3)Institute for Nanomaterials, Advanced Technologies and Innovation, Technical University of Liberec, Czech Republic, (4)Department of Experimental Limnology, Leibniz-Institute of Freshwater Ecology and Inland Fisheries, Germany*

It is well known that microplastics (MPs) from conventional plastics facilitate horizontal gene transfer (HGT) of antibiotic resistance genes (ARG). This study investigates whether MPs derived from bio-based plastics, such as polylactic acid (PLA) and poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV), exhibit similar behaviour. We used a trimethoprim-resistant Escherichia coli strain hosting the gfp-tagged plasmid pKJK5 as the donor, and a natural lake microbial community as recipients. MPs from virgin PHBV, virgin PLA and commercial PLA were selected with chitosan serving as a natural control. The gene transfer frequency was evaluated both on the surface of MPs and in the liquid suspension phases by flow cytometry. There was no difference in HGT between virgin and commercial PLA. However, PHBV showed significantly higher gene transfer frequency than both types of PLA (virgin and commercial) and the control. Pseudomonas, Aeromonas and Sphingomonas were the dominant bacterial groups in the lake which took up the plasmid on the surface of these MPs. These findings highlight the need of a regulatory framework to assess and manage the environmental risk with the use of biodegradable plastics. This work received funding from the European Union's Horizon 2020 Research and Innovation programme, under

the Grant Agreement number 965367 (PlasticFate). Yousuf Dar Jaffer was funded by the Indian Council of Agricultural Research, New Delhi, through the ICAR-Netaji Subhas International Fellowship (grant number: 18(02)/2019-EQR/Edn

1.10.P-Tu098 Microplastic Pollution: A Hidden Driver of Antibiotic Resistance Gene Transfer?

Ting Zhang[1]*, Maaike Vercauteren*[1]*, Tom Coenye*[2] *and Jana Asselman*[1]*, (1)Blue Growth Research Lab, Ghent University, Belgium, (2)Laboratory of Pharmaceutical Microbiology, Ghent University, Belgium*

Microplastics (MPs) have been detected globally, from beaches and ocean depths to air and sediment pollution. The widespread use of antibiotics in treating bacterial infections has increased their presence as emerging contaminants in aquatic environments, as wastewater treatment systems often fail to remove them. Antibiotics add selective pressure to bacteria, promoting antibiotic resistance and contributing to infections that undermine modern medicine. Microplastics, due to their small size, large surface area, hydrophobicity, and low degradability, serve as vectors for microbial colonization and biofilm formation. Compared to natural materials like rocks and leaves, MPs have a greater ability to support microbial communities. Additionally, MPs can adsorb environmental contaminants, including antibiotics, which makes biofilms on MPs hotspots for horizontal gene transfer. This process facilitates the spread of antibiotic resistance genes (ARGs) to potentially pathogenic bacterial species within microbial communities. Bacteria can exchange resistance genes easily via horizontal gene transfer, a process that is enhanced in biofilms due to the proximity of cells. We investigated how varying concentrations of polyvinyl chloride (PVC) and polystyrene (PS) MPs affect the frequency of ARG transfer in laboratory conditions. Furthermore, we explored how different MPs influence biofilm formation and ARG transfer efficiency. Escherichia coli cultures were grown in lysogeny broth (LB) medium, and MPs were added at concentrations ranging from 0 to 800 mg/L. After 24 and 48 hours, particles were collected, and bacteria attached to the particles were cultured on plates. MPs were characterized using dynamic light scattering (DLS) and scanning electron microscopy (SEM) to study their effect on biofilm growth. Surface roughness of MPs was found to influence biofilm formation, and the efficiency of antibiotic gene transfer varied significantly with the type of MPs. Compared to the control group without MPs, biofilms formed on MP surfaces significantly enhanced bacterial survival rates and increased the efficiency of ARG transfer. Future research will include field sampling to study ARG transfer dynamics in natural aquatic environments, offering insights into how MPs contribute to the spread of antibiotic resistance in real-world conditions.

1.10.P-Tu099 Chironomids as Vectors for Microplastic Transfer Across Ecosystems

Dimitrija Savic-Zdravkovic[1]*, Jelena Slavisa Stojanovic*[2]*, Ana Vladan Samardžić*[1]*, Melita Mustafic*[1]*, Dragana Asceric*[1] *and Djuradj Milosevic*[3]*, (1)Faculty of Sciences and Mathematics, University of Nis, Serbia, (2)Biology and Ecology, Faculty of Sciences and Mathematics, University of Niš, Nis, Serbia, (3)Faculty of Sciences and Mathematics, University of Niš, Serbia*

The transfer of microplastics (MPs) from aquatic to terrestrial ecosystems represents an emerging pathway of contamination with significant ecological implications. Chironomids (Chironomus riparius), which undergo aquatic larval development before emerging as terrestrial adults, serve as key vectors for MP transfer. This study investigated the ingestion, retention, and expulsion of MPs in C. riparius exposed to a complex mixture of polyethylene (PE), polyvinyl chloride (PVC), and polyamide (PA) particles at environmentally relevant concentrations. Using an OECD-compliant chronic exposure model, we monitored life-history traits and quantified MPs in both emerging adults and exuviae to assess the efficiency of particle transfer across life stages. Results revealed that MPs were consistently transferred from the aquatic larval stage to terrestrial adults, confirming C. riparius as a conduit for MP dispersal. However, exuviae contained significantly higher concentrations of MPs than adult specimens, indicating molting as a potential detoxification pathway. The use of a mixed MP composition in this study provides critical insights into the behavior of diverse polymers in sediment-rich environments, reflecting real-world contamination scenarios. These findings highlight the dual role of chironomids as both victims and vectors of MP pollution, emphasizing their importance in understanding the cross-ecosystem impacts of microplastics. This research underscores the need for comprehensive assessments of MP transfer dynamics in benthic invertebrates to better predict their ecological consequences and inform management strategies for contaminated habitats. This research was conducted as part of the Plastic Underground Integrated Cross-Sectoral Solutons to Micro and Nanoplstic Pollution in Soil and Groundwater Ecosystems project HORIZON-MSCA-2021-DN, funded by the European Union's Horizon Europe program under Grant Agreement No. 1010727777

1.10.P-Tu100 Natural Particles to be used as Reference for the Risk Assessment of Particulate Pollutants

Sebastian Hoss[1]*, Katrin Wendt-Potthoff*[2]*, Martin G.J. Loder*[3] *and Christian Laforsch*[3]*, (1)Ecossa, Germany, (2)Helmholtz Center for Environmental Research, Germany, (3)University of Bayreuth, Animal Ecology Bayreuth, Germany*
Due to the increasing entry of microparticles into the environment, sensitivity to the health risk of particles in air, water and soil has increased significantly over the last two decades, both in society and in science. There is now no question that microparticles can also have a harmful effect on living beings through specific mechanisms. However, this environmental risk must be assessed using appropriate methods tailored to these mechanisms. The ecotoxicological effect and exposure assessment of particulate pollutants involves significantly more uncertainty factors than that of dissolved chemicals, which makes reliable risk assessment difficult. The potential mechanisms of action of the microparticles are often not clear, involving combined direct chemical and mechanical as well as indirect effects (e.g. feed dilution; binding of nutrients) that are difficult to separate. Since organisms in their natural environment are also exposed to organic and mineral microparticles that are similar to particulate pollutants introduced by humans in terms of their physical and chemical properties as well as their ecotoxicological behavior, it is important to distinguish pollutant-specific effects from general particle effects. Through increased knowledge about the effectiveness or effect-relevant properties of natural particles and the use of application-specific, tailor-made natural reference particles in ecotoxicological tests, specific effects of particulate pollutants can be identified. With this poster, we want to present a research project (NatuReP), where natural microparticles, which are similar in their morphological and physical properties to selected particulate pollutants, are to be examined with regard to their ecotoxicological behavior in various environmental matrices (water, sediment, soil) and with regard to their suitability as reference particles for the ecotoxicological assessment of particulate pollutants. To this end, we apply (1) state-of-the-art analytical methods for characterizing microparticles (chemical, physical, transport), (2) a wide range of ecotoxicological test systems (with organisms of different organizational and trophic levels), (3) and suitable statistical methods for correlating particle properties and -effect. The aim of this project is to identify naturally occurring particles to serve as tailored reference which can be recommended for use in the environmental risk assessment of particulate pollutants in practice. This project is funded by the German Federal Environmental Foundation (DBU 38446-01)

1.11 Unraveling the Complexities of PFAS From Environmental Toxicology to Human Health

1.11.T-01 A tale of Banned and Novel PFAS: Approach to Developmental Toxicity in Zebrafish Embryo

Opeoluwa Ogunsuyi[1]*, Maud Philipps*[1]*, Marianne Houin*[1]*, Arno C. Gutleb*[2]*, Kahina Mehennaoui*[3] *and Sebastien Cambier*[2]*, (1)Luxembourg Institute of Science and Technology, Luxembourg, (2)Erin, Luxembourg Institute of Science and Technology, Luxembourg, (3)Luxembourg Institute of Science and Technology, Luxembourg*
The persistence, bioaccumulation, and detrimental effects to the environment and human health of perfluorooctanoic acid (PFOA) and perfluoroocatne sulfonate (PFOS) have led to their global ban, prompting the introduction of novel PFAS (perfluoroalkyl substances) alternatives. The most predominant among the PFAS alternatives are the perfluoroether carboxylic acids (PFECA) and perfluoroether sulfonic acids (PFESA). However, the environmental health and toxicity concerns associated with the PFECA and PFESA are largely unexplored. In this study, the zebrafish (Danio rerio) was utilised as a toxicological model to investigate the developmental toxicity of representatives of PFECAs, such as hexafluoropropylene oxide trimer acid (HFPO-TA) and perfluoro-3,6,9 trioxadecanoic acid (PFO3DA), and PFESAs, such as perfluoro-3,6-dioxa-4-methyl-7-octenesulfonic acid (NBP1) and 7H-perfluoro-4-methyl-3,6-dioxaoctanesulfonic acid (NBP2), alongside the most widely studied and banned PFAS, PFOA, and PFOS potassium salt (PFOS-K). We assessed the acute toxicity by calculating the median lethal concentration (LC50) in zebrafish embryos exposed to the six previously mentioned PFASs at concentrations ranging from 0 to 100 mg/L. Additionally, developmental anomalies, hatching rate, heart rate, and body length were evaluated under exposure to environmentally relevant PFAS concentrations (7, 70, 350, and 700 µg/L) in the period from 6 and 96 hours post-fertilisation (hpf). Results showed that the LC50 values of PFOA (>100 mg/L) and PFOS-K (54.56 mg/L) aligned with earlier studies. Likewise, the calculated LC50 values show the hierarchy of toxic potency as follows: NBP1 > PFOS-K > PFO3DA > NBP2 > HFPO-TA > PFOA. Furthermore, PFASs exposure at environmental concentrations resulted in a diverse occurrence of developmental malformations, including pericardial oedema, uninflated swim bladder, notochord malformation, blood congestion, yolk sac oedema/deformation, impaired fin development, and short body length, among others at 96 hpf. The heart rate was significantly inhibited except for PFOA and NBP1, which caused a significant increase in heart rate. Meanwhile, the body length of the larva was significantly reduced across the tested PFASs. In summary, the novel PFAS alternatives

may induce developmental toxicity in zebrafish embryos, suggesting that they are not safer substitutes for PFOS and PFOA. This project has received funding from the European Union s Horizon-MSCA-2022-PF-01 under the Marie Sk?odowska-Curie grant agreement No. [101108489].

1.11.T-02 Upscaling PFAS Dynamics from Trophic Chains to Ecosystem Responses in an AFFF Contaminated Environment

Davide Gualandris[1], *Marios Kostakis*[2], *Georgios Gkotsis*[2], *Triantafyllos-Dimitrios Gerokonstantis*[2], *Maria-Christina Nika*[2], *Davide Rotondo*[3], *Candida Lorusso*[3], *Antonio Calisi*[3], *Giorgio Mancinelli*[4], *Nikolaos S. Per- and polyfluoroalkyl substances (PFAS) are synthetic chemicals renowned for their persistence, bioaccumulation, and ecological risks. This study investigates PFAS contamination at a firefighting training site in Trelleborg, Sweden, analyzing 158 environmental and biological samples spanning terrestrial and aquatic ecosystems. Through stable isotope analysis (SIA) to reconstruct trophic interactions and LC-MS/MS quantification of 16 PFAS, bioaccumulation and biomagnification dynamics were assessed. Results reveal that PFOA and PFOS dominate contamination profiles due to their historical use in aqueous film-forming foams (AFFF). Bioconcentration and bioaccumulation factors highlight higher PFAS accumulation in aquatic systems, with biomagnification observed for PFOA and PFOS. In terrestrial ecosystems, short-chain congeners such as PFHxA and PFHpA consistently demonstrate biomagnification trends. This study highlights that short-chain PFAS, once considered less bioaccumulative, can significantly accumulate and even biomagnify in terrestrial food webs. These findings challenge conventional assumptions about their safety as alternatives to long-chain PFAS and underscore their potential ecological risks. This work emphasizes the necessity of integrating short-chain PFAS into environmental risk assessments and adopting stricter regulatory measures to mitigate their impact. This project has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No 101037509 (SCENARIOS project)

1.11.T-03 Blood-based Lipid Perturbations Linked to Per- and Polyfluoroalkyl Substances (PFAS) in Drinking Water and Occupational Exposures

Ashlee Falls[1], *Anna Boatman*[1], *Jack Ryan*[1], *Amie Solosky*[1], *James Dodds*[1], *Jessie Chappel*[1], *Kaylie Kirkwood-Donelson*[2], *Samantha Hall*[3], *Taylor Elizabeth Schronce Hoxie*[4] *and Erin Baker*[1], *(1)University of North Carolina at Chapel Hill, United States, (2)National Institute of Environmental Health Sciences, United States, (3)Duke University, Durham, NC, United States, (4)Duke University, Durham, United States*
Per- and polyfluoroalkyl substances (PFAS) are a class of synthetic, persistent chemicals associated with health concerns, particularly in communities near production and release sites. Firefighters are also often exposed to PFAS through protective turnout gear and aqueous film-forming foam applications. PFAS have been implicated with increased cholesterol in humans, but other lipid species have not been evaluated extensively. In this study, we explore both PFAS presence and lipid changes in human serum for two cohorts, one with high drinking water exposure (DW, n=49) and the other having exposure through their firefighting occupation (FF, n=29). Specifically, a non-targeted analysis platform coupling liquid chromatography, ion mobility spectrometry, collision induced dissociation, and mass spectrometry (LC-IMS-CID-MS) separations was used to evaluate >100 PFAS and >800 lipid species. PFAS and lipids were extracted separately from the serum samples prior to instrumental analysis. Data was then annotated using Skyline software and multidimensional in-house libraries containing LC, IMS, CID, and MS information. Fourteen PFAS were also quantified to understand their levels in the two cohorts. In the quantitative analyses, PFAS concentrations were found to be significantly higher in the DW cohort than in the FFs. To assess lipid changes due to PFAS exposure, all study participants were grouped as either having ?20 ng/mL serum (n=34) or <20 ng/mL (n=44) for the sum of 7 PFAS, based on the National Academies Consensus Study Report guidelines for serum PFAS concentrations expected to have health impacts. Notably, 33 of the 34 samples in the high group were from the DW cohort. In the serum lipidomic analyses, 388 unique lipids from 15 classes were identified. Of these, 23 lipids were found to be statistically significant in the ?20 ng/mL group, with 22 being upregulated, and phosphatidylethanolamines (PEs) and triglycerides (TGs) comprising 60.8% of the significant lipids. While TGs have known associations with PFAS exposures, PEs are newly implicated in PFAS-related dyslipidemia . This is important, as PEs are the second most abundant glycerophospholipid in mammalian cells, following phosphatidylcholines (PCs) and abnormal PC/PE ratios have been linked to an array of

liver diseases and reduced liver regeneration. These lipid changes should encourage further exploration of PFAS toxicity in humans and assist in informing regulatory limits.

1.11.T-04 Next Generation Risk Assessment of Poly- and Perfluoroalkyl Substances through Bayesian Network based Quantitative Adverse Outcome Pathway

Hyunwoo Kim, *Gaeul Yang, Jaeseong Jeong and Jinhee Choi, University of Seoul, Korea, Republic of*

Poly- and perfluoroalkyl substances (PFAS) have recently been linked to potential neurotoxic effects, raising human health concerns. However, with thousands of PFAS compounds in existence, the traditional regulatory approaches face significant challenges addressing their potential risks. Thus, this study aims to evaluate the neurotoxic risks of PFAS using a Next Generation Risk Assessment (NGRA) framework that integrates New Approach Methodologies (NAMs) and an Adverse Outcome Pathway (AOP) framework with Bayesian Network (BN) modeling. The workflow consisted of four key steps. First, in vivo data from regulatory reports and in vitro data from literature, high-throughput screening (HTS) database, and in-house experiments were collected. Second, a neurotoxicity AOP was constructed using the AOP Wiki, with data assigned to specific molecular initiating events (MIEs), key events (KEs), and adverse outcomes (AOs). Third, a BN model was trained to calculate the probabilities of activation for each event, enabling a probabilistic assessment of PFAS risk. Finally, human exposure levels and effect distribution were incorporated to quantitatively evaluate the neurotoxicity risk of PFAS in humans. The results revealed that PFAS acts as an antagonist to thyroid receptors at the MIE level, disrupting signaling pathways and triggering significant activation across all KEs, leading to cell death. At the AO level, these effects manifested as neurotoxicity, including degenerative diseases and cognitive impairments. Probabilistic analysis using the BN model demonstrated a 24% likelihood of reduced cell viability at PFAS concentrations of 100 300 µM. The integration of in vivo and in vitro data provided a comprehensive and quantitative evaluation of PFAS-induced neurotoxicity. And, the risk assessment incorporating human exposure values did not reveal any significant effects. In conclusion, a BN model based quantitative AOP was utilized to evaluate the neurotoxic risks of PFAS by integrating in vivo, in vitro data. This study contributes to the advancement of NGRA approaches by providing a robust framework for assessing the risks of PFAS. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products (RS-2023-00215309), funded by Korea Ministry of Environment (MOE).

1.11.P-Tu103 Toxicogenomic Assessment of PFAS in Modified Zebrafish Embryo Test (FET) and Immune-Challenged Assays

Tim Benad[1], *Sebastian Eilebrecht*[2], *Uwa Steve Ayobahan*[1] *and Bernd Gockener*[1], *(1)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany*

Per- and polyfluoroalkyl substances (PFAS) are a group of synthetic chemicals that are widely used in industrial applications and consumer products due to their durability and resistance to water, oil, and heat. However, their environmental persistence and bioaccumulation in living organisms raise serious concerns about their potential health effects and immunotoxicity. Despite the widespread exposure to PFAS, there is a significant gap in understanding the molecular mechanisms that drive their toxicity, particularly in relation to immunotoxicity. The primary goal of this study is to address this gap by using advanced OMIC technologies to investigate the molecular effects of PFAS exposure in a relevant model organism, zebrafish. Specifically, we aim to examine the toxicological effects of PFOA, a well-known PFAS, and GenX, a PFOA substitute, through gene expression analysis. We will employ the Fish Embryo Toxicity Test (FET) in its conventional form and a modified version that incorporates an immune challenge to assess the impact of PFAS on the immune system. In the conventional FET, zebrafish embryos are exposed to PFAS for 96 hours, followed by RNA sequencing to identify differentially expressed genes (DEGs) linked to toxicity. In the modified FET, pathogen-associated molecular patterns (PAMPs) are introduced to stimulate the immune response, allowing us to evaluate potential immunotoxicity. The resulting data will be analyzed using various bioinformatic tools, including Venn diagrams and heatmaps, to better understand the molecular pathways affected by PFAS exposure. Although results are still being generated, the study is expected to provide valuable insights into the gene expression changes associated with PFAS exposure and contribute to the identification of biomarkers for general toxicity and immunotoxicity. These findings will significantly advance our understanding of PFAS toxicity, especially in the context of immune system disruption, and will help fill a crucial gap in the current toxicological data. This research is highly relevant for advancing the scientific knowledge on PFAS toxicity, which can inform future public health guidelines and policies aimed at reducing PFAS exposure and its associated risks. The goal is to apply this test design to future PFAS alternatives as well, enabling a faster and more efficient ecotoxicological risk assessment, as PFAS compounds are expected to be gradually replaced over time due to their toxicity.

1.11.P-Tu104 Major Alterations in Guppy Reproductive Traits Induced by PFOA and GenX Environmental Concentrations

Marianna Pauletto[1]*, Edoardo Pietropoli*[1]*, Alessandro Devigili*[2]*, Silvia Iori*[1]*, Francesco Santi*[3]*, Francesco Eugenio Leonardi*[3]*, Lorena Lucatello*[1]*, Mery Giantin*[1]*, Andrea Barbarossa*[4]*, Anisa Bardhi*[4]*, Francesca Capolongo*[5]*, Mauro Dacasto*[5] *and Clelia Gasparini*[3]*, (1)University of Padova - Department of Comparative Biomedicine & Food Science, Italy, (2)Univeristy of Padova - Department of Biology, Italy, (3)University of Padova - Department of Biology, Italy, (4)University of Bologna - Department of Veterinary Medical Sciences, Italy, (5)University of Padova - Department of Comparative Biomedicine and Food Science, Italy*

In humans and rodents, exposure to per- and poly-fluoroalkyl substances (PFAS) has been associated with negative reproductive health effects. However, our understanding of their impact on reproduction in aquatic organisms is still limited. To address this knowledge gap, we exposed adult freshwater fish (Poecilia reticulata) to 1 ?g/L of perfluorooctanoic acid (PFOA), a legacy PFAS, or its alternative, the ammonium salt of hexafluoropropylene oxide dimer acid (HFPO-DA; trademark name: GenX), which is considered potentially less hazardous. We assessed PFAS bioaccumulation in whole-body fish and key reproductive traits such as levels of vitellogenin and sexual hormones, sperm quantity and quality, male sexual activity, mating tactic, and colouration, after 90 days of exposure. Moreover, in the 5-months offspring (F1), exposed during pregnancy (P. reticulata is a live-bearing fish) and moved to clean water till reaching maturity, we measured fertility, sperm quantity and quality, and behaviour (boldness). General health conditions (e.g. swim performance, mortality) were also evaluated. Although no clear effects on survival and overall health were observed, sublethal effects were reported. We demonstrated that PFOA and GenX significantly impaired key traits for reproductive success. Levels of estradiol and testosterone were altered in both sexes; moreover, the exposed males performed less courtship behaviour but increased the number of sneak mating attempts, particularly when exposed to PFOA. We discovered that males prenatally exposed to PFOA and GenX presented a decrease in body colouration, a proxy of health status and reproductive success; in addition, PFOA inhibited fish risk-taking behaviour. Finally, detectable amounts of PFOA were found either in F0 directly exposed fish than in F1 adult fish exposed during the prenatal stage (<0.5 µg/g). This study offered a comprehensive comparison of two PFAS and shed light on the toxicity of an emerging PFOA alternative, GenX. Overall, we showed that even at low concentrations GenX, but mostly PFOA, can have subtle but significant harmful effects. These results improve the knowledge on the effects PFAS might have on reproduction, and provide important data for the research on PFAS toxicity in humans. From an environmental risk assessment perspective, these results emphasize the potential ramifications of pollution under natural conditions and their far-reaching consequences for fish populations and ecosystems. This work was supported by the University of Padova under the funding scheme STARS@UNIPD2021 (Prot. no. 3091/2022), and by the Italian Ministry of University and Research (MUR) under the funding scheme Research Projects of National Relevant Interest (Prot. no. 20228ECFT2).

1.11.P-Tu123 Discrepancies between CCK-8 and Trypan Blue Assays in PFAS-Exposed ZF4 Cells: Implications for Metabolic Stress Assessment

Timothy Prince Chidike Ezeorba*, Emilie Brun, Mohamed Abou-Elwafa Abdallah and Iseult Lynch, School of Geography, Earth, and Environmental Sciences, University of Birmingham, United Kingdom*

Perfluoroalkyl substances (PFAS), particularly perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), are persistent environmental contaminants with potential toxicological effects. This study investigated the effects of PFOA and PFOS on zebrafish embryonic fibroblast (ZF4) cells, revealing critical methodological considerations for cytotoxicity assessments. ZF4 cells were exposed to various concentrations of PFOA and PFOS (100-1000 µM) for 24 hours. Cell viability was evaluated using the cell counting kit 8 (CCK-8) assay, trypan blue cell counting, and lactate dehydrogenase (LDH) assay, which measures cell membrane damage and LDH leakage from the cytoplasm. Surprisingly, the CCK-8 assay showed a dose-dependent increase in absorbance readings at concentrations up to 500 µM, particularly for PFOS, suggesting increased cell viability or proliferation. However, concurrent trypan blue cell counts revealed a dose-dependent decrease in cell numbers, with IC50 values determined for both PFOA and PFOS (570.1 µM and 586.1 µM, respectively). LDH assay results were consistent with trypan blue counts. This discrepancy between CCK-8 results and actual cell counts indicates that the CCK-8 assay may produce false-positive results in this context.The increased CCK-8 signal, despite reduced cell numbers, suggests that PFOA and PFOS exposure may induce metabolic stress in ZF4 cells, potentially leading to increased mitochondrial activity. These findings highlight the importance of using multiple assays to assess cell viability and stress responses, especially when studying PFAS toxicity in emerging model cell lines like ZF4. Furthermore, this research suggests the potential value of investigating mitochondrial bioenergetics in PFAS-exposed cells, as metabolic alterations may precede overt cytotoxicity. To further confirm enhanced metabolic stress, future work will include Seahorse experiments to measure cellular respiration and glycolysis. Additionally, mitochondrial functional studies will be conducted using flow cytometry to analyze MitoSOX and TMRM staining, providing insights into mitochondrial superoxide production and membrane potential, respectively. These results contribute to our understanding of PFAS toxicity mechanisms and provide critical methodological considerations for future toxicological studies, emphasizing the need for multiple assays in assessing cell viability and stress responses, particularly when studying emerging model cell lines. The authors gratefully acknowledge the Petroleum Technology Development Fund (PTDF) for awarding a Ph.D. scholarship to Timothy Prince Chidike Ezeorba (PTDF Scholar ID: 22PHD053). We also extend our appreciation to the Society of Environmental Toxicology and Chemistry (SETAC) Europe for providing a Student Registration Grant, enabling the presentation of our findings at the 2025 SETAC Europe Annual Meeting.

1.11.P Unraveling the Complexities of PFAS From Environmental Toxicology to Human Health

1.11.P-Tu101 Effects of Flame Retardants on Survival, Reproduction, Energy Metabolism, and Transcriptional Modulation of Brackish Water Flea *Diaphanosoma celebensis*

Je-Won Yoo, Chaerin Park, Tae-June Choi, Chang-Bae Kim and ***Young-Mi Lee****, Sangmyung University, Korea, Republic of*

Marine plastic pollution has become a major environmental issue worldwide. Plastic products contain harmful chemicals, and because these chemicals can leach into media, they are considered an emerging contaminant in ocean. Flame retardants (FRs) are one of the commonly used additives in plastic industries to enhance products flame resistance. As the use of some brominated FRs (BFRs) have globally banned due to their high ecotoxicity, organophosphate FRs (OPFRs) have recently been proposed as alternatives to BFRs, but information on their toxic effects on marine ecosystem is still lacking. Thus, in this study, we investigated toxic effects of OPFRs [triphenyl phosphate, TPhP; Tris(1,3-dichloro-2-propyl) phosphate, TDCPP], together with representative BFR, hexabromocyclododecanes (HBCDs) on survival, reproduction, energy metabolism of brackish water flea Diaphanosoma celebensis. Subsequently, we further investigated toxic mechanisms of TPhP through transcriptomic analysis. Acute toxicity test showed that both OPFRs were acutely toxic to D. celebensis (48-h LC50 of TPhP and TDCPP: 2.41 and 17.12 mg/L, respectively), but HBCDs did not induce significant mortality up to 20 mg/L. Chronic toxicity test showed that all FRs caused reproductive disorder through reducing fecundity even at the sub-lethal concentrations, but only TPhP negatively affected lifespan. The contents of energy reserves (carbohydrate, protein, and lipid) were differently modulated following exposure to FRs. Transcriptomic analysis showed that genes related to energy metabolism-related pathways including metabolic pathways, AMPK signaling pathway, fatty acid biosynthesis, fatty acid degradation, and metabolism of various amino acids were mainly affected following TPhP exposure. In addition, genes related to nervous system, immune system, and genetic modulation were significantly modulated by TPhP. Our findings showed high toxicity of OPFRs as well as BFRs and suggest that OPFRs, especially TPhP, have potential toxicity to disturb energy metabolism, reproduction, and various biological processes. This study provides a better understanding of the molecular mode of action of FRs in marine zooplankton. This research was supported by the Risk assessment to prepare standards for protecting marine ecosystem of the Korea Institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220383).

1.11.P-Tu102 Investigating In-vivo Toxicity of PFAS on the Development of Zebrafish Embryos as a Model for Environmental Impact

Venkata Koulini Garimella[1]*, Sai Sugitha Sasidharan*[1]*, Indumathi M Nambi*[1] *and Ravikrishna Raghunathan*[2]*, (1)Environmental Engineering Division, Department of Civil Engineering, Indian Institute of Technology Madras, India, (2)Department of Chemical Engineering, Indian Institute of Technology Madras, India*

Per- and polyfluoroalkyl substances (PFAS) represent a broad class of over 10,000 synthetic organic chemicals, recognized for their widespread applications as surfactants and repellents. The rapid pace of industrialization and urbanization in India has intensified concerns regarding the extensive use of PFAS across multiple sectors, including textiles, personal care products, non-stick cookware, electronics, and firefighting foams and gear. PFAS have been detected in various environmental media, including air, water, wastewater, soil, human blood, hair, and breast milk, as well as in biota, where they bioaccumulate within the food chain due to their persistent nature and resistance to degradation. Consequently, PFAS contamination in water sources poses potential health risks to millions of people through drinking water supplies. The widespread presence of PFAS necessitates a comprehensive toxicity assessment to elucidate their adverse health impacts, yet there remains a scarcity of toxicity data for most PFAS used in industrial and consumer products. The zebrafish (Danio rerio) is emerging as a robust animal model for rapid toxicity assessment, offering predictive insights into potential human health hazards. Zebrafish possess morphological and molecular features in their tissues and organs that are either identical or highly analogous to those of other vertebrates, including humans, making them ideal for evaluating PFAS toxicity. This study investigates the developmental effects of exposure to 24 PFASs comprising long-chain and short-chain PFAS and their precursors on zebrafish embryos. The compounds include C4 C14 perfluorocarboxylic acids (PFCAs), C4 C10 perfluorosulfonic acids (PFSAs), perfluorooctanesulfonamide (FOSA), N-methyl perfluorooctanesulfonamidoacetic acid (N-MeFOSAA), N-ethyl perfluorooctanesulfonamidoacetic acid (N-EtFOSAA), and 4:2, 6:2, and 8:2 fluorotelomer sulfonates (FTS). The study examines morphological deformities (spinal cord curvature, body length, head/eye area, head and trunk angle), hatching period, survival rate, heart rate, blood flow rate, and stress responses using ImageJ and histopathological analysis for cellular-level damage. This work provides critical insights into PFAS-associated developmental toxicity, aiding in risk assessment and informing regulatory policies on PFAS exposure limits.

1.11.P-Tu103 Toxicogenomic Assessment of PFAS in Modified Zebrafish Embryo Test (FET) and Immune-Challenged Assays

Tim Benad[1]*, Sebastian Eilebrecht*[2]*, Uwa Steve Ayobahan*[1] *and Bernd Gockener*[1]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany*

Per- and polyfluoroalkyl substances (PFAS) are a group of synthetic chemicals that are widely used in industrial applications and consumer products due to their durability and resistance to water, oil, and heat. However, their environmental persistence and bioaccumulation in living organisms raise serious concerns about their potential health effects and immunotoxicity. Despite the widespread exposure to PFAS, there is a significant gap in understanding the molecular mechanisms that drive their toxicity, particularly in relation to immunotoxicity. The primary goal of this study is to address this gap by using advanced OMIC technologies to investigate the molecular effects of PFAS exposure in a relevant model organism, zebrafish. Specifically, we aim to examine the toxicological effects of PFOA, a well-known PFAS, and GenX, a PFOA substitute, through gene expression analysis. We will employ the Fish Embryo Toxicity Test (FET) in its conventional form and a modified version that incorporates an immune challenge to assess the impact of PFAS on the immune system. In the conventional FET, zebrafish embryos are exposed to PFAS for 96 hours, followed by RNA sequencing to identify differentially expressed genes (DEGs) linked to toxicity. In the modified FET, pathogen-associated molecular patterns (PAMPs) are introduced to stimulate the immune response, allowing us to evaluate potential immunotoxicity. The resulting data will be analyzed using various bioinformatic tools, including Venn diagrams and heatmaps, to better understand the molecular pathways affected by PFAS exposure. Although results are still being generated, the study is expected to provide valuable insights into the gene expression changes associated with PFAS exposure and contribute to the identification of biomarkers for general toxicity and immunotoxicity. These findings will significantly advance our understanding of PFAS toxicity, especially in the context of immune system disruption, and will help fill a crucial gap in the current toxicological data. This research is highly relevant for advancing the scientific knowledge on PFAS toxicity, which can inform future public health guidelines and policies aimed at reducing PFAS exposure and its associated risks. The goal is to apply this test design to future PFAS alternatives as well, enabling a faster and more efficient ecotoxicological risk assessment, as PFAS compounds are expected to be gradually replaced over time due to their toxicity.

1.11.P-Tu104 Major Alterations in Guppy Reproductive Traits Induced by PFOA and GenX Environmental Concentrations

Marianna Pauletto[1]*, Edoardo Pietropoli*[1]*, Alessandro Devigili*[2]*, Silvia Iori*[1]*, Francesco Santi*[3]*, Francesco Eugenio Leonardi*[3]*, Lorena Lucatello*[1]*, Mery Giantin*[1]*, Andrea Barbarossa*[4]*, Anisa Bardhi*[4]*, Francesca Capolongo*[5]*, Mauro Dacasto*[5] *and Clelia Gasparini*[3]*, (1)University of Padova - Department of Comparative Biomedicine & Food Science, Italy, (2)Univeristy of Padova - Department of Biology, Italy, (3)University of Padova - Department of Biology, Italy, (4)University of Bologna - Department of Veterinary Medical Sciences, Italy, (5)University of Padova - Department of Comparative Biomedicine and Food Science, Italy*

In humans and rodents, exposure to per- and poly-fluoroalkyl substances (PFAS) has been associated with negative reproductive health effects. However, our understanding of their impact on reproduction in

aquatic organisms is still limited. To address this knowledge gap, we exposed adult freshwater fish (Poecilia reticulata) to 1 ?g/L of perfluorooctanoic acid (PFOA), a legacy PFAS, or its alternative, the ammonium salt of hexafluoropropylene oxide dimer acid (HFPO-DA; trademark name: GenX), which is considered potentially less hazardous. We assessed PFAS bioaccumulation in whole-body fish and key reproductive traits such as levels of vitellogenin and sexual hormones, sperm quantity and quality, male sexual activity, mating tactic, and colouration, after 90 days of exposure. 1.11.P-Tu105 Hemolytic Activity and Proteomic Insights into PFAS Toxicity in *Eisenia fetida*

***Davide Rotondo*[1]**, *Davide Gualandris[1], Candida Lorusso[2], Marcello Manfredi[1], Antonio Calisi[1] and Francesco Dondero[3], (1)Universit del Piemonte Orientale, Italy, (2)univerisit del piemonte orientale, Italy, (3)univerist del piemonte orientale, Italy*

The evaluation of emerging and legacy contaminants remains a central focus in ecotoxicological research and environmental safety assessment. This study investigates the effects of 34 per- and polyfluoroalkyl substances (PFAS), encompassing diverse chemical classes (legacy and emerging, short- and long-chain, carboxylates, sulfonates, ethers, and polyethers), on the hemolytic activity of cell-free coelomic fluid derived from Eisenia fetida. A combined experimental framework involving in vivo and in vitro exposures was implemented, supplemented by advanced proteomic analyses performed on hemolymph samples using liquid chromatography coupled with mass spectrometry (LC-MS) to quantify hemolysin content and investigate molecular alterations induced by PFAS exposure. In vivo exposures were conducted in adherence to the OECD 207 acute toxicity test, employing PFAS concentrations of 0.6 µM and 229 µM. For in vitro studies, cell-free coelomic fluid was incubated with PFAS at (sub)nanomolar concentrations. Following these exposures, hemolytic activity was assessed using a refined sheep erythrocyte hemolysis assay. Methodological advancements included precise quantification of erythrocyte survival rates and the establishment of a standardized dilution curve for coelomic fluid, ensuring consistent and reproducible measurements. Preliminary findings indicate statistically significant differences in hemolytic activity between controls and PFAS-treated groups, with reduced hemolysis associated with specific chemical subclasses. Proteomic data further identified modifications in hemolysin and other proteins such as CCF-1 related with immune defense mechanisms. This comprehensive approach provides critical insights into the molecular mechanisms underlying PFAS toxicity in non-model organisms, paving the way for the development of sensitive and predictive methodologies for the environmental risk assessment of these pervasive contaminants. This project has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No 101037509 (SCENARIOS project)

1.11.P-Tu106 Modulatory Impact of PFAS on GABA Receptor-Mediated Currents in Neuron-like Cells

***Davide Rotondo*[1]**, *Laura Lagostena[2], Konstantinos D. Papavasileiou[3], Valeria Magnelli[1], Davide Gualandris[1], Aldo Pagano[4], Antonio Calisi[1], Iseult Lynch[5], Antreas Afantitis[3] and Francesco Dondero[1], (1)Universit del Piemonte Orientale, Italy, (2)IBF CNR Genova, Italy, (3)Novamechanics LTD, Cyprus, (4)Universit di Genova, Italy, (5)UniB, United Kingdom*

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental pollutants that have raised concerns due to their widespread distribution and adverse effects on biological processes. Their high stability enables these compounds to accumulate in the environment and living organisms, where they may disrupt critical physiological functions, including hormonal balance, immune function, and neurological and developmental pathways. The pervasive nature and extensive biological impact of PFAS underscore the need for strict regulatory actions and ongoing research to mitigate their harmful effects. In particular, concerns are growing over the neurotoxic potential of PFAS. Although evidence increasingly suggests these chemicals harm the nervous system, the exact mechanisms remain under investigation. This study examines how different PFAS congeners affect gamma-aminobutyric acid (GABA) receptor-mediated currents in differentiated S1 neuroblastoma cells, which exhibit neuron-like characteristics. Using patch clamp electrophysiology, we confirmed the presence of GABA-evoked currents, and PFAS exposure significantly and reversibly reduced these currents. We also conducted molecular docking studies to evaluate PFAS interactions with GABA receptors; those with the highest affinity were selected for further cytotoxicity testing. Additionally, STAB1 neuroblastoma cells were exposed to various concentrations of short-chain PFAS, legacy PFAS, and mono- or polyether PFAS, exhibiting a hormetic response, with cell proliferation at lower concentrations and cytotoxicity at higher concentrations. Our findings show that PFAS can significantly reduce GABA-evoked current amplitude, suggesting disruption of GABA receptor function and contributing to their neurotoxic properties. These results provide the first direct evidence of PFAS impairing GABAergic neurotransmission in neuron-like cells, highlighting the need for further research into their neurological impacts. This project has received funding from the European Union s Horizon 2020 research and innova-tion programme under grant agreement No 101037509 (SCENARIOS project)

1.11.P-Tu107 PFAS and Nanoplastics Co-Exposure Impacts on Human Intestinal Cells: Combining Metabolomics and Phenomics

Andi Alijagic[1]*, Eva Sarndahl*[2]*, Oleksandr Kotlyar*[1]*, Patrik Karlsson*[3]*, Nikolai Scherbak*[1]*, Magnus Engwall*[1] *and Tuulia Hyotylainen*[1]*, (1)Man-Technology-Environment Research Center, orebro University, Sweden, (2)Inflammatory Response and Infection Susceptibility Centre, orebro University, Sweden, (3)Department of Mechanical Engineering, orebro University, Sweden*

Per- and polyfluoroalkyl substances (PFAS) and nanoplastics (NPs) pose significant environmental and health challenges due to their persistence, bioaccumulation potential, and toxicity. While both pollutants are individually known to disrupt metabolic and phenotypic processes, their combined impacts on human gut health remain poorly understood. This study investigated the co-exposure effects of PFAS, specifically perfluorooctanesulfonic acid (PFOS), and polystyrene NPs on human intestinal Caco-2 cells using integrated metabolomics and phenomics approach. Caco-2 cells were exposed to PFOS, NPs, or their combination, and phenotypic alterations were assessed using the Cell Painting assay, a high-content imaging assay coupled with automated image analysis. Metabolic and lipidomic changes were analyzed through ultra-high-performance liquid chromatography quadrupole time-of-flight mass spectrometry (UHPLC-QTOFMS). Phenotypic profiling revealed that co-exposure to PFOS and NPs caused more pronounced effects on subcellular structures, including the F-actin cytoskeleton, Golgi apparatus, and plasma membrane, compared to single exposures. Interestingly, mitochondrial structure was largely affected by NPs alone. Correlation analysis supported a relationship between PFOS and NPs with co-exposure phenotype, indicating shared mechanisms of toxicity. Lipidomic profiling demonstrated that NPs alone induced changes of cellular lipids, while PFOS exposure primarily altered polar metabolite profiles. PFOS alone or under co-exposure revealed changes in carnitines, involved in mitochondrial fatty acid ?-oxidation pathways. The distinct and overlapping impacts of PFOS and NPs on cellular phenotypes and metabolic pathways underscore the complexity of their combined toxicity. This study emphasizes the need for advanced integrative approaches, such as phenomics and metabolomics, to unravel the mechanisms underlying co-exposures to PFAS and nanoplastics. By providing insights into the phenotypic and metabolic disruptions caused by PFOS and NP co-exposure, this work contributes to a better understanding of their combined health risks and supports the development of mechanism-based risk assessment strategies.

1.11.P-Tu108 Evaluating PFAS-Related Human Health and Environmental Risks Before and After the Implementation of the LIFE SOuRCE Solution

Sonia Jou-Claus[1]*,* ***Mireia Mesas***[1]*, Jessica Meijide*[1]*, Carme Bosch*[1]*, Leonidas Perez*[1]*, Joana Baeta*[2]*, Ricard Mora*[2]*, Robin Axelson*[3]*, Patrik Hollman*[4]*, Lutz Ahrens*[5]*, Oscar Skirfors*[5]*, Anja Enell*[6]*, Dan Berggren Kleja*[6]*, Michael Pettersson*[6]*, Sofia Bjalkefur*[7]*, Philip McCleaf*[7] *and Dahn Rosenquist*[8]*, (1)Eurecat, Centre Tecnol gic de Catalunya. Water, Air and Soil Unit, Spain, (2)ESOLVE, Spain, (3)Envytech Solutions AB, Sweden, (4)Nova Diamant AB, Sweden, (5)SLU, Sweden, (6)SGI, Sweden, (7)UVA, Sweden, (8)LAQUA,*

Sweden

LIFE SOuRCE is a European project focusing on the demonstration and evaluation of sustainable on-site remediation technologies for PFAS-contaminated groundwater. Four different techniques are combined and evaluated as treatment trains, called the LIFE SOuRCE solutions. This study aims to evaluate the human health and environmental risks associated with PFAS in groundwater before and after the implementation of the LIFE SOuRCE solutions. The assessment focuses on PFAS exposure risks to human health and environmental impacts on a river ecosystem. Two sites with different risk profiles are analysed, 1) an industrial and agricultural area in Spain for Human Health Risk Assessment (HHRA) and 2) a Swedish river ecosystem for Environmental Risk Assessment (ERA). For HHRA, two exposure scenarios were evaluated at the Spanish site. Scenario 1 involves industrial workers exposed to PFAS-contaminated water during cleaning tasks, evaluating ingestion and dermal contact. Scenario 2 involves farmers using groundwater for crop irrigation and consumers potentially ingesting PFAS through these crops. Lettuce was selected as the test crop. Exposure pathways considered include ingestion and dermal contact for farmers, and ingestion for consumers (adults and children) through PFAS transferred to crops. Baseline data, collected before the LIFE SOuRCE solution implementation, indicated acceptable carcinogenic risk levels (carcinogenic risk values < 1x10E-5) but the systemic risk was above the admissible threshold (hazard index > 1) for both scenarios, due to the presence of PFBA, PFDoDA, PFHpA, PFOS, PFOA, PFPeA and PFUDA. For ERA, PFAS risk to the Swedish river ecosystem and fish populations was assessed, establishing a baseline Toxicity Unit (TU) risk prior to the LIFE SOuRCE solution. Predicted Environmental Concentrations (PEC) were calculated using the highest PFAS concentrations found, and environmental risk was assessed against Predicted No-Effect Concentrations (PNEC) for aquatic organisms, obtained from the NORMAN Ecotoxicology Database. Results showed most PFAS within acceptable levels (TU ? 1); however, PFOS and PFOA concentrations at certain points suggest possible risk to aquatic organisms. Baseline HHRA and ERA results will allow for an evaluation of the effectiveness of PFAS mitigation following the implementation of the LIFE SOuRCE solution.

1.11.P-Tu109 In Silico Classification Model to Screen the Potential Thyroid Hormone System-Disrupting Activity of Per- and Polyfluoroalkyl Substances

Marco Evangelista, *Nicola Chirico and Ester Papa, QSAR Research Unit in Environmental Chemistry and Ecotoxicology, Department of Theoretical and Applied Sciences (DiSTA), University of Insubria, Italy*

Per- and polyfluoroalkyl substances (PFAS) represent a broad class of man-made compounds characterised by highly stable carbon-fluorine bonds, well known for being persistent in the environment, bioaccumulative, and toxic for humans and wildlife. Several studies linked PFAS exposure to multiple biological mechanisms leading to adverse effects on living organisms, including their ability of disrupting the thyroid hormone (TH) system by competing with the TH thyroxine (T4) for binding with the human transthyretin (hTTR), a key TH distributor protein. This biological mechanism can modulate serum TH concentration resulting in severe TH system dysfunctions. To speed up the identification of hazardous compounds, including TH system-disrupting chemicals (THSDCs), international authorities promote the use of in silico methods (e.g. Quantitative Structure-Activity Relationship (QSAR) based approaches). This work aims to develop a new QSAR classification model, following the OECD principles, to predict the binding ability of PFAS with hTTR. A newly published dataset containing binding ability records of 136 structurally heterogeneous PFAS, measured with the 8-anilino-1-naphtalenesulfonic acid (ANSA) based binding in vitro assay, was selected for QSAR development through Linear Discriminant Analysis (LDA). After data curation, the remaining 119 PFAS were categorised into two classes according to their median % activity: 74 PFAS were categorised as strong hTTR binders (median % activity greater or equal to 50%), while 45 PFAS as weak or not hTTR binders (median % activity smaller than 50%). Harmonized SMILES (Simplified Molecular Input Line Entry System) of the structures were used as input for the calculation of simple theoretical molecular descriptors, which were used as variables in the QSAR modeling. For each class, PFAS were sorted by structure, then two every three PFAS were assigned to the training set for QSAR development, and the remaining compounds were assigned to the test set for QSAR external validation. The final model, calibrated using all the available experimental data, is characterised by accuracy, sensitivity, and specificity equal to 87%, 91%, and 80%, respectively. The proposed QSAR extends the applicability domain of previously published similar models for the prediction of the same endpoint, and can be applied as a simple tool for screening the potential thyroid hormone system-disrupting activity of PFAS.

1.11.P-Tu110 Does the Addition of Perfluoro-Moieties Impact Mechanisms of Toxic Action of Organic Chemicals? An In Silico Approach

Paul Thomas[1], *maxime Edelblout*[2] *and Floriane Larras*[2], *(1)KREATi., France, (2)KREATiS, France*

The PFAS exposure problem has become ubiquitous. The poor biodegradability of such substances in the environment has been recognised for decades. This is an unfortunate environmental fate property but a huge benefit for certain applications (the most obvious example being the long-lasting, panphobe property facilitating use of PTFE as a non-stick polymer on saucepans and a PFAS emulisifer (PFOA) to carry it). Due to the multifaceted utility of perfuorinated compounds, industry has diligently placed >4000 PFAS on the market and the EU Commission has recently recognised the potential for forever chemicals to pose a threat to aquatic and terrestrial organisms alike. While much research has been carried out on the persistence of PFAS, and to a lesser extent bioacumulation and fate, less is known about the mechanisms of toxic action of such compounds which can impact the aquatic environment. This poster explores the potential for perfluoration to enhance or reduce acute and chronic toxicity for algae, daphnids and fish. A set of internally validated experimental aquatic toxicity studies on PFAS were selected. Their Mechanisms of toxic Action (MechoA) were allocated using MechoA Premium and the experimental water solubility determined (from exisiting studies or by the iSafeRat® WATSOL module). The data were then plotted on the appropriate iSafeRat® aquatic toxicity QSAR according to the designated MechoA. The models excluded fluorinated substances. The positions of the PFAS points were then compared to the PFAS-free regression lines to acertain whether excess or reduced toxicity was observed compared to the classical QSARs. Their distance to the regression was assessed statistically to evaluate if these compounds could be included to these model with confidence. Data were obtained for several MechoA including non-polar narcotics, polar narcotics, hydrolysis to non-polar narcotics product and hard electrophile reactivity. The substances were then classified excess toxicicity, reduced toxicity or indifferent toxicity compared to the PFAS-free QSARs. Furthermore, as these substances tend to be rather difficult to test for both ecotoxicity and water solubility, NAMs will help elucidate the extent of the PFAS hazard profiles. The results are discussed in the poster.

1.11.P-Tu111 Scientific Basis for Guide Values for 11 PFASs in Soil

*Luca Gelshorn and **Marion Junghans**, Ecotox Centre, Switzerland*

Growing concerns about the health and environmental impacts of PFAS have prompted increased research and regulatory scrutiny. This study aimed at developing the scientific basis for guide values for 11 per- and polyfluoroalkyl substances (PFAS) in soil, with a focus on effects on soil fertility including the protection of biocenosis of organisms with soil direct contact. The study is part of a larger project initiated as a response to a Swiss parliamentary motion to set limit values for PFAS under different Swiss ordinances. A literature search revealed limited availability of effect data for PFAS on soil organisms, with most studies available for PFOS and PFOA. It was not possible to derive guideline values based on the assessment factor method for all 11 PFAS. Hence, the potential of using relative potency factors was explored. In addition to the direct toxicity to soil organisms secondary poisoning to earthworm eating birds and mammals has been assessed. The study acknowledges existing data limitations and emphasizes the need for further research on PFAS compounds beyond PFOS and PFOA. Overall, this research contributes to the development of evidence-based soil guide values for PFAS in Switzerland, addressing both direct and indirect ecological impacts.

1.11.P-Tu112 Transcriptomic Sensitivity of Acute and Chronic In Vitro Exposure to Perfluorooctanoic Acid in Human Vascular Endothelial Cells: Insights from Benchmark Concentration Modeling

***Marija Opacic**, Bojana Stanic and Nebojsa Andric, University of Novi Sad, Faculty of Sciences, Department of Biology and Ecology, Serbia, Serbia*

Perfluorooctanoic acid (PFOA) is a synthetic chemical in the class of per- and polyfluoroalkyl substances (PFAS), which have been widely synthesized and used in various industries and consumer products since the 1940s. Due to their extreme persistence in both the environment and the human body, PFAS, including PFOA, are often referred to as "forever chemicals." PFOA has been linked to a range of adverse health effects, including reproductive and developmental toxicity, hepatotoxicity, renal toxicity, immunotoxicity, neurotoxicity, genotoxicity, and carcinogenicity. However, the effects of PFOA on human vascular endothelial cells remain poorly understood, particularly in terms of sensitive time points where its impact may be most pronounced. The use of in vitro human cell models and new approach methodologies offer valuable alternatives to animal testing, providing relevant data for assessing the effects of PFOA on human health. In this study, we employed benchmark concentration modeling to derive and compare points of departure (POD) for transcriptomic changes (T-POD) in human vascular endothelial cells EA.hy926 following short-term (48 h, acute) and long-term (6 and 12 weeks, chronic) exposure to 1, 10, and 100 µM and 1, 10, and 100 nM PFOA, respectively. Our mRNA sequencing results revealed a substantial number of differentially expressed genes (DEGs) in PFOA-exposed EA.hy926 cells across all concentrations and time points. The highest overall number of DEGs was observed after 6 weeks of exposure, with 10 nM PFOA yielding the highest total of 6,018 DEGs. The T-POD values for 6 and 12 weeks (4.1 nM and 22.1 nM, respectively) indicated greater sensitivity than the T-POD value derived from 48-h exposure (6.3 μM). Functional gene analysis revealed that transcription was a sensitive, yet general molecular pathway affected by short-term exposure. After 6 weeks of exposure, the IL-17 signaling pathway was notably enriched, while after 12 weeks, pathways related to the extracellular matrix, cytokine-cytokine interactions, and cell adhesion were significantly affected. In conclusion, chronic exposure provided more informative data than acute exposure for assessing the risk of PFOA in human endothelial cells. Moreover, the transcriptomic data from long-term exposure offer valuable insights into early molecular pathways linked to PFOA exposure, highlighting their potential to connect toxicity effects across different biological levels.

1.11.P-Tu113 In Vitro Toxicological Assessment of PFAS Using Seahorse Extracellular Flux Analysis

Eva Junque[1]*, Emilie Brun*[2]*, Mael Exner*[2]*, Heather Mercer*[3]*, Francesco Dondero*[4]*, Jonathan Barlow*[2] *and Iseult Lynch*[5]*, (1)University of Birmingham, Birmingham, United Kingdom, (2)University of Birmingham, United Kingdom, (3)University of New Mexico Comprehensive Cancer Center, United States, (4)Universit del Piemonte Orientale, Italy, (5)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom*

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental pollutants with potential adverse effects on human and ecosystem health. This study, conducted as part of the European SCENARIOS project, investigates their toxicological effects on ZF4 zebrafish cells, with a focus on PFAS alternatives. The originality of our approach was to use Seahorse extracellular flux analysis to profile real-time changes in cellular metabolism. Through measurements of oxygen consumption rate (OCR) and proton efflux rate (PER), mitochondrial respiratory energy metabolism and glycolytic activity was assessed. PFAS-induced mitochondrial toxicity was also identified and quantified using the mitochondrial toxicity index (MTI). The traditional CCK8 assay was also employed to provide a comparative measurement of metabolic activity. To assess dose-dependent responses and metabolic disruptions, cells were exposed to a selection of legacy and alternative PFAS compounds, including legacy PFAS like PFOA, PFOS, PFDA and various perfluoroalkyl(poly)ether sulfonic acids at concentrations ranging from 10 to 1000 μM for 24 hours. Additionally, a mixture containing PFBS, PFOS K salt, PF2EOESA, Nafion-BP2 and Nafion BP1 was tested to investigate potential additive, synergistic or antagonistic effects. Our results show significant alterations in OCR and PER, with compensatory shifts in cellular energy supply from mitochondrial ATP to glycolytic ATP, indicating PFAS-induced mitochondrial dysfunction. Nafion BP1, PFDA and PFOA were identified as the most toxic compounds, causing a strong inhibition of mitochondrial oxidative capacity as identified by the MTI. Interestingly, exposure to these compounds reduced cellular metabolic activity by nearly 50% at respective concentrations of 100 μM, 300 μM and 750 μM. We confirm that perfluoroalkyl carboxylic acid toxicity increases with carbon chain length. The three most toxic compounds tested (7 - 10C) caused significant metabolic disruption, whereas shorter-chain PFAS (4C e.g., PFBA, PFBS and PF2EOESA) had minimal impact on ZF4 metabolism. These findings improve our understanding of PFAS toxicity at the cellular level, highlighting disruption mechanisms and providing key data to develop Adverse Outcome Pathways for PFAS, especially those with limited toxicity data. This project has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No. 101037509 (SCENARIOS project).

1.11.P-Tu114 High Serum Concentrations of Perfluoroalkyl Substances (PFAS) in Norwegian Children and Associations with Adverse Health Effects

Maria Averina[1]*, Sandra Huber*[1]*, Jan Brox*[1]*, Merete Eggesbo*[2] *and Anne-Lise Bjorke Monsen*[3]*, (1)Department of Laboratory Medicine, University Hospital of North Norway, Norway, (2)Norwegian University of Science and Technology, Norway, (3)Laboratory of Medical Biochemistry, Forde Hospital Trust, Norway*

The aim of this study was to assess PFAS serum concentrations in Norwegian children of different ages and to evaluate health outcomes associated with PFAS exposure. Several studies have examined PFAS concentrations in Norwegian children and their possible health effects. The results of the studies including 6 months old infants from Bergen, 12 years old children from Oslo and 15-19 years old teenagers from Tromsø will be presented. PFAS were measured by ultrahigh-pressure liquid chromatography tandem mass spectrometry. Observed detection rates for perfluorooctanoate (PFOA), perfluorooctane sulfonate (PFOS) perfluorohexane sulfonate (PFHxS) and perfluorononanoate (PFNA) were 100%. Altogether 78% of the six-month-old infants from Bergen, 25% of the 12-year-old children from Oslo, and 87% of the teenagers from Tromsø had sum concentrations of these four PFAS (?4 PFAS) above the EFSA 2020 limit for maternal blood of 6.9 ng/mL. Serum concentrations of Perfluoroalkyl substances in Norwegian children (N = 1 153). Will be presented as a table.

1.11.P-Tu115 Comparative Acute Toxicity Assessment of Fluorinated and Fluorine-Free Firefighting Foams on Zebrafish Embryos

Simone Helmer[1], *Barbara Gepp, DI*[2], *Ingrid Kolar*[2] *and Romana Hornek-Gausterer*[2], *(1)University of Applied Sciences Vienna, Austria, (2)University of Applied Sciences, Austria*

The ubiquitous presence of per- and polyfluoroalkyl substances (PFAS) in the environment, particularly in groundwater near airports and former military training areas, presents significant challenges for research and remediation efforts. PFAS, synthetic chemicals prized for their water- and dirt-repellent properties, have been extensively used in various applications, including firefighting foams for class B fires in chemical industries and refineries. This study investigated the comparative acute toxicity of a fluorine-containing aqueous film-forming foam (AFFF) and an environmentally friendly, fluorine-free alternative (Vapurex), both manufactured by Dr. Sthamer. The fish embryo acute toxicity test was conducted using Danio rerio (zebrafish) embryos as the model organism. Embryos were exposed to various dilutions of both foam concentrates, ranging from 50% to 0.000000015%, based on the manufacturer's recommended 1% addition rate. Over a 96-hour exposure period, developmental abnormalities and mortality were observed and recorded. Acute mortality was evident for both foaming agents, particularly at higher concentrations (50%, 15%, and 1.5%). Notably, neither foam concentrate allowed for 100% survival across all tested dilutions. Dose-response curves were generated from the obtained results. Our findings indicate that both the fluorine-containing AFFF and the fluorine-free Vapurex exhibit clear acute toxic effects on Danio rerio embryos. However, to draw more definitive conclusions about the comparative toxicity of these firefighting foams to aquatic organisms, further studies exploring a wider range of dilutions and additional endpoints are necessary. This research contributes to the growing body of knowledge on the environmental impacts of firefighting foams and supports informed decision-making in the transition towards more environmentally friendly alternatives.

1.11.P-Tu116 Membrane−Water Partition Coefficients of Per- and Polyfluoroalkyl Substances (PFAS): A Promising Descriptor of their Bioaccumulation and Toxicity

Ge Xie[1], *Ioanna Spyridoula Gkika*[2], *Jiaqi Chen*[3], *Patricia Aguilar-Alarcon*[4], *Steven Droge*[5], *Thomas L. ter Laak*[6], *Cornelis A.M. van Gestel*[7] *and Michiel Kraak*[8], *(1)VU University Amsterdam, Amsterdam, Netherlands, (2)Freshwater and Marine Ecology, University of Amsterdam, Amsterdam, Netherlands, (3)Amsterdam Institute for Life and Environment, Faculty of Science, Vrije Universiteit Amsterdam, Netherlands, (4)Department of Freshwater and Marine Ecology, Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (5)Wageningen Environmental Research, Wageningen University and Research, Netherlands, (6)KWR Water Research Insititute, Netherlands, (7)Vrije Universiteit Amsterdam, Netherlands, (8)Sciencepark 904, University of Amsterdam, Amsterdam, Netherlands*

Per- and polyfluoroalkyl substances (PFAS) are chemicals of high environmental concern due to their widespread presence and high persistency in aquatic and terrestrial ecosystems. Yet, current PFAS exposure and risk assessment are inadequate, as they focus on only a limited subset of compounds, overlooking the large variation in chemical structures and properties of the more than 6000 CAS registered PFAS. Since it is not feasible to test the plethora of FPAS for their environmental fate and effects, a descriptor that is indicative of PFAS exposure, bioaccumulation and ecotoxicity is urgently needed. Classical descriptors like the octanol-water partition coefficient, have proven of limited value in evaluating the environmental behavior of PFAS, due to their unique characteristics and their affinity for phospholipids. Alternatively, the phospholipid membrane-water partition coefficient (Kmw), which determines the membrane permeability of a compound, could be used to assess the environmental fate, bioaccumulation and ecotoxicity of PFAS. Since data on the membrane-water partitioning of PFAS are scarce, the aim of this study was to measure the Kmw for a set of 17 PFAS with different structures, varying chain length and functional groups. To this end, two different methods were employed for the determination of Kmw. The first method was based on the evaluation of the retention capacity of the compounds on a chromatographic column coated with immobilized artificial membrane phospholipids (IAM-HPLC). The second method was based on the sorption of the compounds on solid supported lipid membranes (SSLM). Preliminary results of the first method (for 5 PFAS) aligned with Kmw values previously reported in literature. Both chain length and polar head played a role in the membrane affinity of the tested PFAS. The SSLM experiments are still ongoing and results were not available by the time of abstract submission. Overall, Kmw could be considered a useful descriptor of the bioaccumulation potential and toxicity of PFAS and consequently contribute to a more reliable environmental risk assessment of these forever chemicals.

1.11.P-Tu117 Applying Newly Suggested Simultaneous Analysis of Metabolomics and Lipidomics into Perfluorooctanesulfonate-derived Neurotoxicity Mechanism in Zebrafish Embryos

Eun Ki Min *and Ki-Tae Kim, Seoul National University Science and Technology, Korea, Republic of*
To increase the reliability of data on changes in multi-layered biomolecules, a strategy for performing multi-omics with one sample is needed; however, related studies are lacking. A new strategy for the simultaneous analysis of metabolomics and lipidomics in zebrafish embryos was proposed and applied to explore the neurotoxicity mechanisms of perfluorooctanesulfonate (PFOS). Metabolite and lipid profiled simultaneously with methyl tert-butyl ether (MTBE) were compared with individual results from other extraction solvents. Behavioral alterations were measured after the zebrafish embryos were exposed to 0.1 20 ?M PFOS for 5 days. The metabolite-lipid profiles of the MTBE-based strategy analyzed with optimized larval pooling size of 30 were comparable to those of other extraction solvents, indicating the feasibility and efficiency of MTBE-based multi-omics analysis. Many metabolites and lipids, which were enriched more than those previously reported, completed the toxicity pathways involved in energy metabolism and sphingolipids, improving our understanding of PFOS-induced neurotoxicity mechanism manifested by increased movement under dark conditions. Our novel MTBE-based strategy enabled the multi-omics analysis of one sample with minimal use of zebrafish embryos, which will help advance multi-omics technologies in zebrafish toxicology for elucidating the toxicity mechanisms of per- and polyfluoroalkyl substances and toxic chemicals.

1.11.P-Tu118 Early Detected Snapshot of Neurodevelopment Toxicity in Zebrafish Embryos Exposed to Perfluorooctanesulfonate
Eun Ki Min *and Ki-Tae Kim, Seoul National University Science and Technology, Korea, Republic of*
Rapid multi-omics approaches are essential for generating large-scale biomolecular data to build an inventory of per- and polyfluoroalkyl substances (PFAS) neurotoxicity; however, related studies remain limited. This study aimed to uncover biomolecular mechanisms of PFOS-induced neurotoxicity across developmental stages and identify early detection biomarkers in zebrafish embryos. Zebrafish embryos were exposed to 5 ?M PFOS from 4 hours post-fertilization (hpf) to 120 hpf, with 30 embryos with 6 replicates collected at 72, 96, and 120 hpf. Metabolites and lipids were simultaneously profiled using methyl tert-butyl ether (MTBE) extraction and analyzed with MetaboAnalyst 5.0. Although metabolite and lipid perturbations varied across developmental stages, consistent disruptions in energy metabolism and nervous system function were observed. Key biomarkers included Sulfatide 36:1 (d18:1/18:0), Sulfatide 38:1 (d18:1/20:0), 3,4-dihydroxyphenylalanine (L-DOPA), L-Citrulline, D-Tryptophan, acetyl-L-carnitine, eicosenoic acid, eicosadienoic acid, and arachidonic acid. The MTBE-based strategy efficiently captured dynamic metabolomic and lipidomic perturbation, identifying Sulfatide and L-DOPA as promising biomarkers of PFOS-induced neurotoxicity in developing zebrafish embryos. By enabling the rapid and simultaneous profiling of multi-layered biomolecules, this approach could be used to the early detection of PFAS-induced neurotoxicity and provide a robust framework for toxicity assessments of PFAS and other toxic substances in future studies.

1.11.P-Tu119 Immunotoxicity and Autotoxicity of Poly- and Perfluoroalkyl Substances in Fish
Wenhui Qiu[1]*, Liang Tang*[2] *and Honghong Chen*[3]*, (1)Guangdong Provincial Key Laboratory of Soil and Groundwater Pollution Control, School of Environmental Science and Engineering, Southern University of Science and Technology, China, (2)Key Laboratory of Organic Compound Pollution Control Engineering, School of Environmental and Chemical Engineering, Shanghai University, China, (3)Eastern Institute for Advanced Study, Eastern Institute of Technology, School of Environmental Science and Engineering, Shanghai Jiao Tong University, China*
Previous studies have reported the immunotoxicity of per- and polyfluoroalkyl substances (PFASs), but it remains a significant challenge to assess over 10,000 distinct PFASs registered in the distributed structure-searchable toxicity (DSSTox) database. In our study, we revealed differences in the immunotoxic responses of PFASs, which is dependent on the carbon chain length in zebrafish, providing new insights into the prediction and classification of PFASs mode of toxic action based on carbon chain length. In addition, given the potential degradation of ?perfluorooctane sulfonate precursor (PreFOS) into perfluorooctane sulfonic acid (PFOS) in vivo, there is still debate as to ?the specific nature of PreFOS-induced toxicity, whether autonomous or mediated by its metabolite PFOS. ?The findings from our study suggest that the immunotoxicity effects of ?perfluorooctane sulfonamide (PFOSA), an immediate PreFOS, are primarily due to its own toxicity rather than its metabolite PFOS. This conclusion was supported by dose dependent responses, the severity of observed effects, and multivariate analysis. ?In conclusion, our study reveals that the immunotoxicity of PFASs is related to carbon chain length and auto-toxic response, providing valuable insights for assessing the ecological risks of PFASs.

1.11.P-Tu120 Additive Effects of PFAS Mixtures on Acute Toxicity, Phenotypic and Behavioral Endpoints in Zebrafish Embryos

*Samuel Turken[1], Renee Owen[1], Lena Knodler[1], Janet Kruger[1], Nils Klüver[2], Dorte Herzke[3], Line Smaastuen Haug[3], Oddvar Myhre[3], Jasmin Stockhause[1], Paul Michaelis[1], Tamara Tal[4] and **Wibke Busch**[4], (1)Helmholtz Center for Environmental Research, Germany, (2)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research, Leipzig, Germany, (3)Norwegian Institute of Public Health NIPH, Norway, (4)Helmholtz Center for Environmental Research, Leipzig, Germany*
Per- and polyfluoroalkyl substances (PFAS) are synthetic organic chemicals. Various adverse human health and environmental effects are associated with exposure to PFAS. Many studies described the effect of single PFAS compound in several model organisms, including the zebrafish embryo. However, fewer studies have considered PFAS mixture effects. To elucidate potential mixture effects of prominent PFAS we used a concentration addition (CA), a classical mixture modelling approach. We investigated the effects of single substances and mixtures containing PFOS, PFHxS, PFOA, PFNA, PFDA, and PFUnDA. One of the mixtures is based on acute toxicity effects (LCx) and was designed to exhibit equal toxicity according to CA modelling. Another is environmentally-relevant, based on mixture ratios found in the blood of Scandinavian populations where a concentration range of 0.5-179x of the human blood concentrations (HBC) were tested. Zebrafish were developmentally exposed using different exposure scenarios from 0-5 days post fertilization (dpf) to single substances or different mixture compositions. Acute toxicity, phenotypic, and behavioral effects were measured. At 5 dpf, zebrafish were subjected to an automated visual and acoustic motor response (VAMR) assay comprised of 26 behavior-based endpoints. Multiple behavior effects were observed at sublethal concentrations and included hyperactivity in dark-phase and acoustic startle response endpoints. This work identified a range of developmental and behavioral effects in zebrafish exposed to PFAS and indicate that the adverse effects of PFAS mixtures can be explained by compound additivity.

1.11.P-Tu121 Causal Analysis of PFAS Toxicity and Disease Associations Using Bayesian Networks with Data Integration

***Jaeseong Jeong** and Jinhee Choi, University of Seoul, Korea, Republic of*
Per- and polyfluoroalkyl substances (PFAS), a group of persistent environmental chemicals, have been associated with various health effects, yet the causal relationships with specific diseases remain complex and insufficiently understood. The aim of this study is to conduct a systematic review of the literature on PFAS toxicity and its associations with multiple diseases and to perform a causal analysis using Bayesian Network (BN) modeling. By integrating toxicity data, we seek to examine the strength and direction of PFAS-disease associations within a probabilistic framework. By consolidating findings from existing studies and incorporating quantitative data, we construct a BN to map connections between PFAS toxicity, potential biomarkers, and disease endpoints. The BN model identified potential causal pathways between PFAS and disease outcomes, including associations with endocrine functions. While some pathways showed stronger associations than others, the results indicate specific areas where PFAS exposure may influence disease risk, highlighting oxidative stress and inflammation biomarkers as key intermediate factors. This preliminary analysis underscores the utility of BN modeling for exploring PFAS-related health risks and identifying key pathways. Our findings provide an initial framework for prioritizing future research areas and refining causal models to better assess PFAS impacts on human health. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through 'Core Technology Development Project for Environmental Diseases Prevention and Management', funded by Korea Ministry of Environment (MOE) (2021003310005).

1.11.P-Tu122 Head To Head: How Polar Head Group Drives Toxicity Of Per- And Polyfluoroalkyl Substances To *Daphnia Magna*

***Ge Xie**[1], Milo Leon de Baa,[2], Huub Dagevos[2], Bobbie Fabels[2], Simon Gerbranda[2], Daisy Greuter[2], Ezra Meijer[2] and Michiel Kraak[2], (1)Vrije Universiteit Amsterdam, Netherlands, (2)Universiteit van Amsterdam, Netherlands*
Per- and poly-fluoroalkyl substances (PFAS) are a ubiquitous group of anthropogenic compounds that have raised environmental concerns due to their persistent and bioaccumulative properties. To predict the ecotoxicity of the many untested PFAS, it is imperative to unravel the link between PFAS molecular properties and their ecotoxicity. So far, it has been established that PFAS ecotoxicity increases with increasing fluorinated carbon chain length, but still little is known about the influence of the polar head group on PFAS ecotoxicity. Therefore, the present study aimed to determine the ecotoxicity of PFAS with identical chain length, but different polar head groups to Daphnia magna. Four C4-PFAS were selected: perfluorobutanesulfonamide (FBSA), perfluorobutane sulfonic acid (PFBS), perfluorobutanesulfonyl chloride (PBSCl), and perfluoropentanoic acid (PFPeA). To compare their ecotoxicity, the effects of these four compounds on D. magna neonates (< 24h) mobility were tested according to OECD guideline 202. Six concentrations, including a negative control, were tested per PFAS, with four replicates per

concentration and five daphnids per individual replicate. Daphnid mobility was checked after 24 and 48 hours of exposure. Concentration-effect relationships were fitted to the experimental data from which EC50 values were calculated. The negative controls met the specified OECD requirements. Clear concentration-effect relationships were obtained for the effects of the four PFAS on daphnid mobility, with EC50 values of 12 mg/L FBSA, 1026 mg/L PFBS, 1961 mg/L PBSCl, and 2638 mg/L PFPeA. Hence, strong and significant differences in ecotoxicity between the four compounds were observed, driven by varying polar head groups. FBSA was the most toxic of the tested PFAS and was 220 times more toxic than the least toxic compound. The relatively high ecotoxicity of FBSA may be caused by a specific mode of action, as the sulfonamide head group may induce developmental toxicity. The low ecotoxicity of PFBS and PFPeA confirms their lack of specific modes of action. The sulfonate anion (R-SO3-) of PFBS causes a higher affinity for sorption into the membrane, potentially causing the higher observed toxicity than its carboxylate homolog PFPeA and the non-dissociating PFAS PBSCl. It is concluded that the polar head group strongly influences PFAS ecotoxicity, emphasizing that PFAS environmental hazard strongly depends on their molecular properties. This research was supported by the Open Technology Programme of the Dutch Research Council (NWO) [grant number 18725]

1.11.P-Tu123 Discrepancies between CCK-8 and Trypan Blue Assays in PFAS-Exposed ZF4 Cells: Implications for Metabolic Stress Assessment

Timothy Prince Chidike Ezeorba, *Emilie Brun, Mohamed Abou-Elwafa Abdallah and Iseult Lynch, School of Geography, Earth, and Environmental Sciences, University of Birmingham, United Kingdom*

Perfluoroalkyl substances (PFAS), particularly perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), are persistent environmental contaminants with potential toxicological effects. This study investigated the effects of PFOA and PFOS on zebrafish embryonic fibroblast (ZF4) cells, revealing critical methodological considerations for cytotoxicity assessments. ZF4 cells were exposed to various concentrations of PFOA and PFOS (100-1000 µM) for 24 hours. Cell viability was evaluated using the cell counting kit 8 (CCK-8) assay, trypan blue cell counting, and lactate dehydrogenase (LDH) assay, which measures cell membrane damage and LDH leakage from the cytoplasm. Surprisingly, the CCK-8 assay showed a dose-dependent increase in absorbance readings at concentrations up to 500 µM, particularly for PFOS, suggesting increased cell viability or proliferation. However, concurrent trypan blue cell counts revealed a dose-dependent decrease in cell numbers, with IC50 values determined for both PFOA and PFOS (570.1 µM and 586.1 µM, respectively). LDH assay results were consistent with trypan blue counts. This discrepancy between CCK-8 results and actual cell counts indicates that the CCK-8 assay may produce false-positive results in this context. The increased CCK-8 signal, despite reduced cell numbers, suggests that PFOA and PFOS exposure may induce metabolic stress in ZF4 cells, potentially leading to increased mitochondrial activity. These findings highlight the importance of using multiple assays to assess cell viability and stress responses, especially when studying PFAS toxicity in emerging model cell lines like ZF4. Furthermore, this research suggests the potential value of investigating mitochondrial bioenergetics in PFAS-exposed cells, as metabolic alterations may precede overt cytotoxicity. To further confirm enhanced metabolic stress, future work will include Seahorse experiments to measure cellular respiration and glycolysis. Additionally, mitochondrial functional studies will be conducted using flow cytometry to analyze MitoSOX and TMRM staining, providing insights into mitochondrial superoxide production and membrane potential, respectively. These results contribute to our understanding of PFAS toxicity mechanisms and provide critical methodological considerations for future toxicological studies, emphasizing the need for multiple assays in assessing cell viability and stress responses, particularly when studying emerging model cell lines. The authors gratefully acknowledge the Petroleum Technology Development Fund (PTDF) for awarding a Ph.D. scholarship to Timothy Prince Chidike Ezeorba (PTDF Scholar ID: 22PHD053). We also extend our appreciation to the Society of Environmental Toxicology and Chemistry (SETAC) Europe for providing a Student Registration Grant, enabling the presentation of our findings at the 2025 SETAC Europe Annual Meeting.

1.11.P-Tu124 Evaluation of Immunological Impact of PFAS Exposure on Cytokine Release and Gender-Based Responses in PBMCs

Luisa Nunziangeli[1] *and Giuseppe Emanuele Condorelli*[2]*, (1)Polo d Innovazione di Genomica Genetica e Biologia, Italy, (2)Polo d'innovazione Di Genomica Genetica e Biologia, Italy*

Over the past few decades, humans have been constantly exposed to perfluoroalkyl substances (PFAS), a group of chemicals of major concern due to their widespread use in consumer goods and their resistance to biological degradation. The purpose of this study was to investigate the effects of PFAS on female and male peripheral blood mononuclear cells (PBMC), with a focus on immunomodulatory response by assessing both the pro-inflammatory and anti-inflammatory cytokines release following stimulation with mitogens. In our experiments, pools of human PBMCs from healthy female and male donors were plated

(3 x 105 cells/well) and then exposed to 20 different PFAS congeners. The cells were initially exposed to three increasing concentrations of the chemicals, and then stimulated with either LPS (24 hours) or PHA (72 hours), separately. Stimulated cells, incubated in the absence of PFAS, were used as control. Supernatants were afterwards collected to assess the analysis. A protein microarray analysis of supernatants was performed to assess the release of 10 different pro-inflammatory and anti-inflammatory cytokines. Non-parametric pairwise multiple comparisons were used to test significance of differences in cytokine levels between treated and control cells. Our preliminary results indicated a statistically significant reduction in cytokine concentrations in mitogen-stimulated PBMCs exposed to PFAS. Notably, we observed a more pronounced alteration in the cytokine profile of PBMCs from female donors treated with PFCA group, compared to those from male donors, suggesting a potential gender-specific effect. This project has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No 101037509 (SCENARIOS project).

1.11.P-Tu125 Toxicokinetics of PFOS in Freshwater Macroinvertebrates

***Ayesha Siddiqa**, Wageningen University and Research, Netherlands*

The Increasing use of PFOS has led to their release into the aquatic environment. Toxicokinetics is a key component in the assessment of a chemicals risk to the environment and human health, and is a requirement of many global regulations for chemical management. Chemicals that bioaccumulate are of concern because they have the potential to achieve high concentrations in biota, which can lead to toxicological effects. However, there is only limited knowledge about the effects of long-term exposure to PFOS on freshwater macroinvertebrates. To fill this knowledge gap and to improve our mechanistic understanding of the effects of PFOS on freshwater macroinvertebrates, the current study explored the toxicokinetics of PFOS in two insects and one crustacean species. The tested species in these experiment were the mayfly Cloeon dipterum, the phantom midge Chaoborus obscuripes and the freshwater shrimp Gammarus pulex. In the toxicokinetics test, organisms were exposed to 100 µg/L of PFOS for 3 days during the uptake phase and then transferred to clean water for 3days of elimination. The selection of the exposure concentration during the uptake phase was based on our previous chronic toxicity results for the same species. The survival for the three species at the end of experiment was 77, 63 and 88% for C. dipterum, C.obscuripes and G. pulex, respectively. All water samples have been measured by LC-MS/MS, and the exposure concentrations were within 90 to 130% of the nominated concentration, with an acceptable deviation. During the elimination phase, about 0.05 to 0.7 µg/L of PFOS was detected in the water. G. pulex eliminated the highest amount (0.7 µg/L) compared to C. dipterum and C.obscuripes which eliminated around 0.2 µg/L. These results are quite interesting and suggest that G. pulex may eliminate more PFOS than the other two species. Furthermore, the internal concentration measurements is in progress and will be presented together with some preliminary TK modelling results. PUNJAB EDUCATION ENDOWEMENT FUND PUNJAB,PAKSITAN.

1.11.P-Tu126 An In-depth Analysis of Per- and Polyfluoroalkyl Substances (PFAS) in Prenatal and Cord Blood Samples

***Garry Codling**, Exeter University, United Kingdom*

PFAS are pervasive environmental pollutants found in air, water, food, and consumer products. Their chemical properties, such as persistence, bioaccumulation, and resistance to degradation, make them of concern for human and ecological health. Common PFAS compounds, including PFOS and PFOA, have been detected in human serum with half-lives of several years. Global trends show declining PFAS levels in some regions following regulatory phase-outs, but stable background levels persist in low-exposure areas. This study examines PFAS levels in maternal and cord blood samples, exploring their transfer from mother to foetus and assessing the presence of branched and linear isomers. Samples were collected at 38 weeks of pregnancy and at birth, processed with a generic extraction method, and analysed via high-resolution mass spectrometry for 25 target PFAS, 38 suspect and over 6000 library associated fluorinated compounds. The analysis identified PFOS, PFDoA, PFUdA, PFDA, and PFOA as the most frequently detected compounds. Some emerging PFAS compounds were found in limited samples, while short-chain PFAS, such as PFBA and PFBS, were detected infrequently, reflecting their rapid excretion and localized exposure. Statistical analysis revealed significant differences in PFAS concentrations between maternal and cord blood, with some compounds higher in one matrix than the other. Suspect screening revealed over 200 potential PFAS features, though many represent noise or low-confidence identifications. Variations in detection frequencies and concentrations align with trends reported in other human biomonitoring studies. Notably, branched isomers of PFOS accounted for up to 30% of the detected PFOS, demonstrating diverse exposure sources and potential health implications. This work highlights the challenges of PFAS detection, including the influence of laboratory blanks, instrumental noise, and the diversity of isomers. It emphasizes the need for robust analytical methods to better understand PFAS exposure and their impacts on maternal and foetal health. Samples were supplied and extracted at RECETOX, Masaryk University, while all data processing and investigation was done at Exeter University UK.

1.12.A Endocrine Disruption Assessment: Opportunities to Enhance and Complement Current Approaches

1.12.A.T-01 Animal-free In Vitro Assessment of Receptor-Mediated Endocrine Activity Including Phase-1 Metabolism

***Inska Reichstein**[1], Denise Horte[1], Robin Mazur[1], Florian Junger[1], Andreas Schiwy[2] and Henner Hollert[2], (1)Evolutionary Ecology & Environmental Toxicology, Goethe University, Germany, (2)Evolutionary Ecology & Environmental Toxicology, Goethe University & Environmental Media Related Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (FhG-IME), Germany*

Substances affecting the endocrine system are present in the environment in complex mixtures and pose a risk to organisms and entire ecosystems even at low concentrations, which increases the importance of considering and evaluating endocrine disruptors. For this, standardized in vitro methods according to OECD test guidelines 455 and 458 can be applied to determine the agonistic and antagonistic effect on estrogen and androgen receptors on a cellular level. However, these methods have disadvantages of (1) containing undefined animal components like Fetal Bovine Serum (FBS) possibly leading to less reproducible results and ethical concerns and (2) a lack of metabolic representation of whole organisms which could lead to an over- or underestimation of the samples endocrine activity. In this study, the methods according to OECD TG 455 and 458 should be improved by adapting two of the OECD-relevant cell lines (ER-?CALUX® and AR-CALUX®) to FBS-free conditions and the supplementation with external biotransformation systems (S9 homogenates) derived from rats/humans or their respective animal-free alternative to evaluate the endocrine activity of model substances after metabolism. Overall, the effects without/with metabolism and without/with adapted cell lines will then be compared to assess the assay adaptation and their (beneficial) impact on risk assessment. In the first step, both cell lines could be successfully adapted to a self-developed medium with few ingredients. The sensitivity of the cells to the reference substances 17?-estradiol (ER-?CALUX®) and dihydrotestosterone (AR-CALUX®) was comparable under FBS-containing and FBS-free conditions and similar concentration-dependent response curves could be generated. In the second step, a set of different model substances will be tested for their (anti-)estrogenic or (anti-)androgenic effect with and without metabolism, which will allow an initial comparison of the metabolic performance of the different S9 mixes in endocrine testing. Overall, the comparison of the endocrine effect of several model substances in FBS-containing versus FBS-free medium with and without the addition of S9-homogenates will enable a more comprehensive evaluation of the new method and thus possibly demonstrate that in vitro tests can also be carried out reliably without the use of animal components.

1.12.A.T-02 In Vitro Potencies of Chemicals for Inhibition of Thyroperoxidase (TPO) in Four Fish Species Compared to Mammalian Potencies in the ToxCast Database

***Vann Lynne Boyte**[1], Lauren Eagon[1], Cameron Hunter Collins[1], Chris Lowrey-Dufour[1], Hannah Hartmann[1], Nonnie 'Betsy' Cook[1] and Jonathon Doering[2], (1)Louisiana State University, United States, (2)Louisiana State University, Baton Rouge, United States*

There are many concerns about chemicals in aquatic environments that can disrupt thyroid hormone signaling (THS) in fish. THS is a conserved process, regulated by a series of coordinated events involving several proteins. Additionally, THS in fishes is vital to many biological functions such as growth, development, and metamorphosis. Thyroperoxidase (TPO) is the main enzyme involved in synthesis of the thyroid hormones, tetraiodothyronine (T4), which is converted to the biologically more active form: triiodothyronine (T3). Chemical additives, pharmaceuticals, pesticides, and personal care products in the environment can inhibit the actions of TPO, leading to changes in THS and an overall decreased synthesis of T3 and T4, and a possible decrease in systemic concentrations of T3 and T4.? Currently, screening for chemicals for TPO inhibiting properties has focused on mammalian-based assays, such as those used in the United States Environmental Protection Agency s (USEPA) ToxCast Program. In fish, the limited chemical safety investigations have focused almost entirely on a single non-native model species, the zebrafish (Danio rerio), which may not be representative of all fish species for THS disruption. Thus, little is known about whether chemicals with TPO inhibiting properties in mammals share these properties in fishes and whether there are differences in sensitivities among different species of fish. The present study investigates inhibition of TPO enzymes, using high-throughput animal alternative methods by adapting the previously developed in vitro Amplex Ultrared-Thyroperoxidase (AUR-TPO) assay for use in fishes. Through this, species sensitivity to TPO inhibition between fish and mammals to xenobiotics can be compared. Chemicals with a range of potencies were chosen from the US EPA CompTox Database. Results of this study will determine whether fish species differ in their sensitivity to TPO inhibitors and how potencies compare to mammalian-based assays. Funding was provided by Louisiana Board of Regents

1.12.A.T-03 Metamorphosis as an Endpoint for Thyroid Hormone Disruption in Fish

Lauren Eagon*, Vann Lynne Boyte, Cameron Hunter Collins, Nonnie 'Betsy' Cook and Jonathon Doering, Louisiana State University, United States*

Metamorphosis is a vital biological process characterized by the transition from larval to juvenile stage of development and is most commonly associated with amphibians. Pesticides, chemical additives, pharmaceuticals, and personal care products found in surface waters can disrupt thyroid hormone (TH) signaling leading to accelerated, delayed, or prevented metamorphosis. TH disruption has been well studied in mammals and amphibians, and amphibians are generally sensitive to metamorphic impacts from a wide range of chemicals. In fishes, TH disruption studies have focused on small model species with simple metamorphosis, such as zebrafish (Danio rerio), which are relatively insensitive to disruption. However, some fish species complete a metamorphosis as complex as amphibians and it is unknown whether these fishes with dramatic transformations are more sensitive to chemical disruption relative to zebrafish. The present study aimed to (1) develop and apply an in vitro assay to screen thyroid hormone receptor (THR) disruption in fishes with varying degrees of metamorphic complexity using a known TH agonist, triiodothyronine (T3) and (2) develop a fish metamorphosis toxicity assay using spotted gar (Lepisosteus oculatus) to assess sensitivity to metamorphic chemical disruption in vivo for species with dramatic transformation. The in vitro assay utilizes COS-7 cells transfected with THR constructs for the species of interest, a thyroid response element vector, a reporter vector containing a luciferase gene, and a pRL-TK internal control vector. Cells were exposed to T3 at serial concentrations using 96-well plates, incubated in the dark, and read on a luminescence plate reader following the addition of a dual-luciferase agent. Exposures for gulf killifish (Fundulus grandis), spotted gar, southern flounder (Paralichthys lethostigma), and American eel (Anguilla rostrata) showed median effective concentration (EC50) values ranged by just 8-fold, from 0.0001nM to 0.0008nM. This suggests that sensitivity to THR disruption might not be driven by metamorphic complexity, at least not for T3. There is no current knowledge on whether a lack of species sensitivity differences translates to a lack of differences in metamorphosis. To address this, the in vivo assay will evaluate susceptibility to metamorphic disruption by exposing embryos to sub-lethal concentration of T3 during metamorphosis and comparing exposed individuals to previously identified metamorphic milestones.

1.12.A.T-04 Immunotoxic Effects of Endocrine Disruptors – An Understudied Adverse Outcome in Fish

Lisa Annie Baumann[1]*, Florentina Hasani*[1]*, Pauline Pannetier*[2]*, Maxim Carlier*[1] *and Timo Hamers*[1]*, (1)Vrije Universiteit Amsterdam, Amsterdam Institute for Life & Environment, Section Environmental Health & Toxicology, Netherlands, (2)VIMEP Unit, Ploufragan-Plouzane-Niort Laboratory, Anses, Plouzane & EPOC Laboratory, UMR CNRS 5805, University of Bordeaux, CNRS, Bordeaux INP, Pessac, France*

Endocrine disrupting chemicals (EDCs) are among the most studied environmental pollutants in (eco)toxicology. Despite their scientific and regulatory recognition, little attention has been given to their immunotoxic effects, and current research and data on this topic is mainly limited to human health impacts. Regarding the environment, there is still a lack of knowledge and test protocols for immune-related outcomes in fish. While the impact of estrogenic EDCs on the fish immune system has raised some attention in the last decade, thyroid hormone disrupting compounds (THSDCs) and their effects on the fish immune system are less well studied. This presentation is aimed at describing the immunomodulatory roles of environmental pollutants by summarizing the existing research on the immunotoxicity of EDCs in fish, with focus on the TH system. A literature review was performed on studies about THSDCs and their role in disruption of the fish immune system at different levels of biological organization. The results were summarized according to the adverse outcome pathway (AOP) concept to create a comprehensive overview and visual representation of the results. Additionally, two examples of ongoing research about immunotoxic effects on fish are presented to show which methods can be used in a regulatory context to assess immunotoxicity in fish. As a short-term new approach methodology (NAM), we developed a protocol using zebrafish embryos infected with fluorescently labeled mycobacteria and exposed to potential immunotoxicants. In the context of the ZeroPM project, the effects of 11 PFAS on the innate immune function of zebrafish embryos was assessed. Two of the PFAS caused increased bacterial loads compared to control embryos, which confirms their immunotoxicity described in humans. In the SUSPECT project, a long-term experiment with rainbow trout exposed to sodium fluoride (NaF) and infected with a virus, THSD and immunomodulatory effects were observed at different levels of organization (health status, survival, morphometry, behavior, histopathology, RNAseq). Overall, this work demonstrates that THSDCs can alter fish immune system functioning along the AOP and therefore lead to reduced survival after pathogen infection. Our zebrafish immunotoxicity assay has the potential to be used for the assessment of immunotoxic effects in fish that could be implemented in the OECD testing framework for environmental health and potential extrapolation to humans. Funding was provided from: European Union s Horizon 2020 Research and Innovation Programme under grant agreement 101036756 (ZeroPM). National Environment-Health-Work Research Program of Anses with the support of the Ministries of Environment, Agriculture and Labor (ANSES-22-EST-050) (SUSPECT).

1.12.A.T-05 Elucidating the Mode of Action of Priority Pollutants on the Thyroid Axis by Combining Two Eleuthero-embryonic Bioassays

Sara Cvetkovics[1]*, Jessica Edith Benitez Gonzalez*[1]*, Laurent Sachs*[2]*, Gregory F. Lemkine*[1] *and David Du Pasquier*[1]*, (1)Laboratoire Watchfrog S.A., France, (2)UMR7221, Physiologie Moleculaire et Adaptation, CNRS, MNHN, Paris, France*

Each endocrine axis (e.g., thyroid, estrogenic) can be impacted by chemicals acting through various modes of action (MoA), including receptor interaction, hormone production, transport, or elimination. We propose a method for elucidating the MoA of thyroid disrupting chemicals while addressing two main problems: I) lack of assays for thyroid-active chemicals that utilize fish, II) ethical concerns regarding in vivo testing. One of the OECD test guidelines for identifying endocrine activity is the XETA test (Xenopus Eleuthero-embryonic Thyroid Assay). This assay uses a transgenic Xenopus laevis line harboring a gene coding for GFP under the control of a promoter responsive to thyroid signaling. Fluorescence changes in embryos indicate thyroid axis activity. Additionally, the XETA assay provides insights into the MoA by comparing fluorescence responses in the absence and presence of thyroid hormones. However, some MoA are not detected by XETA. To address this gap, while also providing a fish-based assay for thyroid active chemicals, a new test, TETHYS (Transgenic Eleuthero-embryo Thyroid Specific test), was developed based on a transgenic medaka fish line. In this assay, GFP expression is driven by the thyroglobulin promoter, marking thyroid follicles. Notably, the TETHYS assay can detect MoA like iodine import inhibition, which the XETA cannot. These two tests have two major advantages: they are short (72h) and they are based on the use of eleuthero-embryos which are not regulated under the European Directive on animal experimentation. The goal is to combine the XETA and the TETHYS assays to develop a comprehensive method for elucidating thyroid-disrupting MoA that benefits from whole organism testing, short duration of the tests, and a more ethical approach. This combined approach was already applied to reference substances with known MoA. Following this, 16 priority substances proposed by ANSES will be assessed in the same way. For those chemicals that are showing thyroid axis activity, we will be able to propose possible MoA by comparing the results with those generated for the reference chemicals. Furthermore, transcriptomics analysis will be performed for two of these thyroid disrupting chemicals. This will further help with a more precise identification of their MoA. The work presented here was partly funded by ANSES under grant number ANSES-23-EST-098, and the INCLUE HORIZON MSCA-DN project.

1.12.B Endocrine Disruption Assessment: Opportunities to Enhance and Complement Current Approaches

1.12.B.T-01 Tiered Assessment Scheme Linking NAMs to Adverse Outcomes to Identify Thyroid Disruptors in Aquatic Vertebrates

Laurent L.-M. Lagadic[1]*, Katherine K. Coady*[2]*, Oliver Korner*[3]*, Tara Miller*[4]*, Valentin Mingo*[5]*, Edward Salinas*[1]*, Ursula Sauer*[6]*, Christel Schopfer*[7]*, Lennart Weltje,*[7] *and James Robert Wheeler*[8]*, (1)Bayer AG R&D, Crop Science Division, Environmental Safety, Germany, (2)Bayer AG, Crop Science Division, United States, (3)ADAMA Deutschland, Germany, (4)Syngenta, Jealott s Hill International Research Centre, Jealott s Hill, United Kingdom, (5)Corteva Agriscience, Germany, (6)Scientific Consultancy Animal Welfare, Neubiberg, Germany, (7)BASF SE, Agricultural Solutions - Ecotoxicology, Germany, (8)Corteva Agriscience, ., Netherlands*

According to the World Health Organisation and European Commission definitions, substances shall be considered as endocrine disruptors if they show adverse effects, have endocrine activity and the adverse effects are a consequence of the endocrine mode-of-action (using a weight-of-evidence approach based on biological plausibility), unless the adverse effects are not relevant to humans or non-target organisms at the population level. To date, there is no decision logic on how to establish endocrine disruption via the thyroid modality in non-mammalian vertebrates. We present an evidence-based decision logic to identify thyroid-mediated effect patterns in aquatic vertebrates, i.e. currently amphibians. The decision logic includes internationally agreed test guidelines and proposes detailed considerations on how to select relevant assays and interpret the findings. It combines New Approach Methodologies with higher-tiered tests up to refined assessment including population modelling. If the mammalian dataset, including any in vitro data, is used as the starting point and indicates no thyroid-mediated adversity or mode-of-action, the Xenopus Eleutheroembryonic Thyroid Assay (XETA) may be conducted in place of the Amphibian Metamorphosis Assay (AMA) or its extended, fixed termination stage variant (EAMA) to exclude thyroid-mediated activity in non-mammalian vertebrates. The AMA or EAMA may be performed if there are indications for thyroid adversity in the mammalian dataset or following a positive XETA. The AMA and EAMA inform on both thyroid-mediated activity and potentially population-relevant adversity and consider generalized toxicity occurrence. In evaluating findings, the response patterns of all assay endpoints are considered, including both the consistency and direction of changes. Thyroid-mediated effect patterns identified at the individual level in the amphibian tests are followed by a mode-of-action analysis and where necessary a population relevance assessment. Finally, all data are considered in an overarching weight-of-evidence evaluation. The decision logic can be adapted, e.g., to accommodate fish tests once thyroid endpoints are included therein. It ensures that all scientifically relevant information are considered and that animal testing is minimised, and it can be included in regulatory assessments to facilitate the conclusion on whether substances meet the endocrine disruptor definition for the thyroid modality in non-mammalian vertebrates.

1.12.B.T-02 Assessing the Impact of Dietary Restriction on Endpoints in the Fish Short-Term Reproduction Assay: Implications for Interpreting Endocrine Activity
James Robert Wheeler[1]*, Jeffrey C. Wolf*[2] *and Valentin Mingo*[3]*, (1)Corteva Agriscience, ., Netherlands, (2)EPL, United States, (3)Corteva Agriscience, Germany*
The Fish Short-term Reproduction Assay (FSTRA) is an important in vivo endocrine screening tool used to detect potential endocrine activity of chemicals on the hypothalamic-pituitary-gonadal (HPG) axis. This study aimed to investigate whether a non-chemical stressor, dietary restriction, could influence FSTRA outcomes, particularly in relation to endpoints typically linked to HPG axis activity, as well as effects on fecundity, fertility, and GSI. A standard Test Guideline compliant FSTRA was conducted using five different feeding regimes, providing 100%, 30%, 15%, 7.5%, and 2.5% of the standard laboratory feeding ration. All endpoints outlined in the TGs, including gonad histopathology, were assessed, and the specificity of these endpoints in determining EAS-mediated activity was evaluated. Statistically significant reductions in fecundity, wet body weight change (both sexes) and male GSI were observed across all reduced feed rations (30% to 2.5%), following a clear feed-dependent response. Female GSI was significantly reduced at the 2.5% ration, although non-significant reductions were seen across all rations compared to the reference (100%) ration. A clear monotonic decline in female VTG levels occurred, with statistically significant decreases in the 7.5% and 2.5% ration groups when compared to the reference ration. No statistically significant effects on VTG were observed in males. There were no statistically significant changes in male tubercle score or reductions in fertilization success. Histopathology investigations are on-going, and all results will be available at the time of the conference. These results highlight the need for appropriate Maximum Test Concentration setting that does not focus solely on mortality (e.g., acute LC50 testing), since sub-lethal effects can clearly influence responses in FSTRA studies and these should not be mistaken for evidence of specific endocrine activity. Further, holistic interpretation of all endpoints should be employed to avoid unnecessary repeat or higher tier studies to clarify such non-specific responses. Such approaches would provide a more comprehensive basis for concluding on the endocrine activity of a test substance, and help to differentiate endocrine-mediated effects from non-specific toxicities.

1.12.B.T-03 The Population Relevance of Effect in Mammals: Experience and Future Perspective
Maria Arena[1]*, Simone Rizzuto*[2]*, Aude Kienzler*[2] *and Laura Villamar-Bouza*[1]*, (1)European Food Safety Authority, Italy, (2)European Food Safety Authority, Parma, Italy*
Generally, for environmental risk assessment the entity to be protected in reproductive risk assessment is the population. The selection of the relevant ecotoxicological endpoint as well as the assessment for endocrine disruption in wild mammals are both based on the use of toxicity mammalian toxicology studies. Considering the level of protection for wild mammals (population) is different than the one for human health (individual), effects in mammalian species often need to be reconsidered from a different perspective. When assessing the effects observed in the available toxicological studies, relevant parameters for the effects on wildlife populations are those parameters that show an expectation of adverse effects on the population in the ?eld. Effects on growth (body weight and length), development and reproduction (such as fecundity, fertility, sex ratio, hatching success and offspring survival) in single species in laboratory studies are generally regarded relevant for the maintenance of the wild populations.

Regarding the effect level, a statistically significant difference compared to the control in a relevant parameter and the biological relevance of the observed change should be considered to assess if an observed change is adverse effect at the population level. A number of substances evaluated so far by EFSA have been re-analyzed to report examples of how the assessment for population relevance of adverse effects in mammals has been performed both in the context of endocrine disruption and for the selection of the ecotoxicological relevant endpoint. Based on experience, drawing a conclusion on population relevance is more challenging when effects at organ level are observed. For example, in the context of assessments for endocrine disruption, it may be controversial to conclude on the relevance of effects like increase in the incidence and severity of follicular cell hypertrophy. In future, it would be beneficial to come to an agreed list of apical effects that may be related to a thyroidal mode of action in mammals. In addition, useful tools for better understanding the population relevance of effects observed in laboratory toxicity studies, e.g. effect models, are currently under discussion for their development and possible implementation.

1.12.B.T-04 Risk Management of Environmental Endocrine Disrupting Chemicals (EDCs) - Derivation of Predicted No Effect Concentrations (PNECs)

Morne Van Der Mescht*, Ian Doyle and Steve Dungey, Environment Agency, United Kingdom*

According to Article 60 of the UK Registration, Evaluation, Authorisation and restriction of Chemicals (REACH) legislation, authorisation of a Substance of Very High Concern (SVHC) can be granted in one of two ways: either where adequate control has been demonstrated (with exposure concentrations below an acceptable threshold) or due to socioeconomic need. To date, authorisations for SVHCs that are environmental endocrine disrupting chemicals (EDCs) have only been granted on socioeconomic grounds. There is however, no guidance to applicants about the circumstances under which an acceptable concentration might be determined. A SETAC Pellston® workshop on Ecotoxicological Hazard and Risk Assessment Approaches for Endocrine-Active Substances held in 2016 concluded that a predicted no effect concentration (PNEC) can be determined for EDCs provided that sufficient data are available. We wanted to explore what this means in practice. Our project reviewed three data rich EDCs to establish what PNECs might be considered sufficiently protective of endocrine effects in the aquatic environment, and then applied the findings to eight further EDCs with fewer data to test the concept. Ecotoxicity datasets were compiled and their reliability was assessed before they were used to determine relevant PNECs for each substance. The approach covered oestrogen, androgen, and steroidogenesis (EAS) modalities due to insufficient data being available for thyroid-mediated effects. The report suggests that it is possible to derive precautionary threshold values for EDCs based on no-observed effect concentrations (NOECs) using an appropriate assessment factor (AF). Conventional AFs are considered acceptable where Organisation for Economic Co-operation and Development (OECD) Conceptual Framework (CF) Level 5 data are available, because such studies are multi-generational and cover relevant life cycle traits. However, they are not sufficiently protective of endocrine effects where only OECD CF Level 3 and 4 data are available. Our proposal is to increase the AF in such circumstances, to reflect the higher uncertainty. For one substance which only had an OECD CF Level 3 fish short term reproduction assay (FSTRA) available, our approach was able to derive a PNEC that would be protective for the lowest biomarker NOEC concentration. It is also important that other chronic ecotoxicity data are considered: for two pesticidal substances, algae were more sensitive than fish.

1.12.B.T-05 An Integrative Framework for the Identification and Prioritization of the Risk Assessment of Endocrine Disrupting Chemicals (EDCs)

David Lopez Rodriguez[1]*, Diane Duroux*[2]*, Anne-Simone Parent*[3]*, Jorke Kamstra*[4]*, Juliette Legler*[4] *and Nathalie Chevre*[5]*, (1)University of Lausanne, Switzerland, (2)Department of Computer Science, ETHZ, Switzerland, (3)University of Li ge, Belgium, (4)University of Utrecht, Netherlands, (5)University of Lausanne, Lausanne, Switzerland*

Endocrine-disrupting chemicals (EDCs) affect human health and ecosystems, largely contributing to the current increase in chronic diseases and to worldwide biodiversity loss. For humans, EDC exposure induces metabolic and neurodevelopmental disorders and is widely associated with the reduction of fertility rates in developing countries. For the environment, chemical pollution interferes with ecosystem homeostasis and disrupts the food chain, leading to the irreversible shrinking of bird, amphibians and fish populations across the globe. Despite EDCs being a priority for regulatory agencies, only a small fraction of chemicals authorized for commercial use in the European market have been characterized for ED-activity. To streamline this process, in silico methods are becoming fast and reliable tools to infer chemical toxicity. The aim of this project is to generate and validate a machine learning framework to identify and rank chemicals according to their potential ED-activity. To do so, we first (1) generated an integrative and multidisciplinary database containing physicochemical, human toxicological, and ecotoxicological properties of more than 100 000 EU-relevant chemicals. The database includes over 80 000 parameters, including partition coefficients, chemical-gene/protein associations, hormone binding assays, ecotoxicity for aquatic species and similarity to structural alerts related to endocrine disruption, among others. Secondly, (2) we developed a web-based exploratory tool that allows users to explore chemicals, their properties, and structural similarities. Thirdly, (3) we implemented a machine learning model to identify and rank chemicals based on their potential ED-activity. To improve the transparency of the model, SHapley Additive exPlanations (SHAP) was used to define chemical properties contributing the most to each prediction. Finally, (4) the top-ranking unknown EDCs will be further validated using in vitro reporter assays. In conclusion, we are developing a unique, integrative and multidisciplinary open-source resource for scientists, regulators and industry to evaluate and identify novel EDCs. Our outcomes may be used to prioritize the risk assessment of EDCs, thereby contributing to promote a shift in EU chemical regulations towards a toxic-free environment. The project is funded by the Brussels-Wallonia Federation.

1.12.P Endocrine Disruption Assessment: Opportunities to Enhance and Complement Current Approaches

1.12.P-Tu127 Learnings from Identification of Endocrine Disrupting Properties for the Environment under REACH with focus on Mode of Action Analysis

*Roosa Neuvonen[1], Conor Clenaghan[1], Niklas Andersson[1], Laura Samrani[2], Panagiotis Karamertzanis[2] and **Francesca Pellizzato**[1], (1)European Chemicals Agency (ECHA), Finland, (2)ECHA, Finland*

So far, 17 substances have been identified and included in the Candidate List of Substances of Very High Concern (SVHC) due to their endocrine disrupting (ED) properties for the environment. A substance is considered to have ED properties for the environment if a biologically plausible link can be established between an altered function of the endocrine system and an adverse effect relevant at the population level for wildlife. The major challenge in identifying substances as having ED properties for the environment is to establish a biologically plausible link between the observed endocrine activity and adversity. This is particularly challenging for the environment because the number of endpoints in the available guideline studies is limited. The study aims to collect learnings from the previous assessments to facilitate future regulatory assessments of ED properties for the environment. The ultimate aim is at providing advice on how to improve existing Adverse Outcome Pathways (AOPs) and regulatory test guidelines to better facilitate identification of ED properties. As a first step, an analysis was conducted on the previously identified substances focusing on the mode of action (MoA). Thereafter, for each substance, the type of data used to support the molecular initiating events (MIE), intermediate key events (KEs), and adverse outcomes (AOs) has been analysed in detail i.e. guideline versus non-guideline studies from open literature or databases. A database has been created which maps the postulated MoAs to existing AOPs. This allows evaluation of patterns across substances and assessment of areas needing further investigation. Preliminary findings reveal recurring MoAs across several substances. In particular, the most frequent MoAs could be assigned to the following AOPs in the AOPwiki: AOP 29 Estrogen receptor agonism leading to reproductive dysfunction and AOP 52 ER-agonism leading to skewed sex-ratio due to altered sexual differentiation in males. Both of these AOPs concern estrogenic MoA, however neither of them are endorsed by OECD and would merit prioritisation for inclusion in the OECD work program. In addition, we identified other KEs that warrant further investigation and potential inclusion in the next AOP developments. This study supports future assessment of ED properties for the environment by identifying the most common MoAs and provides recommendations for future AOP development related to environmental endocrine disruption.

1.12.P-Tu128 Use Of The Weight-of-evidence In The Identification Of Endocrine Disruptors Under REACH

*Helene Serra-Nieminen[1], Conor Clenaghan[2] and **Francesca Pellizzato**[2], (1)European Chemicals Agency, Helsinki, Finland, (2)European Chemicals Agency, Finland*

Weight-of-evidence (WoE) approaches have been used for many years with the ultimate goal to synthesize complex information for robust and transparent decision-making. The term WoE is neither a scientifically well-defined term nor an agreed formalised concept, therefore, methods and approaches may vary. A WoE approach is for example used as the basis of the endocrine disruptor (ED) assessment at the EU level, where EDs can be identified as substances of very high concern (SVHC) under the REACH regulation and classified in new hazard classes under the CLP regulation. For the identification of ED, the WoE approach consists of gathering, assembling, weighing and integrating information to determine the extent of support for ED properties, i.e. whether there is the presence of endocrine activity, adverse effect(s) and a biological plausible link between the adverse effect(s) and the endocrine activity. In the commission delegated Regulation (EU) 2023/707 of December 2022 amending the CLP Regulation (EC) No 1272/2008, several important factors are listed to be considered when assessing ED using a WoE approach: (a) positive and negative results; (b) the relevance of the study design for the assessment of adverse effects (including at the population level) and endocrine activity; (c) the adverse effects on reproduction, growth/development, and other relevant adverse effects which are likely to impact on populations; (d) the quality and consistency of the data; (e) the route of exposure, toxicokinetic and metabolism studies; (f) the concept of the limit dose (concentration), and international guidelines on maximum recommended doses (concentrations) and for assessing confounding effects of excessive toxicity; (g) where available, adequate, reliable and representative field or monitoring data or results from population models. While no chemical has yet been classified under CLP for ED properties to the environment, our work aims at assessing how the different factors mentioned above have been considered in the WoE assessment of ED for the environment under REACH. Using a database of about 20 substances, we will focus on aspects such as reliability and relevance, and how the lines of evidence for assessing the biologically plausible link between endocrine activity and adversity are structured. This work will help identify potential areas of improvement for future identification of endocrine disruptors under the CLP regulation. The views expressed in this abstract are solely those of the authors and the content of the poster presentation does not represent the views or position of the European Chemicals Agency.

1.12.P-Tu129 Developing the new CLP Guidance on Endocrine Disrupting properties: Stakeholder engagement, key considerations and discussion points

*Marta Sobanska[1], **Francesca Pellizzato**[1], Kirsi Myohanen[1], Niklas Andersson[1] and Maria Arena[2], (1)European Chemicals Agency, Finland, (2)European Food Safety Authority, Italy*

The Commission Delegated Regulation (EU) 2023/707 of December 2022 has amended the CLP Regulation (EC) No 1272/2008 by adding new hazard classes and criteria for the classification, labelling and packaging of substances and mixtures. This regulatory action was prompted by concerns that substances with endocrine disrupting (ED) properties were not covered by existing hazard classes. The classification of a substance as ED is intended to indicate that the substance may cause an adverse effect via an endocrine mode of action. The ED classification refers separately to EDs for human health and for the environment. The ED criteria require evidence on three elements: adverse effect(s), endocrine activity, and a biological plausible link between them. Ultimately, the ED environment classification will result in allocation of substances to one of two categories, Category 1: Known or presumed endocrine disruptors for the environment or Category 2: Suspected endocrine disruptors for the environment. The new hazard classes have led to a need to develop guidance on the application of the CLP criteria for these hazard classes. The European Chemicals Agency has been managing the process of harmonised classification and labelling for substances and mixtures since the adoption of CLP in 2008 and led the work on the development of the CLP guidance for the new hazard classes. All relevant ECHA stakeholders, namely Member States, the European Commission, EFSA, industry and NGOs participated in the development of this guidance document. The development of the guidance took place from early 2023 until the publication of the guidance in November 2024. This poster will present the process of development of the guidance document and will illustrate the key considerations for reaching a conclusion on the classification. In particular, it will describe the necessary steps to perform a weight-of-evidence assessment, namely the collection of all available relevant information, its evaluation and the decision logic for the classification of substances and mixtures as endocrine disrupting substances as well as the differences of Category 1 and Category 2 classification. It will also discuss the issues that were more controversial during the guidance development for the ED environment such as the approaches regarding non-EATS modalities and population relevance.

1.12.P-Tu130 Variability of Vitellogenin in Fish Studies for Endocrine Assessment

***Simone Rizzuto**[1], Aude Kienzler[1], Laura Villamar-Bouza[2] and Maria Arena[2], (1)European Food Safety Authority, Parma, Italy, (2)European Food Safety Authority, Italy*

Vitellogenin (VTG) is an in vivo mechanistic parameter relevant for the assessment of endocrine properties of chemicals impacting the Hypothalamic Pituitary - Gonadal (HPG) axis in non-target organisms. A recurrent issue with VTG observed in the fish studies submitted for ED assessment of PPPs is a high degree of variability, potentially leading to false negatives. Such variability could be intrinsically related to the fish (e.g., species, age) but also other external variables may have a significant contribution. The impact of the variables on this issue is currently unclear. Therefore, the aim of this work is to understand the impact of different internal and external variables on the variability of VTG, which will set the basis to i) fully trust the available data in the context of the ED assessment and to ii) provide useful indications to laboratories performing the experiments in order to harmonize the procedures leading to the measurement of VTG. A data extraction exercise was carried out on the fish studies submitted for the ED assessment in the context of PPP approval/renewal. VTG data were extracted from individual fish from negative and solvent controls. Physiological parameters of the fish (e.g., age, sex, breeding), external experimental factors (e.g., performing laboratory, experimental conditions, test design, solvent used), and available information for preparation and analysis of VTG were collected. Preliminary results indicate high variability in the VTG measurements. Differences were observed across different laboratories, with two laboratories indicating better consistency in the VTG measurements, potentially related to their level of experience. However, none of the investigated variables e.g., age, testing conditions, demonstrated a significant contribution to the observed variability. We hypothesize that different laboratory practices, which are generally not extensively reported in the study reports and could not be captured in our analysis, may explain the observed differences across laboratories. A relationship with the fish stocks maintained by the different laboratories prior the analysis cannot also be excluded. In conclusion, our work supports to need for harmonization in the VTG analyses across different fish studies in order to fully trust the available data in the context of the ED assessment and avoid useless sacrifice of vertebrate animals. This work is presented under the sole responsibility of the authors who are currently employed with the European Food Safety Authority (EFSA), and may not be considered as an EFSA scientific output. The positions and opinions (if any) presented in this article are those of the authors, and do not necessarily represent the views of EFSA.

1.12.P-Tu131 Amphibian Studies Investigating the Endocrine Disrupting Properties of Chemicals: A Comparison of their Statistical Power

Simone Rizzuto[1]*, Franco Maria Neri*[2]*, Valeria Ercolano*[2]*, Alessio Ippolito*[2]*, Alberto Linguadoca*[2]*, Laura Villamar-Bouza*[2] *and Maria Arena*[2]*, (1)European Food Safety Authority, Parma, Italy, (2)European Food Safety Authority, Italy*

Amphibians are the current model species for investigating the endocrine properties through the Thyroidal modality in non-mammalian species. Two standardized in vivo amphibian study designs are available to sufficiently investigate the endocrine activity and/or adversity of plant protection products (PPPs) through the T-modality. The Amphibian Metamorphosis Assay (AMA, OECD 231) is a mechanistic screening assay, where Xenopus laevis tadpoles are expose since stage Nieuwkoop & Faber (NF) 51 for 21 days. The Larval Amphibian Growth and Developmental Assay (LADGA, OECD 241) instead entails exposing X. laevis embryos at NF stage 8-10 to a minimum of 4 different concentrations of the test chemical as well as control(s) until 10 weeks after the median time to reach metamorphosis (identified as NF stage 62, hereafter time to reach NF62). The LAGDA is the recommended test to sufficiently investigate the endocrine adversity for the T-modality, since it gives primary emphasis to potential population relevant effects. A burning question in the regulatory endocrine assessment of pesticides is whether conducting a LADGA is a necessary step to address concerns identified by a positive AMA. Another one is the consideration of the non-standard fixed-stage version of the AMA, which extends until tadpoles reach stage NF62, aligning with the measurement of the time to reach NF62 carried out in the LAGDA. To further clarify some of the uncertainties around the use of LAGDA, and to help further consideration of the Extended AMA (EAMA) in regulatory context, the statistical power of the three test designs was tested for all the parameters entailed to be measured in the respective study designs (except for thyroid histopathology) by using data from real experimental studies. Our findings showed that the statistical power of the EAMA could be considered in line with the one of OECD standardized tests such as the AMA and the LAGDA which represent a step forward towards further regulatory acceptance of this test design. Our results also showed that the LAGDA is statistically more powerful. However, the magnitude of the observed difference does not justify the submission of a LAGDA to address concerns identified in an AMA, strengthening the conclusions reached by other authors that the findings from the AMA may be sufficient to conclude on the identification of endocrine disruptors through the thyroidal modality. This work is presented under the sole responsibility of the authors who are currently employed with the European Food Safety Authority (EFSA), and may not be considered as an EFSA scientific output. The positions and opinions (if any) presented in this article are those of the authors, and do not necessarily represent the views of EFSA.

1.12.P-Tu132 How to Break the Silos and Strengthen the Weight of Evidence: An Example

Maria Arena[1]*, Simone Rizzuto*[2]*, Aude Kienzler*[2] *and Laura Villamar-Bouza*[1]*, (1)European Food Safety Authority, Italy, (2)European Food Safety Authority, Parma, Italy*

In the context of the assessments for endocrine disruption for the environment, the weight of evidence is fundamental when trying to consider all the available data together and reach a robust conclusion on whether the criteria as laid down in the Regulation 605/2018 are met or not. The strength of the weight of evidence often depends on the data richness on one side, and on the knowledge and gaps therein that may

exist for specific cases on the other side.
The ED assessment of pesticide active substances is performed both for mammalian and non-mammalian species and two separate conclusions are normally drawn since one considers specific data on mammals and the other consider data on fish for Estrogen, Androgen and Steroidogenesis (EAS) modalities and amphibians for the Thyroid modality. Although the ECHA/EFSA Guidance on the hazard identification of endocrine disruptors suggest a holistic approach, this approach is rarely followed, especially for the identification of EDs in humans. In addition, although the endocrine system is known to be conserved across vertebrates, mammals and non-mammalian species may show different sensitivity and therefore a different outcome of the assessment may be possible. The experience and knowledge gained from EFSA so far have shown, however, that in the case of substances suspected to be anti-androgens a conclusion for non-mammalian species may be challenging since the available study designs with fish do not allow to clearly detect anti-androgens. The use of mammalian and non-mammalian data in a holistic manner has resulted in strengthening the weight of evidence and has allowed to reach a conclusion for the environment which would have not been possible if data on non-mammalian species had not been considered.
The poster will show one case of a holistic approach where mammalian and non-mammalian data have been used together. The example will show how data for endocrine activity and adversity for mammalian and non-mammalian species have been assessed and consider together in the Mode of action analysis to strengthen the weight of evidence and conclude the substance under assessment was an endocrine disruptor.

1.12.P-Tu133 Avoiding Unnecessary Animal Testing: Applying a Weight of Evidence Approach to Challenge Regulatory Decisions on Endocrine Disrupting Potential

Jutta Fuhlrott[1]*, Carolin Ewers*[1]*, Elke Eilebrecht*[2]*, Matthias Teigeler*[2] *and Karen Thorpe*[3]*, (1)CFCS Consult, Germany, (2)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (3)Fera Science, York, United Kingdom*

A substance evaluation under Regulation (EC) No. 1907/2006 was initiated by the European Chemicals Agency (ECHA) on a plasticizer used as phthalate substitute, under special focus due to its widespread use in plastics, including PVC applications. The substance was assessed as part of ECHA's broader investigation into PVC additives and an "Assessment of Regulatory Needs" (ARN). At the time of the evaluation, the dossier included the outcomes from a Fish Sexual Development Test (FSDT, OECD TG 234) in which no significant effects on sex ratio or vitellogenin concentration had been observed. Despite the negative outcome for endocrine disrupting (ED) properties in the FSDT, ECHA initially requested the conduct of an extended one-generation reproduction study (EOGRT) in Medaka or zebrafish (OECD TG 240), citing concerns that the substance may possess endocrine-disrupting (ED) properties. In response to the draft decision, a weight of evidence (WoE) analysis was conducted, incorporating in silico, in vitro, and in vivo data from mammalian and aquatic studies. While some in vitro assays showed weak estrogen receptor activity, at concentrations far in excess of aqueous solubility, the WoE analysis indicated that the substance does not fulfil the criteria required for a substance to be classified as an endocrine disruptor. Specifically, there was no evidence for an adverse effect in an intact animal via an endocrine mode of action. In this case, the WoE assessment, coupled with expert opinions and ethical concerns based on the 3R principles (replacement, reduction, and refinement of animal testing), led to a successful appeal with the competent authority agreeing that the fish extended one-generation reproduction toxicity study was not required.
This underscores the importance of evidence-based decision making and highlights the need for improved guidance in interpreting and using WoE assessments in regulatory decision-making for endocrine disruption.

1.12.P-Tu134 Navigating New Challenges and Divergences in Endocrine Disruptor Assessments Under European Regulations

Chloe Eastabrook*, Gareth Le Page and Charles Hazlerigg, Enviresearch, United Kingdom*

The recent release of ECHA's updated Classification, Labelling and Packaging (CLP) guidance introduces endocrine disruptor (ED) hazard classification. Although this updated CLP guidance works in conjunction with ED guidance already available for pesticides and biocides from ECHA EFSA (2018), the addition of ED hazard classification into CLP creates new challenges at every stage of the regulatory process. As CLP regulation does not require any new testing to be conducted to conclude a hazard classification for a substance, this updated guidance highlights the crucial role of Weight-of-Evidence (WoE) assessments in determining a chemical's ED properties. This is because of the CLP s dependence on available data, which when sourced from the open literature can vary significantly in reliability and quality. Consequently, there's a pressing need for robust WoE methodologies and tools, especially for data-poor chemicals that lack regulatory studies or naturally interact with the endocrine system. Challenges with this updated CLP guidance also arise where it diverges from the ECHA EFSA (2018) guidance for pesticides and biocides. While the updated CLP guidance relies heavily on the pesticide and biocide guidance in some places, there are some major divergences between their approaches and classification of ED. For example, CLP introduces a new classification option of suspected ED, in addition to known or presumed ED in the pesticide and biocide guidance, but there is no clear guidance or worked examples provided on how to differentiate these options. The strength of evidence needed to distinguish between categories 1 and 2 will likely vary chemical to chemical, as data sufficiency will impact the WoE assessment. Additionally, the updated CLP guidance supports different tools and encourages classification based on New Approach Methodologies (NAMs) and other predictive data to be included in the WoE, as additional testing is not required. In this poster presentation these approaches to assessing ED under CLP, compared to the pesticide and biocide regulations, will be explored, with a focus on the use and role of WoE within each.

1.12.P-Tu135 A Word of Caution on the Use of Poorly Documented Adverse Outcome Pathways for Endocrine Disruption Assessment

Laurent L.-M. Lagadic[1]*, Valery Forbes*[2]*, Lennart Weltje,*[3] *and James Robert Wheeler*[4]*, (1)Bayer AG, Crop Science Division, Germany, (2)Florida Atlantic University, Biological Sciences, Boca Raton FL, United States, (3)BASF SE, Agricultural Solutions - Ecotoxicology, Germany, (4)Corteva Agriscience, Netherlands*

The adverse outcome pathway (AOP) concept was developed to organize available information describing how the interaction of a chemical with a molecular target (the Molecular Initiating Event, MIE) can result in an adverse outcome (AO) in individuals and, by extension, in a population. In an AOP, the MIE is causally related to the AO through a series of key events (KEs) linked by key-event relationships (KERs). As they are based on a biologically plausible suite of KEs, AOPs can be used in weight-of-evidence approaches to identify endocrine disruptors. An AOP that is sufficiently populated with substance-specific data allows establishing plausible links between KEs leading to an individual-level AO. AOPs should, however, be used with caution for insufficiently documented substances for which only limited in vitro data or in vivo biomarker responses are available. In such cases, AOPs may be misinterpreted as there is an expectation that a MIE or any (early) KE will automatically induce the entire cascade of events always leading to the AO. In reality, many factors can interfere with KERs, so that an AO may not occur even if a MIE has been identified and effects on KEs are empirically observed. For example, a certain level of exposure at the target site is required for a MIE to generate a KE, and for a KE to be sufficiently impacted to activate the next KE. There can also be homeostatic mechanisms, feedback loops, or non-responding KE(s) that may interrupt the cascade of KEs, so that the AO does not manifest. In fish AOPs (e.g. AOPs 23, 25 and 30), the population-level AO invariably refers to a declining population trajectory. There are, however, multiple modeling and comparative studies showing that traits that are sensitive to toxicants, e.g. reproduction, can be of low impact on population growth. Also, field studies have shown no correlation between the exposure to estrogenic compounds and the density and self-sustainability of feminized fish populations. Overall, as there are multiple reasons for an AO not to occur as the result of the interaction of a chemical with a molecular target or a KE, AOPs should not be used as tools to predict individual-level AO from (sub)individual responses. To do this, detailed quantitative AOPs with established potency thresholds for each KE and AO predictions are needed. Higher-tier approaches such as population modelling, or targeted field studies would be required to extrapolate the AO from individual to population.

1.12.P-Tu136 The SETAC MAPPED Workshop: Population Modelling to Assess the Effects of Endocrine Disruption on Freshwater Fish

Udo Hommen[1]*, Charles Hazlerigg*[2]*, Oliver Korner*[3]*, Kate Mintram*[4]*, Erik B Muller*[5]*, Melissa Reed*[6]*, Benjamin Schreiber*[7]*, Joachim Sturve*[8]*, Charles Tyler*[9] *and Thomas G. Preuss*[10]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Enviresearch, United Kingdom, (3)Adama, Germany, (4)Department of Computer Science, Brunel University London, United Kingdom, (5)ibacon, Germany, (6)Health and Safety Executive, United Kingdom, (7)Austrian Agency for Health and Food Safety, Austria, (8)University of Gothenburg, Sweden, (9)University of Exeter, United Kingdom, (10)Bayer AG, Germany*

The SETAC workshop MAPPED aims to improve the applicability of Models to Assess the PoPulation relevance of effects of Endocrine Disruptors (ED) , for fish and amphibians. The poster will present the current status of the fish populations subgroup's homework after the first workshop in September 2024 with a second workshop scheduled to take place in June 2025. The working group has set out to answer two main questions: First, how can we best define focal fish species most appropriate for modelling the effects of ED substances at the population level and second, in what ways can /should these models be used? In relation to the first question, a life history and behavioural trait database will be established using information from the AddmyPet and FishBase databases and this dataset will be used to group freshwater fish according to their trait combinations, with the aim of selecting a set of optimally 5-10 focal species representing the diversity of fish at risk to ED. The selection of focal species will also consider additional characteristics such as geographical distribution, availability of developed population models or data sets for model development and testing. The modelling topic will address the questions of what data to include in the population models, the definition of environmental scenarios, the use of the normal operating range, model validation and how to assess relevance of population level effects. The findings from this work will be published in a SETAC journal.

1.12.P-Tu137 A 2024 Inventory of Test Methods Relevant to Thyroid Hormone System Disruption for Human Health and Environmental Regulatory Hazard Assessment

Lucia Vergauwen[1]*, Lola Bajard*[2]*, Sabrina Tait*[3]*, Ingrid Langezaal*[4]*, Anita Sosnowska*[5]*, Alessandra Roncaglioni*[6]*, Ellen Hessel*[7]*, Annick van den Brand*[7]*, Ann-Cathrin Haigis*[1]*, Jiri Novak*[2]*, Klara Hilscherova*[2]*, Natalia Bulawska*[5]*, Nafsika Papaioannou*[8]*, Elisavet Renieri*[8]*, Eliana Spiliotti*[9]*, Anastasia Spyropoulou*[9]*, Arno C. Gutleb*[10]*, Henrik Holbech*[11]*, Dimitra Nikolopoulou*[9]*, Miriam Jacobs*[12] *and Dries Knapen*[1]*, (1)Zebrafishlab, Veterinary Physiology and Biochemistry, University of Antwerp, Belgium, (2)RECETOX, Masaryk University, Czech Republic, (3)Center for Gender-Specific Medicine, Istituto Superiore di Sanit, Italy, (4)European Commission, Joint Research Centre, Italy, (5)University of Gdansk, Faculty of Chemistry, Poland, (6)Laboratory of Environmental Chemistry and Toxicology, Department of Environmental Health Sciences, Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Italy, (7)National Institute for Public Health and the Environment, Netherlands, (8)HERACLES Research Center on the Exposome and Health, Center for Interdisciplinary Research and Innovation, Aristotle University of Thessaloniki, Greece, (9)Laboratory of Toxicological Control of Pesticides, Scientific Directorate of Pesticides Control and Phytopharmacy, Benaki Phytopathological Institute, Greece, (10)Environmental Sustainability Assessment and Circularity Unit, Luxembourg Institute of Science and Technology, Luxembourg, (11)Department of Biology, University of Southern Denmark, Denmark, (12)UK Health Security Agency, Radiation, Chemical and Environmental Hazards, Harwell Innovation Campus, Chilton, UK, United Kingdom*

Thyroid hormone system disruption (THSD) is a growing concern in chemical hazard assessment due to its impact on human and environmental health and the limited validated methods available for assessing the THSD potential of chemicals. In particular, the general lack of validated in silico and in vitro methods for assessing THS activity is of high concern. In this work, we provide an inventory of test methods relevant to THSD. Building on the Organisation for Economic Co-operation and Development (OECD) Guidance Document 150 and recent international developments, we highlight progress in in silico and in vitro methods, as well as in vivo assays. The provided inventory categorizes available methods according to the levels of the OECD Conceptual Framework, with an assessment of the validation status of each method. At Level 1, 12 in silico models that have been statistically validated and are directly related to THSD have been identified. At Level 2, 67 in vitro methods have been listed including those assessed in key initiatives such as the European Union Network of Laboratories for the Validation of Alternative Methods (EU-NETVAL) validation study to identify potential thyroid disruptors . At Levels 3-5, THSD-sensitive endpoints are being included in existing fish-based OECD Test Guidelines to complement amphibian assays. In total, the inventory counts 108 entries comprising established methods (e.g., OECD Test Guidelines) as well as citable methods that are under further development and in some cases are ready for validation or in the initial stages of validation. This work is part of the Partnership for the Assessment of Risks from Chemicals (PARC), an EU-wide research and innovation programme funded by Horizon Europe and focused on bringing the science to the regulators, among others, in the area of endocrine disruption. To this aim it aligns work on adverse outcome pathway development for endocrine disruption with work on the development of AOP-based approaches for endocrine disruption. Several projects in PARC contributed to this work aiming to support the ongoing development of strategies for regulatory hazard assessment, such as integrated approaches to testing and assessment (IATAs), for endocrine disruptors, addressing critical gaps in the current testing landscape for THSD in both human and environmental health contexts. This project has received funding from the European Union s Horizon Europe Research and Innovation Programme under Grant Agreement No 101057014 (Partnership for the Assessment of Risks from Chemicals [PARC]) and from the University of Antwerp Research Fund (project 44602) and the Belgian Federal Public Service Public Health, Food Chain Safety and Environment, DG Environment, in the framework of the National Action Plan on Endocrine Disruptors (NAPED, DGEM/DPPC/MJE/23079). Views and opinions expressed are those of the author(s) only and do not necessarily reflect those of the European Union or the Health and Digital Executive Agency. Neither the European Union nor the granting authority can be held responsible for them.

1.12.P-Tu138 Mapping, Identification, and Assessment of Endocrine Disrupting Chemicals
***Sandrine Andres**, INERIS, France*
Environmental authorities face significant challenges in managing the risks posed by numerous endocrine-disrupting chemicals (EDCs). Advanced computational ecotoxicology tools, such as quantitative structure-activity relationships (QSARs), are essential in evaluating environmental hazards. To make toxicity data predictions practical for regulatory frameworks, it is crucial to transform this data into coherent, synthesized information through classification and grouping of substances. Under the PARC project's umbrella, we have mapped over 7,000 endocrine-disrupting (ED) substances. The database includes predicted data on substances' intrinsic physico-chemical properties, monitoring data, NORMAN prioritization indicators, ECHA's article service life, consumer uses and widespread uses, process categories, environmental release categories, and over 20 endocrine disruption-related model predictions. We conducted a comprehensive mapping to assess several key aspects. These included evaluating the coherence among different model predictions as well as examining the relationships between various modes of action and the substances. We explored endocrine-disrupting (ED) activities and quantified the number of substances associated with each ED route. This analysis was performed to emphasize the importance of in vitro data within regulatory frameworks, given that regulations predominantly consider pNEC values for daphnia, fish, and algae. Mapping results will serve as a baseline reference for understanding ED activity across various chemicals. This dataset not only enhances our ability to identify and categorize substances based on their potential risks but also provides a valuable baseline for future research and regulatory efforts.

1.12.P-Tu139 Weight of Evidence Endocrine Disruptor Assessments for Hydrocarbon UVCBs
***Rebecca Jayne Brown**[1], Owen Green[1], Kate Roylance[1], Rhiannon Smith[2], Christopher Prosser[3], David MV Saunders[4], Sandrine Sourisseau[5], Sergio A Villalobos[6], Kat Colvin[7], Neslihan Aygun Kocabas[8], George Hinkal[9], Nicholas Synhaeve[9], Delina Lyon[10] and Leslie J Saunders[9], (1)wca, United Kingdom, (2)Wca, United Kingdom, (3)ExxonMobil Biomedical Sciences, United States, (4)Shell Global Solutions, Netherlands, (5)TotalEnergies, France, (6)BP, United States, (7)BP, United Kingdom, (8)TotalEnergies SDR, TotalEnergies, Seneffe, Belgium, (9)Concawe, Belgium, (10)CONCAWE, Belgium*
New hazard classes are being introduced under the Classification, Labelling, and Packaging (CLP) regulations to address endocrine disruption (ED). ED assessments are complex and data-intensive for mono-constituent substances with standardised datasets but the current CLP guidance does not fully consider the challenges for assessing more complex UVCBs (substances of unknown or variable composition, complex reaction products, or biological materials). Currently, classification assessments for ED will largely focus on individual constituents, which implies that there is sufficient data on all components to adequately characterise the ED hazard. Hydrocarbon UVCBs can encompass thousands of different constituents where some of them can be unknown and uncharacterised. A pragmatic approach that considers both the available data for the UVCB whole substance and for the constituents is therefore needed to assess the ED potential of UVCBs. Here, we applied a tailored approach for conducting an ED assessment for hydrocarbon UVCBs. To limit the number of constituents in this first assessment, hydrocarbon constituents at potential concentrations of ?1% in at least one petroleum substance were selected from a list of hydrocarbons with potential endocrine activity and/or reproductive toxicity. Constituent data were then screened for reliability (e.g. in vitro data assessed as unreliable if constituent properties [e.g. volatility, solubility] are not considered). Following this exercise, a stepwise evaluation was followed: i. Data gathering: Collate information from regulatory sources, open databases, and abstract screening of peer-reviewed articles; ii. Initial data summary: Summarise endocrine activity data and in vivo data from studies (with mammals and non-target vertebrates) identified in regulatory sources or ED databases; iii. Vulnerability assessment: Rank constituents based on ED concern, proposing an initial minimum threshold for ED classification; iv. Weight-of-evidence assessment: Begin with the highest-ranked constituents, phasing the analysis so that when a definitive conclusion can be drawn from a limited dataset (e.g. EATS [estrogen, androgen, thyroid and steroidogenesis]-mediated effects), efforts can be focused to other constituents. Our approach aims to enable initial ED conclusions for hydrocarbon UVCBs and potentially support the development of evidence-based read-across strategies for hydrocarbon constituents.

1.12.P-Tu140 Endocrine Disruption Assessment of UVCBs (Substances of Unknown or Variable Composition, Complex Reaction Products or Biological Materials): A Case Study Using Grease Thickeners
*Rhiannon Smith[1], **Rebecca Jayne Brown**[2], Maria Blanco-Rubio[3], David MV Saunders[3], Olivia Lin Tran[2], Lucy Kennelly[4], Kate Roylance[2] and Owen Green[2], (1)wca environment, United Kingdom, (2)wca Environment, United Kingdom, (3)Shell Global Solutions, Netherlands, (4)wca environment, United*

Kingdom
New hazard classes for endocrine disruption (ED) have been introduced under Classification and Labelling (CLP) regulations. Mixture rules are expected to be applied to UVCBs (substances of unknown or variable composition, complex reaction products or biological materials), so that ED classification is based on the most conservative outcome for the whole substance and relevant constituents present above a concentration limit (e.g. 0.1%). An approach for ED assessment of UVCBs has been developed for petroleum substances: gather available data (on whole substance, substance composition and individual constituents), consider whether classification is possible based on existing classifications for individual constituents or whole substance data, and finally evaluate data for individual constituents. This general ED assessment approach for UVCBs has been adapted for use in the initial prioritisation of grease thickeners. Most grease thickeners are either registered at lower tonnage levels, or using read across from similar substances, so ED assessment based on whole substance data is not possible as no or limited relevant whole substance data are available for human health or the environment. Therefore, the prioritisation for ED assessments has focussed on relevant constituents. Compounds relevant for the ED assessment were identified, including the substances themselves and the constituents and impurities therein, immediate transformation products and read across source substances. This expanded the initial list of 50 substances in the grease thickener portfolio to 191 compounds requiring ED evaluation. Substance characterisation is ongoing for some complex substances, which could expand the list further. No constituents have yet been concluded for ED and most have limited relevant data. Grease thickener substances consist primarily of metal salts of carboxylic acids, with differences in chain lengths, functional groups and metal cations, as well as substances with more complex structures. Therefore, the reliability assessment and interpretation of data is likely to be complex, especially as some substances are poorly soluble and metal salts are outside the applicability domain of many in silico models. This case study demonstrates some of the challenges associated with ED assessments for these substances and offers perspectives and strategies for dealing with ED assessments of complex substances. The authors would like to thank the European REACH Grease Thickeners Consortium (ERGTC) for sharing this work.

1.12.P-Tu141 Validation of the tFET: Enhancing the OECD 236 Fish Embryo Toxicity Test with Novel Endpoints to Assess Thyroidal Hormone System Disruption by Chemicals
*Benedikt Luckner[1], Patricia Marini[2], Laura Wanner[1] and **Stefan Josef Hoeger**[3], (1)Innovative Environmental Services, Switzerland, (2)Ecotoxicology, Innovative Environmental Services., Switzerland, (3)Innovative Environmental Services, Witterswil, Switzerland*
Endocrine-disrupting chemicals pose significant risks to human and environmental health, as even low concentrations can severely imbalance physiological homeostasis in organisms, affecting both individuals and populations. Current ecotoxicological assessments, such as the OECD 231 Amphibian Metamorphosis Assay or OECD 248 Xenopus Eleutheroembryonic Thyroid Assay (XETA), evaluate thyroid-disruptive properties but require testing on protected animal life stages, raising ethical concerns. An implementation of further endpoints surrogate for thyroidal disruption into existing TGs such as the OECD 236 Fish Embryo Acute Toxicity Test (FET), designed as an acute toxicity test in fish but limited to non-protected life stages bares the potential to reduce the need for multiple tests and hence to spare resources and animals in line with the 3Rs principle and sustainability. In a collaborative project of academic and industry partners (ERGO Project), an expanded thyroid FET (tFET), with novel endpoints that assess disruptions of the hypothalamic-pituitary-thyroid axis has been designed and shall be validated for regulatory use in ecotoxicological hazard assessment. Participating in the validation process of this modified OECD236 guideline, we will validate the test design and selected surrogate endpoints, e.g. the posterior swim-bladder inflation, changes in the eye histopathology and measuring of thyroidal-related hormone levels in exposed organisms. To minimize systemic toxicity interference, chemical concentrations will be capped at the maximum tolerated dose, defined by the 96-hour LC10 following OECD 236 guidelines. Initial progress includes the identification of potentially suitable substances, pretesting, and determination of appropriate concentration ranges based on 96-hour LC10 values.

1.12.P-Tu142 The Zebrafish Extended One Generation Reproduction Test (ZEOGRT) – Experiences and Current Results from the Validation Exercise
***Matthias Teigeler**[1], Elke Eilebrecht[1], Kornelija Franzen[2], Becky Cahill[3], Richard John Maunder[3], Takahiro Yamagishi[4], Haruna Watanabe[4], Hiroshi Yamamoto[4], Henrik Holbech[5], Dirk Schaudien[6], Gerd Maack[7] and Susanne Walter-Rohde[7], (1)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (3)Scymaris, Brixham Laboratory, United Kingdom, (4)National Institute for Environmental Studies, Ecotoxicity Research Section, Japan, (5)University of Southern Denmark, Denmark, (6)Fraunhofer Institute for Toxicology and Experimental Medicine ITEM, Germany, (7)Umweltbundesamt*

(German Environment Agency), Germany
For the identification of endocrine disrupting properties of chemicals, the WHO/IPCS definition requires a causal link between an endocrine mechanism of action and an adverse effect with population relevance. Within the OECD Conceptual Framework for endocrine testing and assessment, multi-generational tests are assigned to provide data over more extensive parts of the life-cycle of the organisms. In the aquatic environment, fish populations are considered as main targets of endocrine acting compounds. The adopted OECD guideline 240, i.e. the Medaka Extended One Generation Reproduction Test (MEOGRT), was designed and validated for a single test species only. On the initiative from Germany, a similar test approach with zebrafish (Danio rerio) as a further species was developed. Both protocols include the exposure of a parental generation (adult fish), a full Filial 1 (F1) generation (from egg to adult) and a Filial 2 (F2) generation (until hatch of embryos). The development of the Zebrafish EOGRT protocol was placed on the OECD workplan in 2016. The initial phase of the validation process, started in 2018, included four ZEOGRT studies to confirm the applicability of the study protocol. The test substances applied were tamoxifen-citrate (TMX), prochloraz (PRO), dienogest and dexamethasone. The effect results obtained for TMX and PRO were in good compliance with available literature and it was possible to build a bridge to the validation studies conducted for the MEOGRT. The results and evaluations were summarised in a validation report for Phase I and presented to OECD. In the second part of the validation, started in 2022, international cooperation partners were identified to apply the protocol to their labs and to proove the reproducibilty of the test design. In total, one additional study with TMX and two more studies with PRO were successfully conducted. These data will be used to allow an evaluation of inter-lab variability to be presented in a second validation report. To extend the data set, available control data from industry study will be used. The presentation gives an overview on the final results obtained and shows a comparison of effect concentrations derived from the different lab studies. The available results confirm the applicability of the ZEOGRT test protocol. The data obtained are valuable to identify sensitive endpoints and gain mechanistic information used for an endocrine assessment.

1.12.P-Tu143 An Extended Amphibian Metamorphosis Assay (EAMA) with the Reference Compound Propylthiouracil (PTU)

Joseph Marini[1]*, Brianna Burley*[1] *and Jeffrey C. Wolf*[2]*, (1)Smithers Environmental Risk Sciences, United States, (2)Experimental Pathology Laboratories, United States*
The Amphibian Metamorphosis Assay (AMA) is a key in vivo screening assay intended to identify substances which may interfere with the normal function of the hypothalamic-pituitary-thyroid (HPT) axis. The Extended Amphibian Metamorphosis Assay (EAMA) is a recently proposed, modified design that was created to better evaluate thyroid-related endpoints using elements from the Larval Amphibian Growth and Development Assay (LAGDA); specifically, the development endpoint as a time-to-stage evaluation instead of stage determination at study day 21. There are several advantages to this change in design vs. the AMA. For instance, the robustness of the statistical and histological analyses is improved and extending to NF stage 62 encompasses exposure during metamorphic climax, when thyroid hormone plasma concentrations dramatically increase. While regulatory studies have been performed with this extended design, no studies with reference chemicals have been conducted. Therefore the goal of this study was to evaluate EAMA endpoints after exposure to a reference toxicant and compare responses of thyroid-mediated endpoints vs. the fixed-time design. To this end, two extended AMA studies were conducted with propylthiouracil (PTU). Study #1 utilized the concentration range from the OECD test guideline 231 validation exercise: 2.5, 5.0, 10, and 20 mg/L and a dilution water control. A follow-up study employed a 40 mg/L treatment group and a dilution water control. Statistically significant delays in development were observed between the control and the 20 mg/L treatment group at test termination. Metamorphic developmental arrest was observed at the 40 mg/L treatment group, as tadpoles did not develop past NF stage 56. In addition, statistically significant increases in wet body weight, snout-vent length (SVL), and hind limb length normalized by SVL were observed in 40 mg/L-exposed tadpoles compared to the control. Findings in the thyroid glands at 10, 20, and 40 mg/L included concentration-dependent increases in the prevalence and severity of follicular cell hypertrophy and follicular cell hyperplasia as well as decreased colloid. Thyroid hypertrophy was observed at 20 and 40 mg/L. The results were in line with the expected outcome based on the mode of action of PTU as a thyroid hormone synthesis inhibitor and provide data for validation of the EAMA as a reduction and refinement alternative method to the AMA or the LAGDA.

1.12.P-Tu144 Advancing In Vitro Assessment of Iodide Uptake Inhibition: Integrating a Novel Biotransformation Pretreatment Step

Jiri Novak[1]*, Puja Kumari*[1]*, Sebastian Lungu-Mitea*[2] *and* ***Klara Hilscherova***[1]*, (1)RECETOX, Masaryk University, Czech Republic, (2)RECETOX, Masaryk University; Linnaeus University, Department of*

Biology and Environmental Science; Uppsala University, Department of Pharmaceutical Biosciences, Toxicology and Drug Safety, Sweden
Thyroid Hormones (TH) are essential for vertebrate development, growth, and metabolism. The limited knowledge on the TH-disrupting potential of anthropogenic chemicals emphasizes the need for improved methods to assess their impacts on TH homeostasis. Inhibition of the Sodium Iodide Symporter (NIS), a key step in TH production, has been identified as a crucial molecular initiating event affecting the TH system and related adverse effects in various species. The role of NIS has also been implicated in thyroid and other cancers. NIS transported I? radioisotopes are used to diagnose, treat, and monitor thyroid pathologies and NIS can also be used as a diagnostic transgene. Thus, compounds interfering with NIS could affect not only cancer development but also the sensitivity of its diagnosis and its treatment efficiency. We have developed in vitro bioassays to evaluate the effects of chemicals on iodide uptake mediated by NIS, using two stably transfected human cell lines overexpressing human NIS. Their performance was compared against FRTL-5, a rat thyroid cell model with endogenous NIS expression. We have characterized the dose-response relationship for 23 model compounds using a non-radioactive colorimetric Sandell-Kolthoff reaction to detect the uptaken iodide levels along with detailed cytotoxicity assessment. The observed effects were also compared to those detected by other in vitro models in the literature, mostly using radioactivity-based assay. To enhance the physiological relevance, we incorporated an external biotransformation system (BTS), optimized for live-cell use without inducing cytotoxicity or assay interference. The findings show that in vitro metabolic capacities could mitigate the inhibitory effects of certain compounds on iodide uptake and thus metabolic modification of these compounds. Moreover, our experimental results were corroborated by in silico prediction and published in vivo data, at least for the compounds that showed no bioavailability issues. However, there were some limitations for hydrophobic chemicals. To reflect this, we currently suggest implementing the biotransformation-augmented NIS assay only for compounds with a log Kow up to five. Noteworthy, we recommend that potential future users of the BTS-augmented NIS assay always include a set of relevant controls, as these are essential for accurate data interpretation, detecting bioavailability-related effects, and understanding the assay's potential applicability range.

1.12.P-Tu145 Assessment of the In Vitro Test Guideline OECD 455 for Detecting Estrogenic Activity using Animal-Free Conditions and Animal-Free Metabolization Systems

Denise Horte, *Inska Reichstein, Carolin Anna Cecile Bertold, Christian Forberg, Sarah Wohlmann and Henner Hollert, Goethe-Universita?t Frankfurt, Faculty of Biological Sciences, Department Evolutionary Ecology and Environmental Toxicology, Germany*
Regarding cell-based in vitro assays, controversial animal-derived components like the fetal bovine serum (FBS) collected from non-anesthetized calf fetuses and the phenobarbital/ß naphtoflavone induced liver homogenate fraction (S9) collected from rats are frequently used. These components, used for promoting cell growth and for simulating biotransformation processes respectively, are known for interacting with test substances, being potentially contaminated by microorganisms and causing increased variability within the assays due to their undefined composition. To decrease animal cruelty and provide stable comparable assay results efficient alternatives such as chemically defined matrices should be considered. Contributing to this, the aim of this study is to develop the in vitro assay ER? CALUX® for detecting estrogenic activity towards animal-free conditions and the incorporation of animal-free metabolization systems. This will be established by evaluating the lowest amount of FBS needed for a valid ER? CALUX® test result applying the manufacturers validity criteria established for the standard, FBS containing procedure. After evaluating the outcome of this approach, the sensitivity of the optimized assay will be tested by using model substances and groundwater samples from the project gwTriade , a project aiming to establish an integrated assessment of groundwater systems. Therefore, different scenarios will be compared regarding their performance and comparability based on the in vitro test guideline OECD 455: (1) The currently standardized FBS-containing medium (2) The chemically defined medium without FBS and (3) The chemically defined medium with the optimized amount of FBS from the improvement approach. Additionally, those approaches will be tested with the supplementation of animal-derived S9 and biotechnological, animal-free S9 (ewoS9). At present, the addition of 0.1 % FBS to chemically defined medium for conducting a valid in vitro ER? CALUX® seems promising. If evaluated as reproducible in further experiments, this would result in the use of 98 % less FBS per assay plate contributing to a successful reduction in animal components following the 3R s principle of replacing, reducing and refining the use of animals in scientific research. Consequently, this could also contribute in achieving less variability within the assays, providing better reproducible and comparable results on estrogenic activity in environmental samples.

1.12.P-Tu146 Zebrafish Hepatic 3D Spheroid Models for High-Throughput Screening of Endocrine Disruptors Promoting Steatotic Liver Disease

***Maria T. Hultman*[1]**, *Prem Chand[2], Maria Christou[1], Julie Massart[3], Jorke Kamstra[4], Menghang Xia[5], Tuulia Hyotylainen[6], Matej Oresic[7] and You Song[1], (1)Norwegian Institute for Water Research, Norway, (2)Ecotoxicology and risk assessment, Norwegian Institute for Water Research, Norway, (3)Institute National De La Sante Et De La Recherche Medicale, France, (4)Utrecht University, Netherlands, (5)National Center for Advancing Translational Sciences, United States, (6)School of Science and Technology, orebro University, orebro, Sweden, (7)School of Medical Sciences, Faculty of Medicine and Health, orebro University; Turku Bioscience Centre, University of Turku and aabo Akademi University; Department of Life Technologies, University of Turku, Sweden*

Metabolic dysfunction-associated steatotic liver disease (MASLD) is one of the most common liver disorder, affecting approximately a quarter of the world s population. Growing evidence indicates that exposure to endocrine-disrupting chemicals (EDCs) may contribute to the initiation and/or progression of MASLD, either directly or by amplifying the effects of high-fat diets, genetic predispositions, and lifestyle factors. For rapid screening and identification of relevant EDCs and mixtures promoting MASLD, a three-dimensional (3D) in vitro spheroid system derived from the zebrafish (Danio rerio) liver cell line (ZF-L) was optimized for high-throughput (HT) screening (384-well plate format) and chronic testing (up to 14 days of exposure). The spheroids showed good sphericity and viability in a 384-well plate after 16 days, suggesting the suitability of this model for HT chronic toxicity testing. A MASLD-relevant test battery is currently under development, including assays for measuring cytotoxicity (LDH and ATP), lipid storage and metabolism (Nile red and TAG), oxidative stress (ROS) and cell morphology. Three model compounds known to affect lipid metabolism, dichlorodiphenyldichloroethane (ppDDE), perfluorooctanoic acid (PFOA) and triphenyl phosphate (TPP), will be used to validate the test system. High-throughput screening will then be conducted to identify and prioritize relevant EDCs from a large list of the MASLD cohort studies. This novel in vitro high-throughput test system as a new approach methodology (NAM) is foreseen to significantly reduce testing needs in future EDC-MASLD research.

1.12.P-Tu148 Morphological Changes in Brain Development of Zebrafish Embryos After Exposure to Thyroid Hormone System Disrupting Chemicals

***Elise Pesce*[1]**, *Ellen Hessel[2], Nathalie Hendriks[1], Peter Cenijn[1] and Lisa Annie Baumann[1], (1)Vrije Universiteit Amsterdam, Amsterdam Institute for Life & Environment, Section Environmental Health & Toxicology, Netherlands, (2)Centre for Health Protection, National Institute for Public Health and the Environment, Netherlands*

Thyroid Hormone System Disrupting Chemicals (THSDCs) are known to affect the development of the nervous system in vertebrates by interfering with thyroid hormone system (THS) during early-life development. Indeed, THs play a crucial role in brain development, including the differentiation of various brain cell types, such as oligodendrocytes. As a result, assessing THS disruption effects on brain development is a significant concern for environmental and human health safety. We are currently investigating the effects of THS disruption using two different approaches, both involving zebrafish embryos. Fish embryo models are widely used in (eco)toxicological research to investigate the impact of chemicals on whole organisms, as they represent a good alternative to mammal and adult fish testing according to 3R. Our first approach involves a triple-transgenic zebrafish line, which allows for the quantification of three different brain cell types and thereby the detection of developmental neurotoxicity (DNT). In this line, neurons, astrocytes and oligodendrocytes express three distinct fluorescent proteins, driven by the regulatory sequences of enolase 2, glial ?brillary acidic protein, and myelin basic protein, respectively. Previous studies have shown alterations in oligodendrocytes differentiation following exposure to T4 and TH synthesis inhibitors in zebrafish embryos. Consequently, we are investigating exposure to different THS disruption mechanisms of action, that likely result in structural alterations of oligodendrocytes, and potentially affect neurons and astrocytes as well. Secondly, histopathology analysis of specific brain structures is conducted in embryos exposed to THSDCs. Preliminary data from the ERGO project show that THSDCs impair brain development of zebrafish exposed until the juvenile stage. We expect effects to be visible already during embryogenesis and are therefore performing histopathological analyses of embryos exposed to the same set of THSDCs. Distinct histopathology effects may facilitate the identification and interpretation of DNT induced by THSDCs. These new investigative approaches are combined with specific TH-related endpoints as TH levels and thyroid follicle morphology to assess sensitivity and specificity of those novel endpoints. In summary, we believe that new endpoints focusing on DNT could be used for THS disruption assessment.

1.12.P-Tu149 Comparison of Thyroid Disruption Potentials of Urinary Plasticizer Exposure Profiles among Children of Four Asian Countries using Larval Zebrafish

***Yujin Park**, Jung Joeun, Yunchul Ihn, Ah-Reum Jo and Kyungho Choi, Seoul National University, Korea, Republic of*
Due to different regulatory environments, exposure profiles of major plasticizers among children differ by country. However, the toxicological implications of such variation are elusive because of the complexity of toxicity interactions among the plasticizers. In this study, based on the urinary concentrations of major plasticizer metabolites in the children of South Korea (n=87), Thailand (n=110), Indonesia (n=92), and Bangladesh (n=100), a 7-day embryo-larval zebrafish exposure experiment was designed for thyroid hormone disruption-related endpoints. For this purpose, daily intakes (DI, ?g/kg bw/day) of parent compounds (DMP, DEP, DiBP, DnBP, DEHP, DiNP, DEHTP) were estimated with creatinine adjustment. Then, this information was used to estimate their corresponding concentration in the fish plasma, and their concentration in the fish exposure media. The calculating method is as follows. Cp is the blood plasma concentration resulting from a known exposure dose (E). Cp (mol/L)=E[mol/kg bw]×(t_1/2)/0.693×1/(Vd[L/kg bw]) Compared to the SC group (DMSO 0.01%), zebrafish exposed to chemical mixtures representing Bangladesh exposure showed significant reductions in thyroid hormone regulatory genes, synthesis-related genes, and metabolism-related genes. Similarly, the fish exposed to the Indonesian mixture demonstrated a significant decrease in thyroid hormone regulatory gene expression. The mixtures from Korea and Thailand did not exhibit significant alterations. The current observations suggest that the higher quantities of detected plasticizers and composition of traditional plasticizers in Bangladesh and Indonesian mixtures contribute to significant thyroid disruption compared to those of South Korea and Thailand. Further research is warranted to identify the chemicals that explain observed outcomes, providing insights into risk mitigation and regulatory strategies for vulnerable populations. This work was supported by the Research Grant from Seoul National University(900-20240102) This work was supported by the Ministry of Education of the Republic of Korea and the National Research Foundation of Korea (BK21 FOUR 5199990214126)

1.12.P-Tu150 New Data To Determine The Thyroid Mode Of Action Covered By The Xenopus Eleutheroembryonic Thyroid Assay

*David Du Pasquier[1], Barbara ROBIN DUCHESNE[1], Laurent L.-M. Lagadic[2] and **Gregory F. Lemkine**[1], (1)Laboratoire Watchfrog S.A., France, (2)Bayer AG, Crop Science Division, Germany*
In June 2019, the OECD validated the Xenopus Eleutheroembryonic Thyroid Assay (XETA) in the test guideline program in order to support the identification of thyroid active chemicals. Since its validation, the XETA is used for the evaluation of the thyroid modality for biocides and pesticides. To date, we could estimate that more than 30 chemicals were assesed for the thyroid modality using a weight of evidence methodologies including data from a XETA. Following the validation exercice, several studies have been conducted to expand the dataset of reference chemicals. To enhance the dataset of chemicals tested in both amphibian assays, 17 additional chemicals with available Amhibian Metamorphosis Assays were evaluated. A separate study investigated 3 plasmatic transport inhibitors to generate data on this mode of action, which had previously been insufficiently explored. As part of the EU Horizon 2020 program under the ATHENA project, 8 thyroid-active chemicals identified through in vitro screenings were tested. Furthermore, a new study was conducted with 12 chemicals selected based on their specific MoA, further enriching the database for these particular mechanisms. When added to the number of chemicals included in the validation, 56 reference chemicals have now been tested in the XETA. Overall, the various studies demonstrate that the XETA effectively detects plasmatic transport inhibitors as well as thyroid receptor agonists and antagonists. Deiodinase inhibitors and transmembrane transport inhibitors were also identified using the XETA; however, these MoAs were represented by only a limited number of substances, necessitating further confirmation with additional test chemicals. While TPO inhibitors showed positive results in the XETA, for some of them their activity did not align with the expected MoA, further investigations are in progress to explore the physiological mechanisms underlying these results Additionally, all tested NIS inhibitors were inactive in the XETA, indicating that this particular MoA is not captured. The XETA is an ethical and novel short-term screening assay that could efficiently be use in a weight of evidence approach for the thyroid modality. Knowing that substances that inhibit NIS are not detected and that TPO inhibitors are not adequately identified, the result of the XETA could be combined with in vitro TPO and NIS assays (in the process of OECD validation) for comprehensive coverage of all thyroid mechanisms of action. The authors thank Croplife Europe and the EU Horizon 2020 program, ATHENA project, grant number 825161 for financial support.

1.12.P-Tu151 TG252 the Rapid Estrogen ACTivity In Vivo (REACTIV) Assay – Results from the OECD Validation and Next Steps

***Andrew Tindall** and Gregory F. Lemkine, Laboratoire Watchfrog S.A., France*
Huge efforts are currently underway in Europe, Asia and North America to identify chemicals that

interfere with estrogenic signalling. With increasing pressure in Europe to reduce animal testing and test facilities which are saturated with requests for traditional fish tests, both chemical manufacturers and evaluating authorities are beginning to look towards new approach methodologies (NAMs). Eleutheroembryos, aquatic vertebrates, not compliant with the European definition of a laboratory animal, provide physiologically relevant whole animal data while allowing for rapid testing of large numbers of chemicals at a greatly reduced cost. The Rapid Estrogen ACTivity In Vivo (REACTIV) assay is a 24 h assay using transgenic medaka fish eleutheroembryos harbouring the choriogenin h promoter driving expression of gfp. Choriogenin plays an essential structural role in egg formation and responds directly to estrogen axis signalling, like the highly related vitellogenin biomarker. The OECD interlaboratory validation exercise showed highly reproducible results. The transferability of the assay was well demonstrated. All of the inert chemicals which were tested were correctly identified as inert, indicating that the REACTIV assay is highly selective. Data generated for 12 chemicals which act on the estrogen axis via differing modes of action clearly indicated the ability of the REACTIV assay to identify chemicals acting on estrogen axis signalling, either at the receptor level or on downstream steroidogenesis. Only the 5?-reductase inhibitor, dutasteride, gave equivocal results. Following the successful interlaboratory validation exercise the REACTIV assay was ratified by the OECD as a test guideline (TG 252). The REACTIV assay is a rapid 24 h assay that allows the quantification of estrogen axis activity. The eleutheroembryonic life stages on which the assay is based are in line with the three R s principle of animal replacement. Although the results for 5?-reductase inhibitor, dutasteride, gave equivocal results, this mode of action is well covered by the androgen/ anti-androgen sensitive RADAR assay (TG 251). Therefore, combining the REACTIV and RADAR assays with existing data from mammalian tests as well as in vitro and/or in silico could allow the evaluation of estrogen, androgen and steroidogenesis activity of chemicals without the use of laboratory animals, we suggest how they could be integrated into regulatory decision trees and IATAs to achieve this aim.

1.12.P-Tu152 Identification of Chemical Substances with Ecdysteroid Activity in *Daphnia magna* using in Silico Analysis, in Vitro and in Vivo Assays

***Haruna Watanabe**[1], Yusuke Oda[1], Ryoko Abe[1] and Hiroshi Yamamoto[2], (1)National Institute for Environmental Studies, Japan, (2)Health and Environmental Risk Division, National Institute for Environmental Studies, Japan*

Ecdysone is an essential hormone regulating development and molting in arthropods including Daphnia magna. While several ecdysone receptor (EcR) agonists used as insecticides (e.g. tebufenozide) are already known, it is possible that other chemical substances also have ecdysteroid activity. The Extended Tasks on Endocrine Disruption 2022 (EXTEND2022) implemented by the Ministry of Environment, Japan, have developed two-tiered framework for testing and assessment where candidate test chemicals are selected based on literature review and subjected to Tier 1 in vitro reporter gene assay and short-term in vivo screening assay to evaluate endocrine disrupting effects. To efficiently detect ecdysoteroid activity of chemicals, we selected candidate chemicals based on the result of in silico analysis from the literature (Mellor et al., 2011) and conducted in vitro reporter gene assay and short-term in vivo assay using Daphnia magna. Antibiotic chloramphenicol and anti-inflammatory drug aminopyrine were selected from the in silico results because they have diacylhydrazine and methylene? ??lactam motif, respectively, which are essential structure for receptor binding site, however, no EcR transactivation was shown in the reporter gene assay. The short-term in vivo assay demonstrated the significant decrease in the number of molts from offspring to mature adult (8 days) exposed to these chemicals as well as EcR agonist. To distinguish the effect from general toxicity and disruption in ecdysteroid signaling pathway, chitin degrading enzyme chitobiase released into test solution was measured as biomarker specific to molting inhibition. Although EcR agonist such as 20-hydroxyecdysone, tebufenozide, and ponasterone A demonstrated a significant decrease in chitobiase activity compared to control and a positive correlation between chitobiase activity and the number of molts, the candidate chemicals showed no correlation. Therefore, another in silico analysis approach such as molecular docking simulation is needed for prioritizing candidate chemicals. Moreover, by integrated assessment of the data from in silico analysis, in vitro and in vivo assays with biomarkers could accurately identify chemicals with ecdysone activity.

1.12.P-Tu153 Investigation into the Mechanism(s) of Chronic Copper Effects on Zebrafish Reproduction

*Douglas J. Fort[1], Jeffrey C. Wolf[2], Stijn Baken[3], **Yamini Gopalapillai**[4] and Kevin V Brix[5], (1)Fort Environmental Laboratories, United States, (2)Experimental Pathology Laboratories, United States, (3)International Copper Association, Belgium, (4)International Copper Association, Canada, (5)EcoTox, United States*

Chronic exposure to copper (Cu) has been demonstrated to reduce fecundity in several species of fish, but the mechanism(s) causing this reduction are not well understood. We hypothesized that reduced fecundity upon Cu exposure could be caused by either an endocrine mediated process or direct oxidative damage to either the gonads and/or liver. To test this hypothesis, we exposed reproductively active zebrafish (Danio rerio) to Cu concentrations of 0, 6.7, 20, and 60 ?g L-1 for 21 days. We assessed both endocrine and non-endocrine factors, measuring fecundity, gonado- and hepato-somatic index (GSI and HSI), plasma vitellogenin, and two indicators of oxidative stress catalase (CAT) and glutathione peroxidase (GSH-Px) concentration on days 2, 10, and 21 of the exposure. Additionally, we undertook a histopathological evaluation of fish gonads and livers at the end of the exposure. Copper significantly affected fecundity at both 20 and 60 ?g L-1 Cu with reductions in both spawning frequency and number of eggs per spawning event observed. Corresponding to these effects, both CAT and GSH-Px concentrations increased in a dose- and time-dependent manner in both the gonads and liver. Concentrations peaked on day 10 and then declined by day 21, suggesting antioxidant concentrations could not be sustained throughout the entire exposure. Plasma vitellogenin concentrations, GSI, and HSI were not affected by Cu exposure at any concentration. Histological analysis revealed increased hepatic bile duct hyperplasia in male fish. In females, there was a reduction in post-ovulatory follicles in the 20 and 60 ?g L-1 Cu treatments, an increased prevalence of oocyte atresia in the 20 but not 60 ?g L-1 treatment, but no monotonic effect on ovarian developmental stage. Overall, we conclude that folliculogenesis may have been disrupted in the higher Cu treatments resulting in reduced fecundity. Importantly, the lack of changes in GSI and HSI combined with no change in plasma vitellogenin concentrations suggests that the reduction in fecundity is not due to endocrine-mediated effects. The significant increase in CAT and GSH-Px concentrations in the gonads indicates that these tissues were under considerable oxidative stress, which may have contributed to the reduced fecundity. However, histopathology results were somewhat ambiguous and did not provide consistent support for this mechanism leaving uncertainty on the exact adverse outcome pathway that leads to reduced fecundity.

1.12.P-Tu154 Developmental and Reproductive Toxicity of Bisphenol AP in the Great Pond Snail *Lymnaea stagnalis*

Gaetan Yannick Tucoo*, Elvis Genbo Xu and Henrik Holbech, University of Southern Denmark, Department of Biology, Denmark*

As a result of increasing regulations on bisphenol A (BPA), classified as endocrine-disrupting chemical (EDC), BPA alternatives are entering the market. Concerns are rising as contaminations of the environment have already been reported. In this study, we want to use new approache methodologies (NAMs) to assess the risk of BPA alternatives. We investigated the effects of Bisphenol AP (BPAP) on both the embryonic development and the reproduction of the great pond snail L. stagnalis, using endpoints discribed in the litterature, as well as the OECD test guideline 243. Briefly, embryos were exposed 18 days to 0 (control), 31.25, 62.5, 125, 250, 500, and 1,000 µg/L of BPAP. For the reproduction test, adults snails were exposed in semi static conditions to five BPAP concentrations, from 31.25 to 500 µg/L, with a 2 factor. The BPAP concentration was checked in the exposure media for both tests using a UHPLC-3Q-MS/MS. Apart from the embryonic rotation, all endpoints were significantly affected for at least two exposure groups in both test. For the embryos, the heartbeat was significantly lower than the controls for all concentration groups, and their size at day 9 of the embryos exposed to 500 and 1,000 µg BPAP/L was respectively 26.8 and 65.6 % smaller than the controls. At the end of the test, only 50 % of the emrbyos exposed to BPAP at 500 µg/L had hatched, and 100 % of those exposed to 1,000 µg/L had died. For the reproduction test, the lowest BPAP concentration (31.25 µg/L) was enough to reduce the number of laid egg masses by 59.43 % compared to the controls. We determined a BPAP 28d-EC50 for the reproduction of L. stagnalis at 38.7 µg/L, and an 28d-LC50 at 550 µg/L. The BPAP EC50 and LC50 are lower than these of BPA and BPE for other invertebrate species. Our results demonstrate a high sentivity of L. stagnalis to BPAP, showing the relevance of this organism in toxicological studies for chemical risk assessment. We also present concerning data about the safety of the use of BPAP as an alternative to BPA.

1.12.P-Tu155 Chronic Effects of Bisphenol A and Three Structural Analogues on Freshwater Snails and Amphipods

Natalie Reininger *and Jorg Oehlmann, Goethe University Frankfurt, Institute for Ecology, Evolution and Diversity, Germany*

Due to its diverse endocrine disrupting potential, the EU has identified bisphenol A (BPA) as a substance of very high concern, requiring it to be substituted with safer, more sustainable alternatives. Potential alternative bisphenols, also referred to as analogues, were developed to replace BPA and are currently being implemented increasingly into the plastics production. While the toxicity of BPA is well studied, (eco)toxicological effects of the bisphenol analogues are largely unknown. However, the similar molecular structure of the analogues suggests possible comparable toxicological effects. Recent studies on bisphenol analogues have shown strong estrogenic as well as anti-androgenic effects in vitro with similar or sometimes even higher endocrine potential than the reference BPA. A more comprehensive ecotoxicological evaluation is necessary to properly assess the risk of the effects of bisphenol analogues on the aquatic environment. This study evaluates the four bisphenols BPA, BPF, BPS, and BPAF in reproduction tests with two aquatic model organisms. The freshwater snail Potamopyrgus antipodarum was selected as an estrogen-sensitive invertebrate and the freshwater amphipod Hyalella azteca as an estrogen-insensitive invertebrate. Recorded endpoints include the production of offspring, mortality, length and dry weight. Snails exposed to concentrations of bisphenols ranging from 1 to 100 µg/L showed a significant induction in the production of embryos in all tested concentrations. The number of neonates per surviving amphipod female was not significantly affected by bisphenol exposure. The mortality of the amphipods was impacted especially in the highest concentrations (2 mg/L) of the bisphenols BPA, BPF, and BPAF. This study shows that bisphenol analogues can impact invertebrate offspring production in estrogen-sensitive organisms in the same concentrations as bisphenol A. The embryo production of P. antipodarum was affected in concentrations as low as 1 µg/L, posing a serious risk for estrogen-sensitive organisms in freshwater systems.

1.12.P-Tu156 Effects of BPS on the Early Developmental Stage of Stickleback

***Ugo IARIA**, Cyril Turies, Gregory Gaudin, Blanche Goddyn, Remy Beaudouin and Anne Bado-Nilles Dr, INERIS-UMR SEBIO, France*

Bisphenol A (BPA) is an endocrine disruptor known to negatively impact aquatic organisms. Due to its toxicity and persistence, BPA has been restricted, leading to the introduction of substitutes like bisphenol S (BPS). However, the effects of these substitutes are still unclear. Endocrine disruptors affect sensitive developmental periods, potentially disrupting energy balance, which is crucial for survival, reproductive success, and population dynamics. This study investigates the effects of BPS exposure on the early developmental stages of the three-spined stickleback (Gasterosteus aculeatus), a model species sensitive to endocrine disruptors. Fertilized eggs (n = 1151) were randomly distributed in 10-liter tanks injected with BPS at concentrations of 0, 1, 10, or 100 µg/L. Exposure lasted for 38 days. Growth and mortality were monitored, with sample collection at 14 days post-fertilization (dpf), corresponding to yolk sac resorption, and at 38 dpf, marking the end of exposure when individuals were fully developed adults. Samples will be used to evaluate sex ratios, lipid and glycogen levels between groups. Fish in the control group attained a higher average size compared to those exposed to BPS. Increasing BPS concentrations were associated with a progressive decrease in growth. At day 8, the hatching rate in the control group was 54%, while it was approximately 8% for all BPS concentrations (1, 10, 100 µg/L). By day 9, the hatching rate reached 93% for the control group, and 84%, 79%, and 74% for 1, 10, and 100 µg/L, respectively. By day 10, the hatching rate exceeded 95% for all concentrations. These results indicate that BPS exposure delays fish hatching. Sex ratio, lipid and glycogen levels analyses will be conducted to further assess on the physiology. The results will be presented during the congress. This study shows significant sub-lethal effects of BPS exposure on stickleback growth and development, indicating potential risks of using BPS as a BPA substitute. These findings highlight physiological disruptions and support the need for refined risk assessments and stricter regulatory guidelines. This work was carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union s Horizon Europe research and innovation programme under Grant Agreement No 101057014. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or the Health and Digital Executive Agency. 1.12.P-Tu157 Assessing Safety of BPA Alternatives: Impacts on Thyroid hormone System (THS)- and Developmental Neurotoxicity (DNT) Sensitive Endpoints in Zebrafish (*Danio rerio*)

***Pernille Ambus Hansen**[1] and Henrik Holbech[2], (1)University of Southern Denmark, Odense, Denmark, (2)University of Southern Denmark, Denmark*

We investigate if Bisphenol A (BPA)-alternatives like BPE, BPAP, and BPS-MAE affect the thyroid hormone system (THS)-and developmental neurotoxicity (DNT)-sensitive endpoints in zebrafish (Danio rerio). Adverse effects on THS-sensitive endpoints such as a decrease in retinal pigmentary epithelium (RPE) have earlier been reported from BPA in zebrafish. It has also been documented that a decrease in thyroxin (T4) and 3,5,3 -triiodothyronine (T3) in early-life zebrafish larvae can be connected to altered eye development and specifically the retinal pigmentary epithelium (RPE) and delayed inflation of the posterior swimbladder chamber in zebrafish larvae. Additionally, research shows that T4 and T3 play a crucial role in development of the brain in vertebrates. We want to investigate if THS and/or DNT-sensitive endpoints adversely affect the swimming performance, which can be considered an adverse endpoint with population relevance. We demonstrated that some BPA-alternatives like BPE, have the potential to be endocrine disrupters. We found adverse effects on thyroid hormone system-sensitive endpoints in zebrafish embryos due to exposure to BPE. We want to present if the same tendency applies to other BPA alternatives like BPAP and BPS-MAE. Additionally, we want to present the possible effects of BPE, BPAP, and BPS-MAE on developmental neurotoxicity sensitive endpoints, such as, structural changes in the brain. This partnership has received funding from the European Union s Horizon Europe research and innovation programme under Grant Agreement No 101057014

1.12.P-Tu158 New Approaches in the Evaluation of the Thyroid Disruptive Potential of BPA Analogues

*Antonio De la Vieja[1], Patricia Iglesias Hernandez[2], Jennifer Makiadi-Alvarado[1], Maddi Garate-Etxeberria[1], Maria Munoz Palencia[3], Ana Ca as Portilla[3] and **Monica Torres-Ruiz**[3], (1)Unidad Funcional de Investigacion en Enfermedades Cronicas, Instituto de Salud Carlos III, Spain, (2)Unidad Funcional de Investigacion en Enfermedades Cronicas & Centro Nacional de Sanidad Ambiental, Instituto de Salud Carlos III, Spain, (3)Centro Nacional de Sanidad Ambiental, Instituto de Salud Carlos III, Spain*

Bisphenol A (BPA; 2,2-bis(4-hydroxyphenyl)propane) is a synthetic chemical employed in the plastic industry to harden plastics, as an antibacterial agent, and in anti-corrosion coatings. It is used in the elaboration of polycarbonate plastic, a common material found in food and water storage containers, in thermal paper and epoxy resins. In Europe, BPA has been classified as toxic for reproduction and as a candidate substance of very high concern (SVHC) based on its endocrine disruptive potential. Although the European Commission and other governments have proposed its ban in food contact materials and other uses, industries are replacing BPA with other bisphenol analogues with structural similarities such as BPS, BPF, BPE, BPP, BPZ, TBBPA, among others. Some of these substances have been already found in human and environmental matrices but their health effects and mechanisms of action are still largely unknown, with some evidence pointing towards endocrine disruption properties. Therefore, our main objective, framed within work package 5 of PARC (Partnership for the Assessment of Risks from Chemicals), was to evaluate the potential of the above-mentioned BPA analogues as thyroid hormone disruptors using recently developed in vitro test methods. We focused on the effects on iodide and thyroid hormone (TH) transport by their respective transporters NIS and MCT8, as well as their potential to disrupt TH-related gene expression in thyroid cellular models. Our results show that BPA and its analogues altered TH-related gene expression, but effect direction and degree varied depending on the analogue studied, some of which were even more detrimental than BPA. TH and Iodide transport were also affected with similar IC50 results for BPA and its analogues. Our results highlight the importance of new methodologies to further assess the endocrine disruption capabilities of bisphenol substances, especially for early life stages, as well as highlighting the urgency to include these substances in the SVHC candidate list. Financed by: MCIN PID2021-125948OB-I00/AEI/10.13039/501100011033 and PARC project (GA 101057014).

1.12.P-Tu159 CRISPR/Cas9 Makes its Way into Ecotoxicology – A Tale of Estrogenic Antagonism

***Gustavo Guerrero-Limon**[1] and Marc Muller[2], (1)Vitis Regulatory, Belgium, (2)University of Liege, Belgium*

To mimic the effects of endocrine disputing chemicals in zebra fish, we deployed a novel method using the gene editing tool (CRISPR/Cas9) to deactivate the function of specific oestrogen receptors. Endocrine disrupting chemicals are a pressing issue that have been in the spotlight for some time now. Their modulating action on endocrine signalling pathways makes them a particularly interesting topic of research within the field of ecotoxicology. Traditionally, endocrine disrupting properties are studied using exposure assays to suspected chemicals. In this research editing tools have been applied to directly assess the function of specific genes. Among these, the CRISPR/Cas9 method has accelerated progress across many disciplines in biology, helping the elucidation of specific interactions by knocking in or out targeted genes. This versatile tool was applied to directly inactivate three oestrogen receptors in zebrafish (Danio rerio) aimed at mimicking the antagonistic properties of endocrine disruptors. Then, using a panel of biological tests that is commonly applied to assess the overall development of zebrafish larvae, we investigated the antagonistic effects that exposure to endocrine disrupting chemicals would have. We found that the absence of individual functional oestrogen receptors (Esr1, Esr2b, or Gper1) affect behaviour, heart rate and development. Each mutant line was viable and could be grown to adulthood, the larvae tended to be morphologically grossly normal. However, a substantial fraction (70%) of the esr1 mutants presented severe craniofacial deformations, while the remaining 30% of esr1 mutants also exhibited changes in behaviour. esr2b mutants had significantly increased heart rate and significant impacts on craniofacial morphometrics. Finally, mutation of gper1 affected behaviour, smaller size (decreased standard length), and decreased bone mineralization as assessed in the opercle. Although the exact molecular mechanisms underlying these effects will require further investigations, we successfully tested a novel way to assess antagonism with potential to help us understand better the effects of endocrine disrupting chemicals found in our environment. This research project received funding from the European Union s Horizon 2020 research and innovation program under the Marie Sk?odowska-Curie Innovative Training Network (ITN) program PROTECTED, Grant agreement No. 722634.

1.12.P-Tu160 QSAR in Silico Model for Predicting Thyroid Receptor Endocrine Disruption Potential

*Emel Ay-Albrecht[1], Franklin Bauer[2], Zlatomir Todorov[1], Carole Charmeau[3] and **Paul Thomas**[2], (1)KREATiS, France, (2)KREATiS, France, (3)KREATiS, L'ISLE-D'ABEAU, France*

Interest in the impact of endocrine-disrupting chemicals (EDCs) on human health and ecosystems is growing globally. Regulatory agencies have developed frameworks for EDC identification involving in vitro and in vivo testing of Estrogenic, Androgenic, Thyroid and Steroidogenesis (EATS) modalities. While certain E, A and S receptor assays are well-validated, thyroid receptor-specific assays are underdeveloped and lack comprehensive validation. Current regulatory methods rely on in vivo studies of reproductive and developmental toxicity which do not reveal specific interactions with thyroid receptor subtypes (? and ?). Such knowledge gaps are especially significant for petrochemicals and high-production-volume substances.To address these limitations, new approach methodologies (NAMs), including quantitative structure-activity relationship (QSAR) models, are essential for rapid, cost-effective predictions of chemical interactions with endocrine system targets, thus minimizing reliance on animal testing. This study introduces a novel QSAR model designed to predict thyroid receptor-mediated endocrine activity, underpinned by an innovative data curation methodology. The curated dataset was mainly sourced from EPA ToxCast, and refined through a semi-automated curation process guided by expert criteria, ensuring high data quality. The data splitting was performed using the Kennard-Stone algorithm to ensure structural diversity and balanced distribution across the training, validation, and test sets, while also considering the response to achieve better representativity of the target properties. A machine learning algorithm, namely a support vector machine (SVM) using circular molecular fingerprints, was trained and validated. The model demonstrated robust performance, with sensitivity, specificity and f1-score values of 92, 86 and 89% for the validation set, and 84%, 99%, and 87% for the external test set. A defined applicability domain further enhanced prediction reliability, meeting OECD principles for QSAR validation and ECHA regulatory standards. ? Our model's unique curation methodology improves data quality, facilitating more reliable predictions and filling critical gaps in thyroid receptor research. This QSAR tool efficiently identifies endocrine disruption potential, supporting regulatory and industrial assessments, allowing prioritisation of chemicals with lower EATS modality risk, and promoting faster hazard assessments while reducing animal testing.

1.12.P-Tu161 Molecular Modeling Framework to Predict Protein-Ligand Interactions to Detect Endocrine Disrupting Potential of Chemicals, Upgrade and Validation

*Zlatomir Todorov[1] and **Paul Thomas**[2], (1)KREATiS, France, (2)KREATiS, France*

The global effort to identify substances with endocrine disrupting (ED) modalities currently benefits from various computational methods which stand as an alternative but also as a complementary tool to experimental studies. Molecular docking in contrast to other computational techniques requires a minimal amount of training data to establish predictive models. Under the limit of available atomic-scale protein structures, docking can rapidly investigate the possibility for interactions between a protein involved in ED pathways and small molecules of interest. Our team actively develops a framework for acquisition and analysis of molecular docking results. The tool described in this work relies on trustworthy third-party models for the heavy lifting of docking related computations, while automation on preparation of inputs, raw data analysis and cohesion between different external tools is done by in-house programs. Our docking framework differs from other tools by exploiting structural ensembles to generate docking results, moreover, predictions are cast upon statistical assessment of the similarities between ensembles describing the reference and the tested data. In a recent communication we reported that despite the inherent low specificity due to the lack of crucial analysis stages, the framework correctly classified 223 out of 238 in vitro positive molecules. Furthermore, 141 experimental positives were ranked better than decoys (among the 185 of decoys included in the dataset), hence an enrichment factor between 0.56 to 0.73 for six EATS modality targets (Estrogen alpha and beta, Androgen, Thyroid alpha and beta, Progesterone receptors). Here, we present results for a small-batch screening study (external dataset including experimental positives and negatives) on six EATS targets. These results were obtained with the recently updated version of the framework that was developed to correct for the low specificity of the analysis module that was observed previously. Despite the higher computational cost in comparison to trained models this work demonstrates that molecular docking is affordable even for screening studies and is a valuable tool providing mechanistic evidence for prioritizing compounds with respect to their putative ED potential.

1.12.P-Tu162 In Silico Tools for Endocrine Disruption Assessment: A Focus on Human Transthyretin Disruptors

Marco Evangelista, *Nicola Chirico and Ester Papa, QSAR Research Unit in Environmental Chemistry and Ecotoxicology, Department of Theoretical and Applied Sciences, University of Insubria, Italy*

Endocrine Disrupting Chemicals (EDCs) are a structurally heterogeneous group of substances of widespread use and application, whose identification and assessment has become prioritary due to their ability to negatively affect the endocrine system in living organims. In this context, the use of in silico approaches, such as Quantitative Structure-Activity Relationships (QSARs), is suggested to fill data gaps and to support the identification of substances with endocrine activity. This work aims to develop new QSAR models for the prediction of the binding affinity of exogenous chemicals with human transthyretin (hTTR), identified as a relevant molecular initiating event leading to thyroid hormone (TH) system dysfunctions. The modelled endpoint was the logarithm of the Relative competitive Potency (RP), which reflects the ability of a compound to displace the TH thyroxine (T4) from the hTTR. The here proposed models were developed using three new datasets that include, to our knowledge, all the currently available experimental values of RP published in the literature and measured with three different in vitro assays: the radiolabeled [125I]-T4 binding assay (RLBA), the 8-anilino-1-naphtalenesulfonic acid (ANSA) based binding assay, and the fluorescence conjugate isothiocyanate (FITC)-T4 based binding assay. Each dataset is composed of data measured by the same in vitro assay. Theoretical molecular descriptors were generated from harmonized SMILES (Simplified Molecular Input Line Entry System) and were used as variables in QSAR modeling. QSARs development followed the OECD guidelines, in order to guarantee for the internal statistical reliability and the external predictivity of the models when applied to new chemicals. The mechanistic interpretation of the selected molecular descriptors provided insights on the structural features that promote the displacement of T4 from hTTR. Due to the presence of different chemical structures in the three datasets, each QSAR was applied through the QSAR-ME Profiler software to fill missing values in the other two datasets. Compounds with reliable predictions were ranked by PCA analysis according to their experimental or predicted RPs, to discriminate stronger and weaker hTTR binders. The proposed QSARs can be applied to support the identification of chemicals with potential TH system-disrupting activity, which could represent a severe threat for human health and wildlife.

1.13 Challenges and Innovations in Assessing Chemicals and Mixtures with Difficult-to-Test Properties for Environmental Risk

1.13.T-01 Tripartite Perspectives on Optimizing UVCB Testing: Balancing Whole Substance and Representative Constituent Approaches

Samuel Arey[1], Marc Fernandez[2], Sarah A. Hughes[3], Athena Keene[4], Julie Krzykwa[5], Delina Lyon[6], Philipp Mayer[7], Claire Phillips[8], Ursula Sauer[9], Leslie J Saunders[10], Sandrine Sourisseau[11] and ***Sandrine Estelle Deglin***[5]*, (1)Oleolytics, United States, (2)Environment and Climate Change Canada, Canada, (3)Shell Global Solutions, United States, (4)Afton Chemical Corporation, United States, (5)Health and Environmental Sciences Institute, United States, (6)CONCAWE, Belgium, (7)Technical University of Denmark, Denmark, (8)Centre for Environment, Fisheries and Aquaculture Science, United Kingdom, (9)Scientific Consultancy Animal Welfare, Germany, (10)Concawe, Belgium, (11)TOTAL Energies, France*

Complex substances such as multi-constituent substances and UVCBs usually result from either industrial processing, natural substances, or chemical reactions, and make up approximately 20-25% of chemicals registered globally (e.g., under TSCA or REACH). Because of the variable and complex nature of source materials, and variability inherent to production processes, these substances can contain many, sometimes uncharacterized, constituents whose concentrations may vary between batches. To identify and advance the various challenges associated with UVCB testing and assessment, the Health and Environmental Sciences Institute (HESI) organized an international workshop Exploring the complexities of UVCB testing and risk assessment that took place on September 18th and 19th, 2023, in Reykjavik, Iceland. The 25 workshop participants represented academia, governments and regulatory agencies, as well as, the private sector, and originated from Belgium, Canada, Denmark, France, Germany, the Netherlands, Norway, the United Kingdom, and the United States of America. The HESI UVCB workshop aimed at initiating multi-sectoral, tripartite discussions on the advantages and disadvantages of whole substance vs. representative constituent testing and assessment, and how to best combine both approaches. Workshop attendees also identified further research needs, and attempted to establish potential consensus solutions for environmental risk assessment. We will present the insight from the workshop, which contributed to reinforcing the exposure-centric tiered approach previously developed by the Committee for the environmental risk assessment of UVCBs and multi-constituent substances. The case-study based discussions held during the workshop highlighted critical questions that ultimately helped provide some guidance to strategically test different aspects of whole UVCB substances and their representative constituents. Altogether the discussions and case-studies from the workshop generated information that will serve as a foundation to robust risk assessments.

1.13.T-02 UVCB Biodegradation Testing Challenges and Solutions

Heidi Birch[1]*, Karen Dyhr*[1]*, Aurelia Lapczynski*[2] *and Philipp Mayer*[1]*, (1)Technical University of Denmark, Denmark, (2)Research Institute for Fragrance Materials, United States*
Persistence assessment of chemicals is conducted through a tiered approach for biodegradation testing from ready biodegradability screening tests to simulation biodegradation tests. However, these standard tests are not applicable for complex mixtures such as UVCBs (substance of Unknown or Variable compostition, Complex reaction products or Biological Materials). The main testing challenge is the complex nature of UVCBs, since standard tests use non-specific measuring parameters that cannot reveal the degradation of individual UVCB constituents. Biodegradable major constituents could then mask persistent minor constituents. The aim of our work was therefore to develop biodegradation tests for UVCBs that combine whole substance testing with constituent specific analysis. This presentation will cover the development and dimensioning of a ready biodegradability test and a simulation biodegradation test for UVCBs. The dimensioning targeted also the challenges posed by volatile and hydrophobic constituents, present in many UVCBs, and prone to losses during testing. The developed methods were demonstrated with black pepper and lavender essential oil UVCBs. The simulation biodegradation tests were conducted at low test concentrations and constituent specific primary biodegradation of unknown constituents was obtained through Arrow SPME GC-MS-scan. The ready biodegradability test was conducted at a higher test concentration confirmed to be below inhibitory levels. It combined whole substance mineralization through contact less oxygen measurements with the primary degradation of UVCB constituents through SPME GC-MS-scan analysis. The experiments showed fast degradation of essential oil constituents. The study demonstrates how biodegradation at different test tiers can be determined for UVCBs with a careful design of the experiments.

1.13.T-03 Ecotoxicity Testing of Cationic Surfactant Benzalkoniums (BACs) Using a Novel Passive Dosing Method

Anh T.Ngoc Do[1]*, Kyoshiro Hiki*[1]*, Haruna Watanabe*[1]*, Hiroshi Yamamoto*[2] *and Satoshi Endo*[1]*, (1)National Institute for Environmental Studies, Japan, (2)Health and Environmental Risk Division, National Institute for Environmental Studies, Japan*
In aquatic toxicity tests, controlling and describing the exposure conditions is challenging when the substance is susceptible to absorptive loss within the test system. To address those issues, this study introduced a new passive dosing method in the acute immobilization test on Daphnia magna (OECD TG No.202) of cationic surfactants benzalkoniums (BACs) with the alkyl chain length of 14 18 carbons. Thirteen materials were tested for their sorption capacity in choosing a suitable passive dosing material. Series of loading and desorption experiments were conducted to examine the stabilization of the exposure concentration (Cw) via equilibrium partitioning. Consequently, the 48h-acute ecotoxicity tests of benzalkoniums on D. magna using passive dosing and conventional solvent spiking methods were compared in terms of Cw stability and toxicity results. The results showed that poly(ethersulfone) (PES) membrane appeared to be an optimal passive dosing reservoir (i.e., log KPESw ~ 4), with which equilibrium desorption was reached within 24 h under gentle shaking and the Cw remained constant afterward. In the acute ecotoxicity, the Cw stayed unchanged during the testing period in both the dosing methods. However, in the solvent spiking test, the Cw was lower than the nominal concentration (Cnom) for C12-C18-BACs, particularly at low exposure concentrations with a difference of 20 60 % compared to Cnom. The observation in the toxicity of BACs revealed that the solvent spiking tests displayed the U-shape trend of the median effect concentration (EC50), i.e., decreasing from C6-BAC to C14-BAC and increasing from C14 to C18-BAC. In contrast, EC50 values of BACs from C14 to C18 measured by the passive dosing method were similar or slightly decreasing, implying higher toxicity of C16 and C18-BACs than those performed by the solvent spiking method. The toxicity tests indicated the 48h-EC50 values of the long-chain BACs to D. magna were at single ?g/L range. The findings in this study suggest the potential of applying this innovative passive dosing approach in the extension to other aquatic organisms in both acute and chronic toxicity tests of BACs or other cationic surfactants under relevant environment conditions, which should be useful support for risk assessment of cationic surfactants in the aquatic environment.

1.13.T-04 The Influence of pH on the Toxicity of Ionizable Agrochemicals to Freshwater Invertebrates

Anna Huang*, Steven Droge and Ivo Roessink, Wageningen Environmental Research, Netherlands*

A wide range of environmentally concerning chemicals belong to the group of ionizable organic chemicals (IOCs). Among agrochemicals, up to one-third are ionizable. IOCs can exist in aquatic environments in multiple forms, changing their form based on pH variations determined by their acid dissociation constants (pKa). The neutral form of IOCs has a higher potential to reach target sites within organisms and is often observed to be more toxic. Therefore, it is essential to understand the pH-dependent behaviour of IOCs to accurately assess their environmental impact. However, directly assessing the toxicity of IOCs at different pH levels is not easy, as pH can also impact the functioning of biological systems in addition to influencing the dissociation of IOCs. To disentangle these issues, we raised several research questions: (1) Does pH alone cause adverse effects on aquatic species? (2) Do non-ionizable chemicals exhibit pH-dependent toxicity? (3) Do ionizable chemicals show varying toxicity across pH levels, and what theoretical framework explains this? To answer these questions, we conducted three tests. Test 1 assessed the mortality of five aquatic species across pH levels 6.5, 7.5 and 8.5, showing less than 20% mortality in four species and 33% mortality in Gammarus pulex at pH 8.5. Test 2 evaluated the toxicity of the non-ionizable compound flupyradifurone on Cloeon dipterum and Hyalella azteca at the same three pH levels, showing no pH-dependent toxicity. Test 3 investigated the toxicity of the ionizable fungicide fluazinam (weak acid, pKa 7.34) across the three pH levels, showing that pH influences both chemical degradation and toxicity. Preliminary results showed that (1) the chemical degraded more rapidly at lower pH levels; (2) the EC?? is five times lower at pH 6.5 compared to pH 8.5 for H. azteca, (3) a strong linear regression supported the ionizable toxicity theory that both the neutral and ionized forms are active and act additively in toxicity. Our study systematically addresses concerns regarding ionizable chemicals by demonstrating that the influence of pH on these compounds is driven by their chemical dissociation rather than direct pH effects on biological systems. As water pH levels in European surface waters can easily vary from 6 to 9, the finding that fluazinam's EC?? is five times lower at 6.5 than at pH 8.5 can have implications for its ecological risk assessment under worst-case pH scenarios.

1.13.T-05 From Theory to Practice: Tackling Challenges and Innovations in Assessing Risks from PFAS and Tyre Wear Particles

***Andy Booth**[1], Lisbet Sorensen[2], Rian Ruhl[3], Thomie Vlachogianni[4] and Thomas Maes[5], (1)SINTEF, Norway, (2)NTNU, Norway, (3)WUR, Netherlands, (4)MIO-ECSDE, Greece, (5)GRID-Arendal; SEAMOHT, Norway*

The SOS-ZEROPOL2030 project supports the EU s ambition of achieving "Zero Pollution" in its seas. It focuses on two challenging pollutants: per- and polyfluoroalkyl substances (PFAS) and tyre wear particles (TWPs). These case studies, selected for their complexity and data gaps, stress-test a scenario-based risk assessment framework addressing varying levels of data availability: Scenario 1 assumes sufficient exposure and hazard data, enabling robust assessments; Scenario 2a/2b involves data gaps in either exposure or hazard data, requiring models to fill gaps with reduced robustness; Scenario 3 relies entirely on models due to insufficient data, introducing significant uncertainties. The framework identifies data gaps and shows how modelling can partially address these, contributing to the SOS-ZEROPOL2030 roadmap. PFAS exposure data is abundant in northern European seas but limited in the Mediterranean and Black Sea. While sufficient toxicity data exists for legacy PFAS like PFOS and PFOA, data on novel PFAS are limited. Assessments show over 25% of sampling stations in some regions exceed toxicity thresholds for legacy PFAS, while fewer exceed thresholds for novel compounds. Challenges include inconsistent monitoring, limited data coverage, and analytical constraints. Recommendations include expanding monitoring to cover novel PFAS, improving analytical methods, and conducting long-term data collection. TWP assessments examined TWPs, tyre wear leachates (TWLs), and tyre wear chemicals (TWCs). Insufficient empirical data necessitates reliance on models. Findings suggest TWP emissions in water rarely exceed thresholds but highlight concerns about sediment accumulation and TWL/TWC toxicity. TWCs, as complex mixtures, complicate measurement and attribution in risk assessments. Recommendations include developing methods for TWP quantification and TWC identification, generating toxicity data on sublethal and chronic effects, and incorporating TWCs into monitoring programmes. SOS-ZEROPOL2030 highlights the need for enhanced data collection, innovative modelling, and coordinated policies. Its framework provides pathways for sustainable solutions aligned with the EU s zero-pollution vision, such as an EU-wide ban on non-essential PFAS and technological solutions to reduce emissions of TWPs in urban hotspots, enhanced monitoring, and the promotion of PFAS-free alternatives or alternative transport mechanisms. SOS-ZEROPOL2030 is funded by the European Union s Horizon Europe programme under grant agreement No. 101060213.

1.13.P Challenges and Innovations in Assessing Chemicals and Mixtures with Difficult-to-Test Properties for Environmental Risk

1.13.P-Th020 What Drives Alga Toxicity of Primary Fatty Amines?

*Jens Bietz[1], Janis Fuller[2] and **Dirk Scheerbaum**[2], (1)Clariant Produkte (Deutschland), Germany, (2)Noack Laboratorien, Germany*

Primary fatty amines (PFAs) are high production chemicals bearing a set of properties which include them in the category of difficult-to-test-substances as defined in the OECD Guidance Document on Aquatic Toxicity Testing of Difficult Substances and Mixtures (OECD 23). These substances can be biodegradable, multi-constituents/UVCBs as well as surface-active, adsorbing and ionic. In the range of environmental relevant pH-values PFAs are completely protonated (cationic surfactants) making it difficult to maintain stable concentrations in environmental toxicity and fate studies. This can be due to formation of micelles and dispersions and in addition due to adsorption processes to test vessels or negatively charged biological materials. Examples for this kind of material are algal cells, which are present in alga toxicity and chronic daphnia studies. Generally proposed adaptions of the test design of such studies include the usage of truly dissolved concentrations for the evaluation of the results. This concept is based on the idea that only the dissolved fraction of the test substance is bioavailable. However, in case of positively charged surfactants it is highly questionable if this represents the truth: Adsorption to the test organism most probably will lead to an increase of the local concentration rather than to a decrease as the decreasing dissolved fraction in the water phase suggests. To investigate the real distribution of PFAs in the test system a green alga study on growth inhibition with a radiolabeled primary fatty amine is performed. The truly dissolved fraction, as well as the amount of adsorbed substance to surfaces of different textures, are analytically determined. Based on the results the suitability of different evaluation schemes will be discussed.

1.13.P-Th021 Method Development and Analytical Challenges for the Quantitation of Complex Industrial Chemicals in Support of Environmental Fate and Ecotoxicology Studies

***Stephen Brewin**, Environmental Sciences, Labcorp, Indianapolis, United Kingdom*

Due to the evolving regulatory landscape for registration under REACH, environmental studies that were typically performed for crop protection chemicals are moving towards assessing a broader array of complex chemicals, including industrial chemicals, naturals, botanicals and chemicals of Unknown or Variable Composition, Complex Reaction Products or Biological Materials (UVCBs). The registration of these substances introduces unique challenges due to the nature of the chemicals themselves, ranging from technical constraints in conducting regulatory fate studies to the feasibility of radiolabelling and the analytical limitations encountered in non-radiolabelled ("cold") analysis. The nature of these substances also presents numerous challenges when also providing support for other study types, such as ecotoxicology studies, where difficulties in achieving the required levels of sensitivity to confirm application of the dose to the test media are frequently faced. Many industrial chemicals present numerous analytical challenges, due to a variety of issues associated with their often varied and complex composition. To develop suitable analytical methods, there are a number of considerations that need to be addressed. For example, determining the the nature of the analyte is particularly important, as a single component is more straight forward to quantify as the properties of the molecule can be considered when selecting and optimizing a suitable quantitation technique. However, a multiple component mixture (e.g. UVCB) consists of a range of components of differing chemical properties and abundance, often leading to a representative marker or even multiple markers being selected for quantitation. It is desirable to monitor as many marker components as possible to provide a more thorough representation of the test material. There are numerous challenges when developing analytical methods for these types of test items, such as selecting and optimizing appropriate analytical instrumentation for the analyte or selected marker components, developing suitable extraction and extract clean-up techniques, assessing the possibility of including degradation products for certain study types as well as achieving successful validation of the resulting method. This poster describes the considerations, challenges and approaches to developing and validating analytical methods for complex industrial chemicals in support of environmental fate and ecotoxicology studies.

1.13.P-Th022 Sorption of Cationic Surfactants by Clay Mineral and Organic Matter: Isotherm Measurements with Conventional Batch and New Passive Sampling Methods

***Satoshi Endo**[1], Anh T.Ngoc Do[1], Sakura Yoshii[1], Masami Koshikawa[1], Yoko Katakura[2] and Sadao Matsuzawa[2], (1)National Institute for Environmental Studies, Japan, (2)National Institute for Environmental Studies, Japan*

Cationic surfactants are used in a wide range of applications, including disinfectants in disease control and fabric softeners in laundry aftertreatment. Due to their generally high toxicity to aquatic organisms, research on their environmental fate and effects is needed. Soil and sediment particles are often negatively charged and can strongly adsorb cationic surfactants. In this study, adsorption isotherms of the cationic

surfactants benzalkoniums (BAC) and dialkyldimethylammoniums (DADMAC) were measured on clay mineral (kaolinite) and organic matter (peat) samples. In parallel to the conventional centrifugation method, the free dissolved concentration was measured by the passive sampling (PS) method using a solid-phase microextraction fiber to evaluate the validity of the PS method. Kaolinite was pretreated with 1M NaCl solution to exchange any bound cations with Na+. Peat was washed with diluted NaOH solution to remove excess acids. Suspensions of these samples were prepared using 15 mM NaCl solution at pH 7. Batch adsorption experiments were performed by adding the suspension, target substance, and polyacrylate (PA) fiber to 2 mL microtubes. After 1 night to 24 h of rotary shaking, the tubes were centrifuged, the supernatant, PA fiber, and kaolinite were collected and extracted, and cationic surfactant concentrations were determined by LC-MS analysis. The same experiment was performed without natural sorbent to determine the sorption isotherms on the PA fiber.
The adsorption isotherms were all nonlinear (Freundlich exponent 0.5-0.7), although no clear surface saturation at high concentrations was observed for either material. The longer the chain length, the stronger the adsorption, but the increment of the adsorption coefficient per C was not constant. The results of adsorption experiments using the conventional centrifugal separation method and the PS method were comparable for long-chain BACs on kaolinite. However, different results were obtained for short-chain BACs on kaolinite and peat when investigated by the centrifuge and PS methods. It is likely that the fouling of the PA fiber with the natural sorbent affected the amount extracted for short-chain BACs. Based on the results, we conclude that the adsorption coefficients and isotherms of cationic surfactants can be measured by the PS method using PA fibers when the adsorption coefficient is PA >> natural sorbent and the effect of fouling is insignificant. This study was funded by JSPS KAKENHI JP22H03765.

1.13.P-Th023 Chemical Mapping of Naturals Constituents through the Persistence, Bioaccumulation, Mobility and Toxicity (PBMT) Prism: Qualitative Analysis as a Precursor to Literature Data

Kevin BONNOT[1], *Sylvia Gimeno*[1], *Balint Tamasi*[2] *and Franz Roos*[2], *(1)dsm-firmenich, Belgium, (2)dsm-firmenich, Switzerland*

Ingredients from natural sources, in particular essential oils, are widely formulated in consumers products such as cosmetics, perfumery, and household products. Understanding the environmental and ecotoxicological impact of those Natural Complex Substances (NCS) has become a priority, notably with the implementation of the More than One Constituent Substances (MOCS) concept under the recent update of the EU Classification, Labelling and Package Regulation (EC No 1271/2008). However, the complex and variable composition of NCS presents a unique challenge for the assessment of their environmental impact. We will make use of the information gathered on over 1,000 naturals constituents, as to their Persistence, Bioaccumulation, Mobility and Toxicity potential and statistical analyses that will help understand and predict the fate and effects of naturals constituents. The first part of the study presents an innovative method of Hierarchical Clustering on Principal Components (HCPC), based on chemical families. The HCPC approach is particularly well-suited to the classification of complex substances, as it allows for the identification of distinct chemical families based on both structural similarities and environmental properties. This method clusters molecular fragments (qualitative data) and 2D descriptors (quantitative data), and is enriched by unsupervised statistical analysis methods such as Partial Least Squares (PLS) regression and sparse PLS. These advanced techniques enable us to uncover patterns in the molecular structures of naturals constituents and establish correlations with key environmental parameters, such as persistence, bioaccumulation, mobility, and toxicity. In the second phase, a visualization based on regulatory thresholds for PBT/PMT is used to categorize clusters of components according to CLP criteria. This study, by focusing on molecular structure, it enables the qualitative prediction of the environmental impact of substances. From the clusters created and the descriptors and fragments characterizing these groups, we will identify key molecular descriptors critical for the assessment of naturals constituents. These findings are crucial for advancing the understanding of the environmental fate of these substances and the applicability of the MOCS concept to substances of botanical origin, for which there is a 5-year derogation.

1.13.P-Th024 Application of GC×GC methodology to Assess the Bioaccumulation Potential of Hydrocarbon UVCBs in Fish

Leslie J Saunders[1], *Martin Lommatzsch*[2], *Richard John Maunder*[3], *Thomas Hawkins*[3], *Christopher Prosser*[4], *Aaron Redman*[4] *and Delina Lyon*[5], *(1)Concawe, Belgium, (2)Laboratory Lommatzsch and Sager, Germany, (3)Scymaris, United Kingdom, (4)ExxonMobil Biomedical Science, United States, (5)CONCAWE, Belgium*

The assessment of chemical bioaccumulation in fish is an important component of global chemical assessment and regulatory programs. Bioaccumulation assessments for petroleum substances remain difficult because (i) they are comprised of complex and variable combinations of hydrocarbons (i.e., UVCBs); and (ii) there are limited test data for the thousands of possible hydrocarbon constituents in petroleum substances, due to limited commercial availability of the individual constituents and/or their incompatibility with standard test systems. Furthermore, standardized tests tend to be optimized for single constituents and may not function well for complex substances, as individual components within the substance may differ widely in their partitioning behaviour and biological fate. In the present study we characterize the dietary accumulation of a petroleum substance (i.e., middle distillate oil) in rainbow trout using an OECD 305 dietary bioaccumulation test design. Here we use two-dimensional gas chromatography (GC×GC) analytical and data integration methods to characterize the uptake and elimination of constituents in fish. This whole-substance-with-peak-tracking test design has been successfully applied in seawater biodegradation tests. However, the biological samples collected in bioaccumulation tests present additional challenges for adequate peak separation and identification in GC×GC analyses. In a previous pilot study, fish food and tissue matrices interfered with hydrocarbon peak separation and identification. To remove residual lipids and polyenes, we implemented alkaline digestion and epoxidation steps which greatly reduced analyte interference and carryover between chromatogram runs. Addition of an HPLC pre-fractionation step to separate saturated and aromatic hydrocarbon fractions also greatly reduced peak overlap and interference. We have now applied these improvements to evaluate bioaccumulation and biotransformation behaviour of hydrocarbon UVCBs in fish using a whole-substance-with-peak-tracking test design.

1.13.P-Th025 Evaluation of the Environmental Safety of Basil Extract (*Ocimum basilicum*) in Aquaculture Feeds

Alessandra Maganza[1]*, Monia Renzi*[2]*, Serena Anselmi*[3]*, Francesca Provenza*[3]*, Fabio Bondavalli*[4]*, Giuseppe Esposito*[5]*, Silvia Colussi*[6]*, Marino Prearo*[5] *and Paolo Pastorino*[5]*, (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments; Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (2)Department of Life Sciences, University of Trieste, Italy, (3)Bioscience Research Center srl, Italy, (4)The Veterinary Medical Research Institute for Piedmont, Italy, (5)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments, Italy, (6)The Veterinary Medical Research Institute for Piedmont, Liguria and the Aosta Valley; Universit Cattolica del sacro Cuore, Italy*

Plant extracts (PEs) and essential oils (EOs) show potential as natural antimicrobials. These compounds are volatile, typically colorless, lipid-soluble mixtures composed mainly of terpenes and terpenoids. In veterinary medicine, especially for pets and livestock, PEs and EOs may serve as promising alternatives to synthetic antimicrobials, potentially useful against infections and improve production quality, without leaving the residues commonly associated with synthetic drugs in food products. Supercritical fluid extraction (SFE), often using solvents like carbon dioxide (CO?), is the primary method for obtaining PEs and EOs. Although EOs and PEs are increasingly used in livestock, their environmental impact remains under-researched, likely due to the assumption that plant-based compounds are naturally safe.

In this study, basil supercritical fluid extract (F1-BEO) was chosen, as basil (Ocimum basilicum) has shown antioxidant, antimicrobial, insecticidal, nematocidal, and fungistatic properties, especially relevant in aquaculture. Ecotoxicity tests were conducted under controlled conditions, using fish feed supplemented with 3% w/w of F1-BEO (substance A), pure F1-BEO extract (substance B), and fish feed without F1-BEO (substance C). These were tested across three model species from different trophic levels (bacteria, primary producers, and primary consumers) representing both freshwater (Aliivibrio fischeri, Raphidocelis subcapitata, Daphnia magna) and marine (A. fischeri, Phaeodactylum tricornutum, Paracentrotus lividus) ecosystems. The results showed a reduction in bioluminescence of A. fischeri at tested concentrations only for substance A. Dissolving fish feed in algal media promoted microalgal growth without any observed toxic effect. However, primary consumers in both freshwater and marine environments exhibited acute toxicity across all substances tested. Notably, P. lividus displayed higher embryotoxicity with substances A (EC50 1.80 mg/L) and C (EC50 4.6 mg/L) compared to substance B (EC50 7.10 mg/L), implying toxicity linked to feed dissolution. In contrast, for D. magna, substance B exhibited greater toxicity (EC50 0.34 mg/L) than substances A (EC50 3.98 mg/L) and C (EC50 5.50 mg/L). These substances may pose potential toxicity risks within aquatic ecosystems, particularly for primary consumers. Further research on PEs and EOs is essential to understand their environmental impact and behavior in aquatic environments more comprehensively. This study was funded by Resil Trout Project (23E03).

1.13.P-Th026 Building a Pilot Database of UVCB Chemical Characterization Information: Compiling Data on Substances of Unknown or Variable Composition, Complex Reaction Products, and Biological Materials (UVCBs)

*Erin Maloney[1], Marc Fernandez[2], Lillian Cesh[2], Caitlin Tejowinoto[2], Antony John Williams[3], Charles Lowe[3], Emma Schymanski[4], **Julie Krzykwa**[5] and Sandrine Estelle Deglin[5], (1)Shell Global Solutions, Netherlands, (2)Environment and Climate Change Canada, Canada, (3)US Environmental Protection Agency, United States, (4)Luxembourg Centre for Systems Biomedicine, University of Luxembourg, Luxembourg, (5)Health and Environmental Sciences Institute, United States*
Substances of unknown or variable composition, complex reaction products, and biological materials (UVCBs) represent 20 25% of the chemicals registered globally and pose unique challenges for risk evaluation. To help address these challenges, a tripartite group within the Health and Environmental Sciences Institute (HESI) has been developing a tiered, exposure-based UVCB framework to guide prioritization and risk assessment of UVCBs. The initial step of the proposed approach (Tier 0) focuses on basic characterization to flag potential hazards, persistence, or bioaccumulation. However, this evaluation is highly dependent on the availability of Tier 0 data, including rudimentary exposure, compositional, and ecotoxicity data. Despite the prevalence of UVCB substances in the chemical space, the publicly accessible data available for these substances is often limited. Moreover, substance characterization in these databases is incomplete or incorrect leading to issues associated with linking data to a specific UVCB substance. Altogether, this underscores the need for a fit-for-purpose, publicly accessible UVCB database. A subgroup of the HESI UVCB committee is developing a pilot database of Tier 0 information for UVCBs to assess feasibility and develop efficient data-collation methodologies. Data collected includes substance identifiers, structural descriptors, registration data, physicochemical properties, use and process information, and ecotoxicity data. These data are being collated for both whole substances and representative constituents from online databases, registration dossiers, and scientific literature. The methods and challenges encountered during this effort have been documented to allow for reproducibility and aid in identifying potential improvements in future efforts to expand the database (e.g., steps to automate the data mining processes). This pilot demonstrates the feasibility of the project and highlights the challenges associated with developing a UVCB database. It also empowers registrants, risk assessors, and regulators to apply the UVCB framework more effectively by providing information that can be utilized for prioritization, risk assessment, and read across. Support from industrial and regulatory partners will be vital in facilitating data collection and the realization of the full potential of such a database. The views expressed in this article are those of the authors and do not necessarily represent the views or policies of the US EPA.

1.13.P-Th027 Graphene Grey Areas in Daphnia Ecotoxicity Exposures: Mixtures, Movement and Monitoring

***Iseult Lynch**[1], Katie Reilly[2] and Alberto Katsumiti[3], (1)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom, (2)University of Birmingham, United Kingdom, (3)GAIKER Technology Centre, Basque Research and Technology Alliance, Spain*
Graphene and silicon nanomaterials are widely used as dry lubricants for sporting equipment, boats, machines, engines etc. Aquatic ecotoxicity assessments with these materials is challenging as they are often hydrophobic due to the surface properties of the particles, in addition, they can often be applied in combination with mineral oil to act as a carrier for the particles, further increasing the hydrophobicity and changing the surface properties. The ecotoxicity of these advanced materials is important to understand, including any potential adaptation to the standard aquatic testing approach to take into consideration the physico-chemical properties of the materials and how they may change in different environments. Daphnia magna have widely been used for ecotoxicity testing of different materials, including chemical, advanced materials (including nanomaterials) and microplastics in isolation and in varying combinations. Due to the robust foundation of endpoints and research to date, Daphnia are an excellent model to explore aquatic risk in freshwater environments. A panel of commercially available materials were assessed; Graphene, Graphene + Silicon, Silicon, Graphene + oil, mineral oil. This included the characterisation of the particles using DLS and zeta potential in control medium and also in the testing medium (with the Daphnia) to determine how the materials may change during the test period. Acute toxicity testing was also undertaken with Daphnia magna (Bham 2) following the OECD 202 TG recommendations, before sublethal testing was undertaken looking at molecular markers such as increase in ROS in addition to changes in behaviour such as movement and swimming. Variations with experimental design and exposure order were trialled to determine if this had any significant impact on the outcomes of the tests, for example, adding the toxicant to the test vessel prior to the medium and Daphnia vs adding the toxicant last, and subsequently using different ages/development stages of the Daphnia for sublethal assays. Advanced materials are challenging to assess due to the surface properties, in this case hydrophobic particles, which prove difficult to evaluate effectively using the current protocols which are optimised for chemicals. Modification, such as exposure order, age of Daphnia etc in addition to physico-chemical characterisation can increase our understanding of the risk of AdMa in freshwater ecosystems. MACRAMÉ has received

funding from the European Union s Horizon Europe research and innovation programme under grant agreement No. 101092686 with UKRI co-funding via the Horizon Europe Guarantee Fund.

1.13.P-Th028 Why are Commercial Surfactants Difficult to Test? Examination of the Challenges associated with Chronic Aquatic Testing

***Erin Maloney**[1], James Dawick[2], Lauren McAnally[2], Frank Seitz[3], Chiara Maria Vitale[4], Jens Bietz[5], Marc Geurts[6], Liesa-Kristin Beuter[7], Sabrina Wilhelm[8] and Philipp Hopp[8], (1)Shell Global Solutions, Netherlands, (2)Innospec Limited, United Kingdom, (3)Sasol Germany, Germany, (4)Procter & Gamble, Belgium, (5)Clariant, Germany, (6)Nouryon, Netherlands, (7)Nouryon, Sweden, (8)BASF Personal Care and Nutrition, Germany*

Chronic aquatic toxicity testing can be very complex but is often a standard information requirement for the production, import, and sale of detergent surfactants in the EU. The OECD Guidance Document on Aquatic Toxicity Testing of Difficult Substances and Mixtures (OECD GD 23) identifies surface activity as a difficult test substance property. However, commercial surfactants also tend to have a variety of properties making them difficult to test. They can be poorly soluble, toxic at low concentrations, photodegradable, rapidly biodegradable, adsorbing, ionized, multi-constituent, and/or UVCB substances. These properties can make it difficult to choose appropriate application procedures, test designs, and analytical strategies, even with due consideration of OECD GD 23 recommendations. Altogether, this can introduce significant testing difficulties, resulting in potential test failure and/or generation of effect values which are not suitable for quantitative risk assessment or classification and labeling. Moreover, this can pose challenges associated with adequately meeting registration requirements or regulatory deadlines, and can introduce animal welfare issues (e.g., excessive use of vertebrate fish during testing). As such, there is a need to identify pragmatic and tangible strategies through which chronic aquatic test requirements for surfactants can be addressed and optimized. Therefore, a project was developed through ERASM (https://www.erasm.org) which leverages existing data and the expertise of industrial scientists and research organizations to address the issue of conducting chronic aquatic toxicity testing with surfactants. This project has compiled proprietary and publicly accessible chronic testing data on non-ionic (alcohol ethoxylates), anionic (alkyl ether sulfates), and cationic (e.g., alkyl etherdiamines) surfactants, identifying difficult test properties for substances within each surfactant group, methods employed, and the challenges faced during testing. Supplemented with literature-derived data, this dataset will be used to generate guidance (akin to OECD GD 23) that can be employed while conducting chronic aquatic toxicity tests with detergent surfactants. Overall, this will optimize chronic aquatic toxicity testing with surfactants, improving the likelihood of test success and utility of generated data while reducing the use of vertebrate test organisms.

1.13.P-Th029 Providing Structures for Unknown Constituents of Hydrocarbon UVCBs: In-Silico 'De Novo' Creation of Nonpolar Hydrocarbons

***Yves Verhaegen**[1] and Delina Lyon[2], (1)Concawe, Belgium, (2)CONCAWE, Belgium*

Petroleum substances (PS) are archetypical UVCBs (Unknown or Variable composition, Complex reaction products, Biological materials), and can consist of a few hundred (e.g., solvent Naphtha) to potentially more than quinquavigintillion (1078) unique hydrocarbon constituents (e.g., bitumen). Yet, the identity has been fully resolved through traditional chemical analysis for only for a few hundred of these constituents. Current methods for in-silico creation of chemical structures recombine structural moieties (e.g., backbones and side-groups) present in existing chemical databases. While such methods perform well in creating simple paraffins (alkanes) and aromatics, they fail to create the more complex and numerous structures: olefinic (alkene) and naphthenic (cyclo-alkane and -alkene) aliphatics and aromatics. In this poster, we discuss our newly developed KNIME workflow which generates all stable hydrocarbon isomers atom-by-atom, using only basic chemistry rules (e.g., tetravalency, hybridization, bond lengths and angles). Currently, in excess of 1 billion (109) unique C5 - C17 stable nonpolar hydrocarbon isomers have been created, in which the olefinic and naphthenic structures largely outnumber the paraffinic and aromatic structures.

The availability of such an exhaustive database could dislodge some of the current analytical and regulatory limitations related to hydrocarbon UVCBs: chromatographic retention indices and mass spectra (MS) could be predicted for these structures, to improve peak identification in non-target chromatographic and MS data. Concurrently, suspect screening can verify the existence of those hypothetical constituents which are of potential environmental or health concern and for which further testing might be required.

1.13.P-Th030 Optimizing OECD 236 FET for Challenging Substances: Evaluation of a Closed-System Design for Reliable Aquatic Toxicity Testing

*Benedikt Luckner[1], Patricia Marini[2] and **Stefan Josef Hoeger**[3], (1)Innovative Environmental Services,*

Switzerland, (2)Ecotoxicology, Innovative Environmental Services, Switzerland, (3)Innovative Environmental Services, Witterswil, Switzerland
To assess the intrinsic hazard of chemicals to aquatic organisms, standardized toxicological tests have to be performed according to established test guidelines. While conventional designs are suitable for soluble and stable substances, challenges arise with substances having complex physico-chemical properties, as highlighted in OECD 23 and ISO 14442 guidance documents on aquatic toxicity testing of difficult substances and mixtures. Measures have to be taken to ensure exposure concentrations to be as stable as possible, e.g. testing in closed systems in case of high volatility. However, such custom-tailored test designs bare the potential to negatively impact the sensitivity of test organisms, due to e.g. impaired gas exchange, thus potentially introducing bias compared to the conventional design. For OECD 236 FET studies polysterene plates are commonly used. Limitations of this design are reached when it comes to testing of highly volatile or highly absorbing substances or polymers for which leaching of polymers from the plates pose an irritating source of background contamination. In any case, assuring that the modified test design does not alter the sensitivity of the organisms is a crucial aspect to warrant the reliability of data. We evaluate the usability of PTFE-capped glass vials as a closed system for the OECD 236 FET for maintaining stable substance concentrations without altering the sensitivity of test organisms compared to the conventional design. In addition, this alternative might facilitate testing of substances with other challenging properties like highly adhesive substances or polymers. To assess possible variation in sensitivity, multiple parallel OECD 236 FET studies will be conducted with embryos from the same spawnings in either the conventional or closed-system design exposed to the reference substance of the guideline (3,4-Dichloroaniline). Further, the suitability of the closed-system design to maintain stable substance concentrations during the test period will be assessed with several highly volatile substances in comparison to the conventional design with and without daily water renewal. Additionally, the total organic carbon will be measured to assess its suitability for testing of polymers without background contamination.

1.13.P-Th031 Evaluating the Reliability and Relevance of (Eco)Toxicity Studies on Micro- and Nanoplastics: SciRAPplastic and PlasticCRED

Ida Due[1]*, Anna Beronius*[2]*, Anders Baun*[1] *and Nanna B. Hartmann*[1]*, (1)Department of Environmental Contamination and Chemicals, DTU Sustain, Technical University of Denmark, Denmark, (2)C6 Biochemical toxicology, Institute of Environmental Medicine, Karolinska Institutet, Sweden*
Pollution from micro- and nanoplastics is a growing concern for scientists, regulatory and political bodies, and the general public. Despite extensive scientific efforts to identify potential health and environmental effects, assessing the overall health risk based on current research remains challenging. This difficulty comes from several factors, including technical challenges and a lack of harmonized definitions and methodological practices in micro- and nanoplastic research. Furthermore, limited transparency and inadequate reporting undermine the comparability of published study results. Our work addresses these challenges by developing tools to systematically evaluate the reliability and relevance of (eco)toxicity studies on micro- and nanoplastic effects. We have reviewed and revised existing tools to match specific needs for micro- and nanoplastics research. More specifically, we have focused on two existing frameworks: Science in Risk Assessment and Policy (SciRAP) and Criteria for Evaluating and Reporting ecotoxicity Data (CRED). These include SciRAP for in vivo studies, SciRAPnano for in vitro studies, and nanoCRED for ecotoxicity studies. This work is further based on a comprehensive literature review of physicochemical properties, and critical technical and methodological concerns for research on micro- and nanoplastics. Furthermore, we developed reporting checklists and guidance, outlining critical information and technical or methodological aspects that should be considered and reported specifically in micro- and nanoplastic studies. The outcome of our work is three tools known as SciRAPplastic (in vivo and in vitro) and plasticCRED (ecotoxicity), tailored to evaluate the reliability and relevance of micro- and nanoplatic (eco)toxicity studies. These tools can be applied as part of a weight-of-evidence assessment to evaluate reliability and relevance of scientific studies for regulatory purpose. The reporting checklists and guidance aim to support researchers in reporting essential information to ensure their studies meet reliability and relevance standards in a regulatory context. This work contributes to the identification of (eco)toxicity studies that assess environmental and health effects of micro- and nanoplastics, which provide data that are both reliable and relevant to serve as scientific evidence for legislation. The authors thank the EU Commission for funding this project that is part of Plasticheal.

1.13.P-Th032 Investigating Intrinsic Toxicity of Rare Earths to Algae – How Far to Go When Ecological Relevance Is Limited?

Nele Deleebeeck[1] *and Laura Lef vre*[2]*, (1)Arcadis Belgium, Belgium, (2)Arcadis Belgium, Belgium*
To fulfil the REACH information requirements in its registration dossiers, the Rare Earth Consortium has

performed algal growth inhibition studies (OECD 201) with a large part of the substances in their portfolio. Because of the strong interaction of rare earths with the phosphate in the test medium, standard tests do not yield information on the intrinsic toxicity of the rare earths, as all rare earths are precipitated when phosphate is in excess in the test medium (no exposure) whereas all phosphate is precipitated when the rare earths are in excess (no phosphate = no algal growth possible). Because reluctance was experienced of the CROs to look for an alternative phosphate source that would stay available to the algae during the test, no further testing was performed and a weight of evidence document summarising all data generated as well as existing literature data was written for inclusion in the dossiers. In this assessment, modelling with Visual Minteq confirmed dissolved rare earth and phosphate measurements that were made during the different experiments. It was concluded that the results of these standard tests are not useful for classification purposes or for PNEC/ERV derivation and that the secondary effect of phosphate deprivation is considering typical phosphate concentrations in the environment unlikely to occur at ecosystem level. Recently however, further attempts to investigate intrinsic toxicity of rare earths to algae have been made in several academic projects, trying to replace the inorganic phosphate source in the standard algal test medium by organically complexed forms, resistant to the complexation and precipitation with rare earths. Although these experiments confirm that rare earths show intrinsic toxicity to algae, robustness of the medium adjustments is to be further investigated. Identified issues as well as ecological relevance of the findings of these studies will be further discussed in this contribution.

1.13.P-Th033 Combination of Effect Directed Analysis and Pull-down Assay Coupled to Non-target Analysis for Identification of Endocrine Disruptors in Treated Wastewater

Petra Mikusova[1], Branislav Vrana[1], Marek Stiborek[1], Zdenek Simek[1], Andrea Vojs Staňová[2], Katerina Grabicova[2], Roman Grabic[2] and ***Klara Hilscherova**[1]*, *(1)RECETOX, Masaryk University, Czech Republic, (2)University of South Bohemia in ceske Bud?jovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Czech Republic*

While the quality of surface water has improved over recent decades, the presence of diverse micropollutants entering water bodies via treated wastewater (WW) remains a significant concern. These substances can induce adverse biological effects, posing risks to aquatic ecosystems and potentially impacting human health. Causative chemicals occur in highly complex mixtures, and often remain unidentified due to the absence of effective methods for their identification and analysis. This study employed an innovative strategy to improve the efficiency of the identification of endocrine disruptors in treated WW. Treated municipal WW was sampled using passive samplers that captured a broad spectrum of micropollutants over a 16-week period. The collected sample was analysed using two strategies aimed at simplifying sample composition and identifying bioactive compounds. The sample showed strong potency to inhibit binding of thyroid hormone thyroxine (T4) to its plasma transport protein transthyretin (TTR). The observed bioactivity could not be explained by the compounds detected through targeted analysis. Consequently, effect-directed analysis (EDA) and pull-down assays (PDA), coupled with non-targeted analysis (NTA) based on HPLC-HRMS, were employed to separate and identify the causative chemicals. In the EDA, 2 levels of orthogonal fractionation were performed and 2 fractions with highest activity were subjected to NTA and further investigation. The direct NTA of these 2 fractions did not allow identification of suspected or novel TTR ligands due to the remaining high complexity. Both the full extract and the most active fractions were subjected to the PDA, utilizing highly specific protein-ligand interactions to separate the active ligands. These were addressed by NTA conducted in 2 independent laboratories and activity of several identified TTR ligands was confirmed in the TTR bioassay. The results demonstrated that combining EDA and PDA yielded the highest identification rate, as the fractionation steps facilitated the binding and detection of less potent and/or less abundant TTR ligands in pull-down assay. The 2 laboratories, each employing different NTA workflows, successfully identified several ligands, with each laboratory contributing additional ligands outside the overlap. Unlike EDA, the PDA showed sufficient reduction of chromatographic peaks in the highly complex environmental sample, making it an effective tool for identifying bioactive ligands.

1.13.P-Th034 Metrics for Structural Diversity in Chemical Mixtures

***Mark Parnis**[1] and Sandrine Estelle Deglin[2], (1)Canadian Environmental Modelling Centre, Department of Chemistry, Trent University, Canada, (2)Health and Environmental Sciences Institute, France*

Metrics are presented for the quantification of structural diversity in chemical mixtures. Structural diversity is quantified in terms of a calculated chemical distance between mixture components based on the Abraham solvent descriptors for mixture components. Three distance metrics for structural diversity are presented, one based on the maximum difference between Abraham descriptors for components (Max-Min), one in which the first is modified to exclude minor components (Modified Max-Min), and one based on a mole-fraction weighted sum of Abraham descriptor differences between all possible mixture component pairs (Weighted Sum). Results for binary, ternary and quaternary model mixtures as well as for kerosene and Virginia cedar oil are presented and compared. The respective merits of the three approaches are discussed in the context of UVCB mixtures.

Track 2. Ecotoxicology Becomes Stress Ecology: From Populations to Ecosystems and Landscapes

2.01.A Ecological Impacts of Chemical Mixtures and Multiple Stressors: From Evaluation to Prediction

2.01.A.T-01 Chemical Mixtures and Multiple Stressors: Same but Different?

Ralf Bernhard Schaefer[1], *Michelle Jackson*[2], *Noel Juvigny-Khenafou*[3], *Stephen Osakpolor*[4], *Leo Posthuma*[5], *Anke Schneeweiss*[6], *Jurg W. Spaak*[7] *and Rolf Vinebrooke*[8], *(1)RC One Health Ruhr, University Duisburg-Essen, Germany, (2)University Oxford, Germany, (3)University Stirling, Germany, (4)BASF, Germany, (5)RIVM, Radboud University, Germany, (6)Umweltbundesamt, Germany, (7)RPTU, Germany, (8)University Alberta, Germany*

Ecosystems are strongly influenced by multiple anthropogenic stressors, including a wide range of chemicals and their mixtures. Studies on the effects of multiple stressors have largely focussed on nonchemical stressors, whereas studies on chemical mixtures have largely ignored other stressors. However, both research areas face similar challenges and require similar tools and methods to predict the joint effects of chemicals or nonchemical stressors, and frameworks to integrate multiple chemical and nonchemical stressors are missing. We provide an overview of the research paradigms, tools, and methods commonly used in multiple stressor and chemical mixture research and discuss potential domains of cross-fertilization and joint challenges. First, we compare the general paradigms of ecotoxicology and (applied) ecology to explain the historical divide. Subsequently, we compare methods and approaches for the identification of interactions, stressor characterization, and designing experiments. We suggest that both multiple stressor and chemical mixture research are too focused on interactions and would benefit from integration regarding null model selection. Stressor characterization is typically more costly for chemical mixtures. While for chemical mixtures comprehensive classification systems at suborganismal level have been developed, recent classification systems for multiple stressors account for environmental context. Both research areas suffer from rather simplified experimental designs that focus on only a limited number of stressors, chemicals, and treatments. We discuss concepts that can guide more realistic designs capturing spatiotemporal stressor dynamics. We suggest that process-based and data-driven models are particularly promising to tackle the challenge of prediction of effects of chemical mixtures and nonchemical stressors on (meta-)communities and (meta-)food webs. We propose a framework to integrate the assessment of effects for multiple stressors and chemical mixtures.

2.01.A.T-02 Does Cytochrome P450 inhibition lead to Synergy? A Mechanistic Study of Azole-Pesticide Mixtures in Enchytraeus crypticus (Annelida)

Kevin Noort[1], *Alex Robinson*[1], *Stephen James Short*[1], *Henriette Selck*[2] *and David Spurgeon*[3], *(1)UK Centre for Ecology & Hydrology, United Kingdom, (2)Roskilde University, Denmark, (3)UK Centre for Ecology and Hydrology, United Kingdom*

Chemical mixtures can exhibit additive, synergistic, or antagonistic effects. Synergistic interactions are particularly concerning as they amplify toxicity beyond predicted levels. Among known contributors to synergy, azole fungicides play a significant role due to their inhibition of cytochrome P450 monooxygenases (CYPs), essential enzymes in the phase I metabolism of lipophilic pesticides. However, a direct quantitative link between azole CYP inhibition and synergy has not been fully established. This study explores whether in vivo CYP inhibition can predict synergy in binary mixtures of azole fungicides and pesticides (azoxystrobin or cypermethrin). Using Enchytraeus crypticus as a model soil organism, CYP inhibition was quantified with an ECOD assay during azole exposure. Dose-response curves for three imidazoles (prochloraz, imazalil, miconazole) and three triazoles (propiconazole, prothioconazole-desthio, epoxiconazole) were constructed. Concurrently, survival dose-response curves were developed for azoles, pesticides, and their mixtures in a 96h survival study. Mixtures were tested using a full factorial design, combining three lethality levels of pesticides (LC10, LC25, LC50) with four inhibition levels of azoles (IC01, IC10, IC20, IC50). Mixture effects were modelled using concentration addition (CA) and observed deviations from model predictions were quantified in model deviation ratios (MDRs). MDRs, indicating synergy (?2) or antagonism (?0.5), were correlated with CYP inhibition to establish predictive relationships. Preliminary results confirm robust, reproducible CYP inhibition by azoles in E. crypticus. Initial survival tests provide accurate LCxx values for pesticides, enabling further synergy assessments. Data will be presented and discussed, linking CYP inhibition and synergistic toxicity. EU-funded Horizon 2020 MSCA-ITN program CHRONIC, Grant Agreement No. 956009

2.01.A.T-03 Synergistic Interaction Between a Toxicant and Food Stress is Further Exacerbated by Temperature

Naeem Shahid*, Ayesha Siddique and Matthias Liess, Helmholtz Center for Environmental Research, Germany*

Global biodiversity is declining at an unprecedented rate in response to multiple environmental stressors. Effective biodiversity management requires a deeper understanding of the relevant mechanisms behind such ecological impacts. A key challenge is understanding synergistic interactions between multiple stressors and predicting their combined effects. Here we used Daphnia magna to investigate the interaction between a pyrethroid insecticide esfenvalerate and two non-chemical environmental stressors: elevated temperature and food limitation. We hypothesized that the stressors with different modes of action can act synergistically. Our findings showed additive effects of food limitation and elevated temperature (25°C, null model effect addition (EA)) with model deviation ratio (MDR) ranging from 0.7 to 0.9. In contrast, we observed strong synergistic interactions between esfenvalerate and food limitation at 20°C, considerably further amplified at 25°C. Additionally, for all stress combinations, the synergism intensified over time indicating the latent effects of the pesticide. Consequently, multiple stress substantially reduced the lethal concentration of esfenvalerate by a factor of 19 for the LC50 (0.45 to 0.024 ?g/L) and 130 for the LC10 (0.096 to 0.00074 ?g/L). Although predicting multiple stressor impacts is challenging, the stress addition model (SAM) proved effective in predicting combined effects. Investigating these interactions with field-relevant pesticide mixtures provides a more realistic approach; therefore, we will also present results on such combined effects.

2.01.A.T-04 Acclimation and Recovery to Pharmaceutical Pollution in a Common Host Fish Under Parasitic Infection

Lea Lorrain-Soligon *and Aurelie Goutte, Sorbonne Universite- CNRS-EPHE, France*

Freshwater ecosystems face increasing pressure from multiple stressors, including pharmaceutical contamination and biological interactions, yet their combined impacts remain poorly understood. This study investigates the interplay between chemical exposure and parasitism, focusing on the European chub (Squalius cephalus), a widespread freshwater fish. Specifically, we examined the effects of paracetamol exposure and acanthocephalan parasite infection on behavior and coloration across acute (16 ?g·g?¹ for two days), chronic (1.6 ?g·g?¹ for three weeks), and recovery phases (three weeks). Acute exposure significantly reduced activity and disrupted coloration, while chronic exposure resulted in subtler behavioral changes. Parasitism did not mitigate acute impacts but slightly increased activity during chronic exposure, highlighting complex stressor interactions. Importantly, all measured effects subsided during recovery, indicating the reversible nature of these stressor-induced changes. Our findings emphasize the ecological significance of temporal dynamics and biotic interactions in modulating pollutant effects. By integrating biological stressors, chemical mixtures, and temporal exposure patterns, this research underscores the importance of considering multifactorial influences for accurate risk assessment and ecosystem management. This study was founded by the ANR HELP (ANR-22-CE34-0014), and conducted at the CEREEP Ecotron Ile de France.

2.01.A.T-05 Toxic Heatwave: Chemical Pre-Exposure Alters Springtail Survival in Rising Extreme Temperatures

Micha Wehrli[1]*, Jian Ge*[2]*, Stine Slotsbo*[3] *and Martin Holmstrup*[3]*, (1)Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Department of Ecoscience, Aarhus University, Aarhus, Denmark, (3)Department of Ecoscience, Aarhus University, Denmark*

Climate change and chemical pollution are accelerating biodiversity loss, emphasizing the need to understand interactions between multiple stressors such as toxic chemicals and extreme temperatures. We investigated this using the Framework of Thermal Death Time analysis (TDT) with 3-week pre-exposed springtails. This was achieved by exposing Folsomia Candida (Collembola, Isotomidae), to one control, and two different sublethal treatments of copper and the fungicide fluazianam at a previously found field dose (2 and 10 mg/kg dw soil) at an acclimation temperature of 20 and 24 degrees over 3 weeks. The exposure soils are a LUFA 2.2 standard test soil for the fluazinam exposure and a soil sampled from a copper polluted site in Hygum, Denmark (Former wood treatment facility, with copper sulfate). Subsequently, the animals were exposed to static thermal tolerance assays for increasing exposure times, to generate logistic dose-response curves (survival versus exposure time), for each exposure temperature.

This was used to define how much time is needed to reach 50% mortality (Lt50) at each respective temperature (i.e. a dose of thermal stress). Results showed an effect of acclimation temperature, where 24 °C acclimated animals survived up to twice as long as 20 °C acclimated organisms. Congruently, we found that the two pre-exposure soils strongly affected the springtails' thermal sensitivity where the Lt50 at 33 °C for the 20 °C acclimated animals was 299 minutes (5h) for Hygum soil and 697 minutes (11h) for LUFA soil. This suggests that different soil types drastically change heat sensitivity. Finally, we found the decrease in heat tolerance was larger for fluazinam-exposed animals. This was not the case for 24 °C acclimated organisms where the Lt50 times were not reduced significantly. We also measured the internal concentrations of fluazinam and found increased levels of the parent compound and a hydroxy-metabolite at higher acclimation temperature and the higher exposure concentration. These findings highlight that toxic chemicals significantly alter susceptibility to extreme heat events, with effects modulated by acclimation temperature and soil type. This complexity underscores the challenges for ecological risk assessment and temperature-dependent toxicokinetic-toxicodynamic (TK-TD) modeling in a warming climate.

2.01.B Ecological Impacts of Chemical Mixtures and Multiple Stressors: From Evaluation to Prediction

2.01.B.T-01 Organic Matter Decomposition Responds Differently to Temperature Elevation at Medium Pesticide Concentrations

Verena Schreiner[1]*, E. Juliana Perez M.*[2]*, Robert Koch*[1]*, Naeem Shahid*[3]*, Ayesha Siddique*[3]*, Matthias Liess*[3] *and Ralf Bernhard Schaefer*[1]*, (1)University of Duisburg-Essen; Research Center One Health, Germany, (2)RPTU, Germany, (3)UFZ Leipzig, Germany*

The decomposition of allochthonous organic matter is the base of the so-called brown food web, which dominates in headwater streams. Stressors such as pesticides and temperature increase are known to affect organic matter decomposition by impacting associated organisms such as aquatic fungi or macroinvertebrate shredders. To be as close to natural systems as possible, we conducted an outdoor stream mesocosm study with repeated pesticide exposure and two temperature levels to investigate effects on microbial and total (microbially and macroinvertebrate?mediated) decomposition at three time points. We hypothesised that microbial and total decomposition will be reduced with increasing pesticide exposure, while the temperature increase at high exposure levels intensified the reduction but mitigated the effects at low exposure levels. We repeatedly spiked four levels of a realistic mixture containing 13 pesticides were repeatedly spiked to heated (temperature increase ~3.5 °C) and non-heated mesocosms. Per mesocosm, we deployed three fine and coarse mesh bags each filled with black alder leaves (Alnus glutinosa, (L.) Gaertn.) for two weeks allowing for microbial and total (microbial and macroinvertebrate) decomposition, respectively, at three time points spanning over two study years. We investigated effects on organic matter decomposition, fungal biomass, exo-enzyme activity as well as fungal communities. In contrast to our expectations, the temperature-normalised microbial decomposition did not vary between any of the different treatments. The absence of a pesticide effect at this concentration level might be caused by permanently altered fungal communities. That the initial fungal communities (July 23) differed between control and high pesticide exposure, while they overlapped later (August 23) points in this direction. The total decomposition only minorly responded to high pesticide exposure, which contrasts previous findings. At medium concentrations, the total decomposition at ambient temperatures differed from the controls for the two August time points, with a strong increase in the second study year. This is possibly related to higher macroinvertebrate feeding rates related to compensation for the single stress of pesticides, while an additional temperature increase disguised this effect. During the conference, we will present and discuss data on the fungal community over all time points, the fungal biomass as well as the fungal exo-enzyme activity.

2.01.B.T-02 Understanding Spatial Drivers of Lake Biodiversity using eDNA

Niamh Eastwood[1]*, Arron Watson*[2]*, Jiarui Zhou*[3] *and Luisa Orsini*[3]*, (1)University of Birmingham, Birmingham, United Kingdom, (2)University of Birmingham, United Kingdom, (3)School of Biosciences, University of Birmingham, United Kingdom*

Biodiversity is negatively impacted by anthropogenic environmental changes such as land use change, chemical pollution and climate change. Freshwater biodiversity in particular provides key ecosystem services yet suffers from river inflow bringing agricultural runoff and urban discharge. Identifying the causes of biodiversity decline across is challenging due to the intricate interplay between biodiversity and environmental stresses. In this study, we used environmental DNA extracted from 52 lakes in England and applied multi-objective optimization explainable multi-view learning, a machine learning approach to discover complex relationships. We identified landscape-level drivers of community biodiversity in lake ecosystems. Plant protection products, such insecticides and fungicides were identified as the most important factors driving biodiversity dynamics, followed by physico-chemical parameters. Our holistic, data-driven approach provides insights into large-scale biodiversity changes and could inform conservation efforts and regulatory interventions to protect biodiversity from harmful pollutants.

2.01.B.T-03 Interactive Effect of Urban Stressors: Fluoxetine, Light Regime and Noise

Asma Mohammed Al Shuraiqi *and Michael J Barry, Biology department, Sultan Qaboos University, Oman*

There is a worldwide trend towards urbanization. More and more people are moving to cities, encroaching on surrounding natural areas. Urbanization brings multiple stressors to aquatic ecosystems including chemicals, noise pollution and artificial light at night (ALAN). To date, there is no information on interactions between these three forms of stress. The aim of our study was to investigate the effects of a common chemical contaminant (fluoxetine), ALAN and sudden noise (a motorboat pass by) on the key behaviors in a model fish species, Danio rerio. We hypothesized that when a fish s endogenous systems are compromised by external stressors and anthropogenic noise increases the signal to noise ratio for useful auditory information, that their ability to respond to predators will be reduced. In this study zebrafish were exposed to fluoxetine (0 ng/L, 3 ng/L, and 300 ng/L with 4 replicates per treatment; sample size: 11 male: 11 female per replicate) and two light regime (2 replicates: 12 h light: 12 h dark, and other 2 replicates: 12 h light: 12 h 50% of light intensity) for 27 days. Then fish boldness, anxiety, feeding behavior and habitat preference in the presence of a visual predation cue (bird) were measured (recording videos using USB camera) with or without motorboat engine noise using underwater speaker. All recorded behavior videos were analyzed using SwarmSight software. The results showed that fluoxetine alone decreased zebrafish boldness, although effects were dose- sex-dependent. Zebrafish exposed to artificial light at night showed higher activity levels and were bolder than fish that were raised in an environment with a normal photoperiod. Noise exposure often resulted in increased activity. In several experiments, fluoxetine suppressed the effects artificial light at night, suggesting an antagonistic interaction. Fluoxetine also reduced behavioral responses to sudden noise in several experiments. In the habitat preference test, there was no effect of noise on fish activity in the absence of a predator. However, when the bird was present, noise increased activity by almost 100%. Overall, all three factors affected responses to predation, leading to behaviors that may increase zebrafish vulnerability. This study highlighting the importance of considering multiple forms of stress and their interactions when assessing the effects of urbanization of aquatic systems. The authors thank The Research Council Oman (TRC) (RC/GRG-SCI/BIOL/21/04) grant to AAS and a Sultan Qaboos University internal grant (IG/SCI/BIOL/21/01) to MJB.

2.01.B.T-04 Trojan Horse Mechanism in Soil: Myth or Legend?

Sam van Loon[1]*, Ge Xie*[1]*, Claus Svendsen*[2] *and Cornelis A.M. van Gestel*[1]*, (1)Vrije Universiteit Amsterdam, Netherlands, (2)Centre of Ecology and Hydrology Wallingford, United Kingdom*

The trojan horse effect, the theory that microplastics (MPs) may adsorb chemicals in the natural environment with the subsequent release of said chemicals upon entering an organism, is often assumed in the terrestrial environment. Although it has been described for the aquatic environment, the assumption that it also happens in the terrestrial environment remains largely unfounded. The literature that is available may provide only slight insight into the complex interactions of MPs with other xenobiotics, as they often consist of binary mixture experiments of metals and MPs, and do not show competition for binding to the MPs. These studies also do not provide insight into the combined effects of co-exposure to other ubiquitous environmental contaminants like poly- and perfluorinated alkyl substances (PFAS). This study uses binary and ternary mixture toxicity experiments with adult Folsomia candida to show the interactions of xenobiotics in mixtures with MPs. The lipophilic pesticide chlorpyrifos (Log Kow = 4.96) and the hydrophilic pesticide imidacloprid (Log Kow = 0.57), along with the amphiphilic PFAS perfluorobutane sulfonamide (FBSA) were tested in combination with linear low density polyethylene MPs (10-50µm). Besides the binary mixture toxicity assessments of all combinations of compounds, tests were also performed to examine the ternary mixture toxicity of MPs, FBSA and either of the pesticides, as well as MPs and both pesticides, allowing for the examination of the complex interactions of the different xenobiotics with the MPs, as well as providing insight into the competitive binding of the xenobiotics to the plastic particles. Five replicates of Lufa 2.2 soil containing different combinations of the mentioned compounds were tested at 0.25, 0.5, 1, 2, and 4 toxic units (TUs), based on previously determined EC50 values for reproduction. This allowed us to evaluate the full effect plane, including synergism and antagonism, but also dose-ratio and dose-level dependent effects of the binary and ternary mixtures. Although the data has all been collected now, the analysis is ongoing and results will be presented during the meeting in Vienna. Preliminary data shows compound-specific interactions with the MPs. This study will therefore provide valuable insight not only in the ecotoxicological effects of these mixtures, but also

on complex mixture toxicity itself. This research was funded by the PAPILLONS project, European Union's Horizon 2020 Research and Innovation Programme: Grant Agreement Number 101000210; https://www.papillons-h2020.eu/, and by the Open Technology Program of the Netherlands Organization for Scientific Research (NWO), domain Applied and Engineering Sciences (TTW) under project number 18725.

2.01.P-Mo119 Assessing the Toxicity of a Mixture of Benzotriazole Ultraviolet Stabilizers to Zebrafish (*Danio rerio*): Insights into Embryotoxic and Molecular Effects

***Luis Terrazas Salgado*[1]**, *Justin Dubiel[1], Lauren Zink[2], Zhe Lu[3] and Steve Wiseman[1], (1)Department of Biological Sciences, University of Lethbridge, Canada, (2)University of British Columbia, British Columbia, Canada, (3)Institut des Sciences de la Mer de Rimouski, Universite du Quebec Rimouski, Canada*

Benzotriazole ultraviolet (BUV) stabilizers are a group of industrial chemicals used in industrial (e. g. textiles, plastic, building materials) and personal care products (e.g. sunscreens, body lotions, hair dyes) to protect materials or skin from damage against harmful UV-radiation. They are considered a class of emerging environmental contaminants, although they have been around for nearly six decades and they can absorb UV rays from sunlight (within the 280-400 nm spectrum). BUVs (e.g., UV-P, UV-326, UV-327, UV-328, and UV-329) have been detected in different marine compartments worldwide, such as marine waters and sediments A variety of marine animals, from small crustaceans to large mammals, have accumulated BUVs. BUVS have been detected in aquatic environments at concentrations ranging from 0.05 to 99,200 ng/L; however, there are few studies on the effects of BUVS mixtures on aquatic organisms. Studies show that BUVS can affect behavioral responses and acetylcholinesterase activity, indicators of neurotoxicity. Additional studies support the hypothesis that BUVSs induce oxidative stress and neuroinflammation in fish. The objective of this study was to evaluate the embryotoxicity of a mixture of BUVS and to use whole transcriptome sequencing to link toxicities with effects. We selected 5 UVBs including UV-326, UV-327, UV-328, UV-329, and UV-P for toxicological analysis, as these are among the most frequently detected in aquatic environments. Using microinjection, freshly fertilized embryos were exposed zebrafish embryos to 3 different doses of the BUVS mixtures before gastrulation, and effects on mortality, hatch success, heart rate, and malformations were evacuated until 14 days post-fertilization. We observed an increase in mortality dependent on the dose of BUVS, for the control group mortality was 2%, and 15, 23, and 33 % for the groups treated with BUVS. Likewise, BUVS caused a decrease in heart rate at 48 hours post-fertilization, the control group presented an average of 161 beats per minute (bpm), while the treated groups averaged 159, 157, and 156 bpm. Also, the larval size, eye area, yolk area, and melanophores in the head area in the treated groups decreased compared to the control group. Whole transcriptome (mRNA, non-coding RNAs) analysis is currently being performed to determine the molecular basis of the observed effects. This study provides new insight into the toxicity and hazards of aquatic organisms.

2.01.P-Mo130 CheOSmix - A Data-Reuse Approach to Determining Chemical Mixture Risk Driver Heterogeneity in European Freshwater

Jana Schor[1], Tobias Schulze[2], Nadin Ulrich[1], Ilhan Mutlu[1], Kazi Nafiul Hassan[1], Martin Krauss[3], Werner Brack[3], Triet Doan[4], Sven Bingert[4], Jan Bumberger[1], Wibke Busch[5] and ***Joerg Hackermueller*[1]***, (1)Helmholtz Center for Environmental Research, Germany, (2)German Environment Agency, Germany, (3)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research, Leipzig, Germany, (4)Gesellschaft fur wissenschaftliche Datenverarbeitung mbH Gottingen, Germany, (5)Helmholtz Center for Environmental Research, Leipzig, Germany*

Chemical pollution of aquatic environments involves complex combinations of substances. Mixture exposure can provoke combined effects even if the concentrations of individual substances remain below their effect thresholds. Therefore, efforts are ongoing to better consider mixture effects in chemical safety regulation. A debate accompanies these efforts on whether only a few substances drive the aquatic mixture risk and, thus, whether more strictly regulating these individual substances would be sufficient or whether a large heterogeneous set of driver substances needs to be considered. Here, we employed a data-reuse strategy to investigate the heterogeneity of drivers of chemical mixture risk to aquatic species. We initially demonstrate that drivers are heterogeneous using data from a single measurement campaign that enables comparing drivers between sites due to a set of consistently measured substances. Subsequently, we extended our analysis to an extensive collection of chemical monitoring data from the NORMAN network. These data originate from different measurement campaigns that focused on diverging sets of substances at various time points. We, therefore, aggregated the data quarterly and per quarter cluster sites according to the set of measured substances. Our study concludes that an extensive list of substances drives chemical mixture risk across Europe and that these substances were highly heterogeneous between

locations. Notably, the drivers of mixture risk were species-specific and exhibited variability over time. Also, we established that lacking monitoring data hindered a more precise analysis, particularly regarding temporal variability. We have stored all collected and curated data in a graph database. We present a chatbot that builds on a graph database - grounded large-language AI model to translate between the researcher and our database and, therefore, allows querying this knowledge for non-computer science experts.

2.01.P-Mo155 Co-occurrence of Microplastics and Contaminants of Emerging Concern in River Water, Sediment and Fish: The Case Study of Júcar River basin (Spain)
***Vasiliki Soursou**[1], Julian Campo[2], Jacopo La Nasa[3], Francesca Modugno[4] and Yolanda Pico[5], (1)University of Valencia, Valencia, Spain, (2)CSIC, Spain, (3)University of Pisa, Italy, (4)Department of Chemistry and Industrial Chemistry, University of Pisa, Italy, (5)University of Valencia, Moncada, Valencia, Spain*
There is rising concern about the environmental pollution by microplastics (MPs), especially about their ability to accumulate various types of contaminants on their surface. These contaminants include pesticides, pharmaceutical and personal care products (PPCPs), per-/ poly-fluoroalkyl substances (PFASs) and polycyclic aromatic hydrocarbons (PAHs). The co-occurrence and combined toxicity of MPs and organic pollutants needs to be studied. Thus, the presence of MPs, pesticides, PFASs, PPCPs and PAHs in water, sediment and fish samples from the Júcar River basin (Spain) was determined. The Júcar River flows through three different provinces, being one of the most important rivers in E Spain. The extraction was optimized for each matrix and contaminant. Density separation and digestion were combined for MPs extraction from water and sediment, while a microwave-assisted digestion was performed for MPs present in the fish gastrointestinal track. For the organic pollutants, solid-phase extraction and microwave-assisted extraction were adapted for each matrix. For MPs, ?FTIR and Pyrolysis coupled with Gas Chromatography-Mass Spectrometry (Py-GC-MS) were utilized, while the PAHs were analysed using GC-MS and the rest of the contaminants were analyzed by High Pressure Liquid Chromatography-High Resolution Mass Spectrometry (HPLC-HRMS/MS), in both target and non-target modes. ?FTIR indicated the presence of MPs in all water samples (0.1- 6.9 MPs L-1), whereas 73% of the sediment samples and 66% of the fish samples were polluted by MPs (sediments: 20- 140 MPs Kg-1, fish: 6.7- 26.7 MPs g-1). The main polymer types were polyethylene (water and sediments) and polyvinyl chloride (fish). Tebuconazole and difenoconazole were the most abundant pesticides in water. Perfluorobutane sulfonate and the painkillers ibuprofen and tramadol, were found in all water samples. The initial water analyses points to correlations between MPs and pesticides (i.e. propazine, imazalil, thiabendazole) and the flame retardant tris(chloropropyl) phosphate, particularly at two sampling points (highest MP amounts). Completing all analyses of sediment and fish samples will provide a better understanding of MPs and emerging contaminants co-occurrence. The risk assessment that is currently being performed, allows the estimation of the environmental toxicity that multiple anthropogenic pressures cause to wildlife and human health in a basin representative of the Mediterranean. This work has been supported by the Generalitat Valenciana (GV) through the Prometeo Programme CIPROM/2021/032. V. Soursou also acknowledges her pre-doctoral contract ACIF/2021/408 and the grant CIBEFP/2023/154, both funded by the GV. The latter allowed her to work at the University of Pisa, Italy for 3 months.

2.01.C Ecological Impacts of Chemical Mixtures and Multiple Stressors: From Evaluation to Prediction

2.01.C.T-01 Bioenergetic Responses Shape the Impacts of Pharmaceuticals and Warming on Freshwater Arthropods and Ecosystem Functioning
***Claire Duchet**[1], Julie Verheyen[2], Ria Van Houdt[2], Katerina Grabicova[3], Vladimira Dekanova[4], Robby Stoks[2] and David Boukal[3], (1)Faculty of Science, University of South Bohemia, Czech Republic, (2)University of Leuven, Belgium, (3)University of South Bohemia, Czech Republic, (4)University of Lisbon, Portugal*
Freshwater ecosystems face growing threats from pharmaceutical contaminants (PhACs) and climate change-induced warming. However, the combined effects of these stressors on freshwater taxa remain poorly understood, particularly the mechanisms connecting (sub)individual responses to broader ecological impacts. We explored the effects of environmentally realistic concentrations of PhACs and warming on two aquatic arthropods, Asellus aquaticus (Isopoda) and Cloeon dipterum (Ephemeroptera), in outdoor pond mesocosms during winter and summer. By assessing physiological traits (bioenergetic responses and oxidative damage) alongside population densities and ecosystem functions, we identified seasonal patterns in sensitivity to both stressors. In winter, PhACs reduced energy availability and increased oxidative damage, while in summer, PhACs elevated energy availability and decreased

oxidative damage. Ecosystem functions, such as leaf litter decomposition and insect emergence, reflected population- and bioenergetic-level responses. Reduced leaf litter decomposition was linked to declining Asellus abundance under combined stressors, whereas decreased Cloeon emergence in summer was attributed to PhAC-induced fitness reductions. Warming alone consistently reduced arthropod abundances and emergence, except for increased Asellus abundance in winter. Crucially, the bioenergetic-mediated effects of these stressors outweighed their direct impacts. This study underscores the vulnerability of aquatic arthropods to PhACs and warming, highlighting consequences for energy metabolism, population dynamics, and ecosystem functioning. These findings emphasize the need for integrated strategies to mitigate the ecological impacts of emerging contaminants and climate change.

2.01.C.T-02 Integrating Statistical Models and Multiple-Stressor Null Models: A Framework for Analysing Stressor Interactions

__Iris Madge Pimentel__[1], Dania Albini[2], Arne J. Beermann[1], Florian Leese[1], Samuel Macaulay[3], Christoph Matthaei[4], James A. Orr[5], Jeremy J. Piggott[6] and Ralf Bernhard Schaefer[1], (1)University Duisburg-Essen, Germany, (2)University of Exeter, United Kingdom, (3)University of Oxford, United Kingdom, (4)University of Otago, New Zealand, (5)University of Queensland, Australia, (6)Trinity College Dublin, Ireland

Understanding how environmental and toxicant stressors interact is crucial in multiple-stressor and ecotoxicological research. Stressor interactions are identified as deviations from theoretical null models that describe how stressors combine. Selecting an appropriate null model is a critical step and should be grounded in theory. In the co-tolerance framework, three distinct null models are used to characterize combined stressor effects. They assume that stressors act independently, but they differ in their assumptions on how stressor sensitivities correlate within a community or population: the multiplicative model (no correlation), the simple addition model (negative correlation), and the dominance model (positive correlation). To evaluate the magnitude to which joint stressor effects deviate from null model predictions, the model deviation ratio is commonly used. Fixed thresholds are used to identify interactions; however, this approach does not account for empirical uncertainty. Alternatively, regression models can evaluate statistical significance of interaction terms, however, they introduce constraints by imposing a specific null hypothesis on stressor combinations that cannot flexibly be changed by the analyst. To address these challenges, we present a theoretical framework that (1) clearly communicates which regression model specification aligns with which null model and (2) uses post-estimation hypothesis testing to evaluate a specific null model, if regression results cannot directly be used. Interaction estimates can be calculated from adjusted model predictions, and associated standard errors are derived using either the delta method, posterior simulations or bootstrapping. This approach enables analysts to flexibly test different null models independent from regression model structure, ensuring robustness in describing empirical patterns. We illustrate our approach with a case study and validate the calculated confidence intervals through data simulations. This work is funded by Deutsche Forschungsgemeinschaft (DFG, German Research Foundation: CRC 1439/1 (RESIST) [grant number 426547801]).

2.01.C.T-03 Probabilistic Risk Assessment of Chemical Mixtures: Cumulative Effects and Joint Risk of Pesticides in Freshwater Biological Communities

Nikiforos Alygizakis[1], Remy Beaudouin[2], Mirco Bundschuh[3], Belen Gonzalez-Gaya[4], Udo Hommen[5], Anders L. Madsen[6], Sophie Mentzel[7], Andreu Rico[8], Francisco Sylvester[9], Samuel Welch[7], Paul van den Brink[10] and __Jannicke Moe__[7], (1)University of Athens, Greece, (2)INERIS, France, (3)University of Kaiserslautern-Landau, Germany, (4)Plentzia Marine Station, University of the Basque Country, Spain, (5)Fraunhofer IME, Germany, (6)HUGIN EXPERT & Aalborg University, Denmark, (7)Norwegian Institute for Water Research, Norway, (8)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (9)Faculty of Biological Sciences, Goethe University Frankfurt, Frankfurt, Germany, (10)Wageningen University and Research, Netherlands

We have developed a hierarchical probabilistic model (object-oriented Bayesian network - BN) for exploring ecological risk of pesticides mixtures to non-target biological endpoints in freshwater ecosystems. Our study is based on a monitoring dataset for 10 stream sites in Germany, with three pesticides per site, in total 13 different pesticides. Traditional environmental risk assessment (ERA) approaches are largely based on single-substance and single-species testing. Two major challenges for more realistic ERA are therefore assessing chemical mixtures and community-level responses. Modelling methods developed for handling these challenges typically aim to reduce the complexity of the chemical stressors (e.g., a Mixture Assessment Factor) and of the community response. Our BN model, in contrast, incorporates an empirical dose-response relationship for each pesticide-to-endpoint pathway. For each pesticide, we used the model PERPEST to predict the probability of three alternative effect classes (none, slight, clear) for up to 10 biological endpoints, using a database of mesocosm studies and case-based reasoning. We then used the BN to aggregate the effect probabilities from single pesticides, via pesticide groups with similar mode of action, to mixtures by joint probability (Boolean or) expressions. Furthermore, the BN aggregates the probability of effect classes from the level of individual endpoints (e.g., algae, rotifers, insects), to endpoint groups (e.g., plants, zooplankton, macroinvertebrates), and subsequently to the community level. This BN enables exploring of pesticide risks from different angles by joint probability calculation in combination with alternative assessment rules. For example, at a given site, we can address questions such as: (1) What is the probability that at least one pesticide will have a clear effect on at least one biological endpoint? (2) Which endpoint groups are most likely to be affected by the observed pesticide mixture? (3) Which group of pesticides contribute most to community-level risk? This work originates from the NORMAN Network workshop "Improving the use of (semi-)field data for the risk assessment of chemicals" (WG2 Bioassays), organized in November 2022 by the Expert Group on Ecosystem level effects of chemicals of emerging concern on aquatic ecosystems. The pesticide monitoring data were introduced to the workshop by Matthias Liess.

2.01.C.T-04 Derivation of Field-Based Macroinvertebrate Sensitivities and Stressor-Specific Indicators

Jonas Groning *and Matthias Liess, Department of Ecotoxicology, Helmholtz Centre for Environmental Research, Germany*

Aquatic ecosystems are exposed to multiple stressors. A large number of metrics and indicators exist to describe their effects. While common stressor-integrating metrics (e.g. ecological quality ratio) allow a general description of ecological status, stressor-specific indicators (e.g. saprobic index, SPEARpesticides) necessary for effect attribution are rare. Therefore, we have developed a method to derive specific indicators for a variety of environmental stressors based on field-based estimates of macroinvertebrate taxa sensitivities. Based on a comprehensive stream monitoring data set from 101 stream sections, including measurements of various environmental and anthropogenic stressors and macroinvertebrate abundances, we fitted dose-response curves and derived median effective doses (ED50s) for each taxon and stressor. Subsequently, we calculated the empirical SPEAR (empirical SPecies At Risk, e-SPEAR) bioindicator, which represents the abundance-weighted mean ED50 of the macroinvertebrate community to one stressor. Indicator performance and specifity was assessed using single and multiple linear regressions. We were able to derive ED50s for 139 macroinvertebrate taxa and 15 stressors. Taxa sensitivities were highly correlated for individual stressor combinations (Pearson correlation, up to $r > 0.50$ or $r < -0.50$), indicating the existence of generally more or less sensitive species. Of the 15 e-SPEAR indicators developed, 11 showed significant ($p < 0.05$) linear regressions with the respective stressor values, and 8 indicators performed well ($R^2 > 0.20$). The indicators performed best for pesticide toxicity, oxygen, hydromorphology and nitrate ($R^2 > 0.30$), followed by ammonium, flow velocity, pH and grabby substrate. This ranking may indicate stressor importance, as more dominant stressors would produce more pronounced community dose-response relationships. The multiple regressions revealed that the stressors corresponding to the e-SPEARs had the highest individual contribution to the total explained variance (39% to 94% of R^2). Accordingly, although taxa sensitivities and stressor gradients were highly correlated, we were able to generate indicators with a high stressor specificity. The indicators allow a specific attribution of effects to individual stressors, which is essential for targeted monitoring and management.

2.01.C.T-05 Sequential Toxicity of Pesticides to *Enchytraeus Crypticus*: Using Toxicokinetic−Toxicodynamic Modelling

Emily Eagles[1]*, Fie Rubner-Petersen*[2]*, Sylvain Bart*[3]*, Darren Sleep*[1]*, Stephen James Short*[1]*, Elma Lahive*[1]*, Nina Cedergreen*[2] *and David Spurgeon*[4]*, (1)UK Centre for Ecology & Hydrology, United Kingdom, (2)University Copenhagen, Denmark, (3)MO-ECO2, France, (4)UK Centre for Ecology and Hydrology, United Kingdom*

Considering the toxicity of pesticides in scenarios which relate to those seen in the environment is important in determining the risk posed to organisms. Although the presence of multiple chemicals in mixtures is acknowledged in toxicity studies, there may be a sequential timeline of exposure due to application timings. The time between exposure pulses may allow for recovery, be it toxicokinetic via excretion and metabolism or toxicodynamic via damage repair. However, if a subsequent exposure pulse occurs before recovery then carry-over toxicity from the first chemical may occur. Here we assess the effects of sequential exposure of Enchytraeus crypticus to combinations of pesticides in acute aquatic exposures. Cypermethrin along with one of three other pesticides, chlorothalonil, azoxystrobin or prochloraz, were applied in sequence separated by a recovery period. In all cases there was a sequence effect seen. When cypermethrin was applied during the first pulse, the slow recovery caused carry-over toxicity and higher mortality by the end of the study, this contrasted with exposure to the same combination in the reverse order. Chemical analysis supported that the short recovery period used did not allow for complete toxicokinetic recovery to cypermethrin, as internal concentrations were still elevated during the second pulse period, hence simultaneous exposure was present for some period during these studies. Using toxicokinetic?toxicodynamic modelling to predict the effects of the sequential studies indicated the importance of understanding the carry-over effects following pulse exposures, as the cypermethrin predictions did not accurately align with the delay period seen before toxicity effects are observed. At some concentrations synergism leading to toxicity above that predicted may also play a role in the difference between observed and predicted toxicity in the model. The occurrence of both carry-over toxicity and sequence effect in these studies highlight the importance of considering the potential for sequential exposure when determining the risk of pesticide mixtures.

2.01.P Ecological Impacts of Chemical Mixtures and Multiple Stressors: From Evaluation to Prediction

2.01.P-Mo109 Long-term Trends for Biodiversity in a Multi-Stressor Environment

Jan Koschorreck, *German Environment Agency, Germany*

The triple planetary crisis chemical pollution, biodiversity loss, and climate change poses significant challenges for environmental management and monitoring. Recent advances in environmental chemistry and biology have generated unprecedented data, yet their transformative potential remains largely unused due to a lack of standardization, expertise, and resources, as well as sociological barriers. National Environmental Specimen Banks (ESBs), established in the late 20th century, have pioneered systematic sampling and archiving of biological and non-biological matrices to support chemical monitoring, review the effectiveness of chemicals management and enable retrospective and future research. The German ESB, one of the most advanced of its kind, has archived over 500,000 subsamples from terrestrial, freshwater, and coastal ecosystems over four decades. 15 species, including fish, molluscs, terrestrial vertebrates, seabirds, tree leaves, suspended matter and soils, were continuously sampled according to strict protocols. Uniquely, the cold chain begins in the field after sampling with the samples being stored over liquid nitrogen. Samples are cryo-archived at temperatures below ?150°C, preserving their integrity for comprehensive analyses. These samples have been extensively characterized for pollutants (e.g. organic pollutants as well as metals and chlorinated, brominated and fluorinated pollutants) and tested using innovative approaches, including high-resolution mass spectrometry (HRMS) non-target screening (NTS), transcriptomics, and eDNA metabarcoding as well as a wide range of classical ecotoxicity tests. These methods have enabled retrospective tracking of biodiversity changes, invasive species occurrences, and population genomics trends, offering insights into the interplay between chemical pollution and biodiversity shifts. The German ESB demonstrates the potential for integrated monitoring that links chemical and biodiversity data to understand environmental changes and predict future trends. The bank s samples and data are available to the scientific community, fostering collaborative research to inform chemical management, environmental monitoring, and nature conservation policies. These efforts contribute to advancing integrated environmental assessment and addressing the challenges of the planetary crisis.

2.01.P-Mo110 Defining a Safe Operating Space for European River Biodiversity in the Context of Multiple Stressors – DESTRESS Project

Jennifer Laurent[1]*, Anna Sobek*[2]*, Jes Rasmussen*[3]*, Paulina Ramirez- Monsalve*[4]*, Katarina Ana Cetinic*[5]*, Daniela Cortes*[6]*, Milo Leon de Baat*[7]*, Peter Haase*[6]*, Ciaran Murray*[4]*, Anders Nielsen*[8]*, Iris Pit*[7]*, Susanne Claudia Schneider*[5]*, James Sinclair*[6]*, Dennis Trolle*[8] *and Annemarie van Wezel*[7]*, (1)Stockholm University, Sweden, (2)Environmental Science, Stockholm University, Sweden, (3)Aarhus University, Denmark, (4)Norsk institutt for vannforskning, Denmark, (5)Norsk institutt for vannforskning, Norway, (6)Senckenberg Research Institute, Germany, (7)University of Amsterdam, Netherlands, (8)WaterITech, Denmark*

The triple planetary crisis climate change, chemical pollution, and biodiversity loss represents an interconnected challenge with profound implications for river ecosystems. These factors affect not only freshwater ecosystems biodiversity but also the management of water resources, for human consumption in terms of quantity and quality. In this context, the DESTRESS project aims to understand how the interactions between multiple stressors flow regimes, chemical pollution, and land use affect river biodiversity. By identifying the thresholds and boundaries for ecological resilience, DESTRESS seeks to support sustainable management strategies tailored to current challenges. In DESTRESS, we use long-term biodiversity time-series on river macroinvertebrates collected across Europe and environmental data to relate biodiversity trends to extreme hydrological events and chemical contamination. This transdisciplinary approach integrates macroinvertebrate inventories, flow metrics, and toxicity models across geographical regions within Europe. Data science and machine learning techniques will be applied to analyze large datasets, and identify patterns and resilience thresholds of biodiversity to anthropogenic stressors. Additionally, direct collaboration with water managers and authorities at various levels will ensure that the analyses focus on actionable solutions for water management and biodiversity conservation. The expected results will provide a deeper understanding of the critical thresholds beyond which stressors and hydrological pressures begin to cause biodiversity losses. These results will provide recommendations for water managers on ecologically acceptable thresholds to protect biodiversity while ensuring sustainable water resource management. Ultimately, the DESTRESS project aims to provide Safe Operating Spaces as operational tools for more resilient and adaptive environmental policies.

2.01.P-Mo111 Effect of Cumulative Municipal Wastewater Exposure on Benthic Macroinvertebrate Assemblages: An Experimental Stream Approach

Aphra Mary Sutherland*, Frederick Wrona and David Barrett, University of Calgary, Canada*

Municipal wastewater effluent (MWWE) is a common source of nutrient enrichment in urban waterways but, increasingly, also provides a route for many pharmaceuticals and other chemicals not targeted by wastewater treatment to be released into aquatic systems. Benthic macroinvertebrates community endpoints such as species diversity metrics and changes in composition have been utilized to assess responses to nutrient enrichment, but these endpoints are not well characterized in systems where MWWE contains increasingly diverse chemical mixtures and in systems with contributions from consecutive wastewater treatment plants (WWTPs). Community endpoints may be better evaluated for complex MWWE mixtures in the environment in artificial stream systems where MWWE exposure can be controlled, while maintaining elements of the in-situ receiving environment. An assessment of a range of benthic macroinvertebrate community endpoints was performed at the Advancing Canadian Water Assets facility in Calgary, Canada using a control stream (Bow River water with background MWWE) and a treatment stream with an additional 5% of total stream volume input of treated MWWE. Benthic macroinvertebrate communities characterized by conventional area-limited Surber samples showed no differences between control and treatment streams. In contrast, when using more highly controlled artificial substrate samplers, exposed in the streams for six weeks, displayed significantly lower taxonomic diversity and evenness in the treatment streams, while the relative contribution of the dominant taxa was significantly higher. No additional measure of community assemblage characterization, such as raw abundance or distribution of major taxonomic groups, showed differences between the two streams, suggesting that non-nutrient components of MWWE, even when combined from cumulative MWWE exposures, are not associated with observed impacts at the community level. Additionally, differences in the artificial substrate samplers suggest that colonizing communities may be more sensitive to cumulative MWWE exposure than established communities, which may affect the long-term resilience of the stream. This study emphasizes the need for biomonitoring programs to consider using multiple approaches to assess impacts of complex urban pollutants.

2.01.P-Mo112 Basal Autotrophic and Heterotrophic Food Web Responses to Municipal Wastewater Effluent Exposure

Breanna Sayles*, Frederick Wrona and David Barrett, University of Calgary, Canada*

Municipal wastewater effluent (MWWE) release into urban rivers act as a main point source of nutrients and increasingly the addition of environmental substances of concern (ESOCs), such as pharmaceuticals and personal care products, which can alter the physiology and ecology of aquatic organisms. While there have been active efforts to reduce the deleterious effects of MWWE loading on river systems, our understanding of nutrient-ESOC interactions and potential impacts on basal components of the food web is relatively limited. To address this, experimental streams at the Advancing Canadian Water Assets (ACWA) in Calgary, Alberta, Canada, were used to examine the responses of basal autotrophic and heterotrophic communities to a controlled incremental gradient of MWWE exposure over six weeks. Three stream treatments were deployed including a control (the nearby Bow River water only - BR), a 5% (v/v) MWWE addition (PC5), and a 15% (v/v) addition (PC15). An integrated suite of controlled bioassays incorporating artificial substrates (rock baskets), nutrient diffusing substrata, and cotton strips were used to assess the effects of increasing MWWE concentrations on algal standing crop and heterotrophic production, nutrient limitation, and organic matter decomposition rates. Increased MWWE exposure concentration was found to suppress autotrophic standing crop. Nutrient-ESOC interactions and potential grazing effects from macroinvertebrates were identified as a potential cause for the patterns observed. Heterotrophic production (via biofilm biomass) showed a subsidy-stress pattern, where PC5 had increased biomass compared to BR and PC15 treatments. However, the elevated MWWE concentration had no impact on organic matter decomposition rates. Relative autotrophic and heterotrophic biomass (measured via autotrophic index) showed increasing MWWE concentrations produced a shift towards more heterotroph dominant biofilm communities with time. The consistent inhibition of autotrophic endpoints highlights the relative MWWE impacts and influence of nutrient-ESOC interactions to autotrophs were greater than that of heterotrophs, introducing implications to efficient energy transfers to higher trophic levels. This study exemplifies the significance of utilizing integrated bioassays in experimental controlled streams to identify how nutrient-ESOC interactions influence autotrophic and heterotrophic biofilm communities and function in urban rivers.

2.01.P-Mo113 Effect of Co-exposition of Cadmium and Phthalate on Development of the Insect Agricultural Pest Spodoptera Littoralis

David Siaussat, *Sorbonne Universite, France*

Our environment is increasingly polluted with various molecules, some of which are considered endocrine disruptors. Metals and phthalates, originating from industrial activities, agricultural practices, or consumer products, are prominent examples of such pollutants. We experimentally investigated the impacts of the heavy metal cadmium and the phthalate DEHP on the moth Spodoptera littoralis. More specifically, larvae were reared in laboratory conditions, where they were exposed to diets contaminated with either two doses of cadmium at concentrations of 62.5 ?g/g or 125 ?g/g, two doses of DEHP at 100 ng/g and 10 ?g/g, or a combination of both low and high doses of the two compounds, with a control group for comparison. Our findings indicate that cadmium delays the developmental transition from larva to adult. Notably, the combination of cadmium and DEHP exacerbated this delay, highlighting a synergistic effect. In contrast, DEHP alone did not affect larval development. Additionally, we observed that cadmium exposure, both alone and in combination with DEHP, led to a lower mass at all larval stages. However, cadmium-exposed individuals that reached adulthood eventually reached a similar mass to those in other groups. Interestingly, while our results did not show any effect of the treatments on hatching success, there was a higher adult mortality rate in the cadmium-treated groups. This suggests that while moths may prioritize reproductive success, their survival at the adult stage is compromised by cadmium exposure. In conclusion, our study demonstrates the impact of cadmium on the development, mass, and adult survival of moths, and reveals synergistic effects when combined with DEHP. These results confirm cadmium as an endocrine disruptor, even at low doses. These insights underscore the importance of understanding the toxicological effects of low doses of pollutants like cadmium and DEHP, both individually and in combination.

2.01.P-Mo114 Zebrafish Physiological and Sub-Cellular Changes under the Combined Exposure of the Nanomaterial Mg-Al LDH and the Antineoplastic Epirubicin

Diana Isabel Oliveira Carneiro, *Daniel Alexandre Bruno, Madalena Vieira, Susana Loureiro, Roberto Martins and Maria D Pavlaki, Centre for Environmental and Marine Studies & Department of Chemistry, University of Aveiro, Portugal*

Engineered nanomaterials like layered double hydroxides (LDH) and antineoplastic agents (AA) are two examples of emerging contaminants (EC) that can be found in the aquatic environment. LDH is applied across various fields, from catalysis to drug delivery, and the chances of ending up in the aquatic environment are high. AA can affect organisms even at low concentrations, and they have already been detected in aquatic environments. These two EC can end up in water bodies originated from different sources: independent usage (each used in different applications) or under a combined use (e.g. drug delivery system for AA). Still, the knowledge about their possible harmful effects is almost null, and it is essential to determine their single and combined toxicity. This study evaluated the single and joint toxicity of Mg-Al LDH and Epirubicin in Danio rerio. D. rerio eggs were exposed to a range of concentrations of Mg-Al LDH (13 to 100 mg/L) and Epirubicin (11.46 to 87 mg/L; 41 to 206 µg/L) for single exposure. A full factorial design was applied using the same concentrations for mixture exposure. After 96 hours of single and mixture exposure, according to the OECD 236 FET protocol, mortality, malformations, and hatching delay were documented. Biochemical markers and DNA damage were also assessed. No mortality or malformations were observed at the concentrations tested of Mg-Al LDH. Epirubicin showed an LC50 of 49.3 mg/L (CI = 45.5 53.0) and a NOEC < 11.5 mg/L based on malformations. The mixture exposure showed no alterations in the LC50 of Epirubicin with the increasing concentrations of LDH, ranging between 46.9 to 59.9 mg/L. In single exposure, Mg-Al LDH didn t cause genotoxicity, while Epirubicin induced 20 30 % DNA damage at concentrations higher than 92 µg/L and biochemical alterations were only observed after 120 h of exposure to Epirubicin at a concentration of 206 µg/L. After mixture exposure, no genotoxicity was observed, however biochemical markers results suggest activation of the antioxidant defense system as indicated by an increased catalase (CAT) and glutathione peroxidase (GPx) activities. Furthermore, no alterations were observed in other enzymatic biomarkers, suggesting that Mg-Al LDH can mitigate the sub-cellular effects caused by Epirubicin on zebrafish larvae. These findings provide valuable insights into the effects promoted by mixtures of EC and may assist in their future

environmental hazard and risk assessment. The authors thank for the financial support to CESAM (UIDB/50017/2020+UIDP/50017/2020+LA/P/0094/2020) to FCT/MEC through national funds. 2.01.P-Mo115 The Acute Oral Toxicity of Pesticide Mixtures Identified in Agricultural Fields to Honey Bees (*Apis mellifera* L.)

Erin Henry[1]*, Coby van Dooremalen*[2] *and Frank van Langevelde*[1]*, (1)Wildlife Ecology and Conservation Group, Wageningen University & Research, Netherlands, (2)Wageningen University and Research, Netherlands*

Honey bees (Apis mellifera L.) are essential pollinators for crops and therefore may spend a significant amount of time near agricultural fields, putting them at risk for pesticide exposure. The effects of pesticides on honey bees are well documented, although most research focuses on single compounds. However, honey bees are exposed to multiple pesticides in the environment while foraging, illustrated by the mixtures of pesticides measured in hive matrices. The objective of this study is to assess the toxicity of pesticide mixtures to honey bees and compare this to predicted toxicity to explore possible interactive effects. We conducted an acute oral toxicity test on honey bees for 11 pesticide mixtures, each comprised of 3-5 compounds of various modes of action, which were identified in soils of agricultural fields of 10 European countries and Argentina. Honey bees were exposed to several concentrations of each mixture and mortality was recorded every 24 hours for 96 hours. We aim to predict the toxicity of these mixtures with concentration addition models, utilizing existing acute oral toxicity data for the single components. Predicted and measured toxicities will be compared to uncover additive or synergistic effects. In particular, mixtures containing groups such as azole fungicides, which have been commonly observed in synergistic mixtures, may exhibit greater differences between measured and predicted toxicities. These results will contribute to an improved understanding of the potential interactions of pesticide mixtures detected in agricultural environments, and how such mixtures may affect honey bees that come into contact with them. This research has received funding from the European Union s Horizon 2020 Programme for research & innovation under grant agreement no. 862568 (SPRINT).

2.01.P-Mo116 Genotoxic Effects of Three Anticancer Drug Mixtures to Zebrafish

Daniel Alexandre Bruno[1]*, Diana Isabel Oliveira Carneiro*[2]*, Rui G. Morgado*[2]*, Susana Loureiro*[2] *and Maria D Pavlaki*[2]*, (1)Centre for Environmental and Marine Studies & Department of Environment and Planning, University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal*

Across the world, millions of patients are undergoing chemotherapy, resulting in an increased consumption of anticancer agents (AA). Once administered to patients, these substances often end up in the environment due to the inefficiency of wastewater treatment plants in fully removing them. Therefore, AA typically coexists with other AA and/or contaminants, thus increasing the need to evaluate the potential effects of such mixtures on non-target aquatic species. This study evaluated the single and joint genotoxic effects of three AA, trabectedin (TRAB), doxorubicin (DOX), and oxaliplatin (OXA), commonly used in cancer treatment patients jointly or in sequence, using the zebrafish model, Danio rerio. Embryos of Danio rerio were exposed to the three AA individually and in combination using sub-lethal concentrations based on previously performed assays. The single-cell gel electrophoresis (comet) assay was performed to evaluate DNA strand breaks in D. rerio exposed to both individual and joint exposures after 96 hours. The Independent Action (IA) model was applied as a reference additivity model to detect and evaluate the interactions (synergism or antagonism) between the three AA. The predicted mixture effects were calculated using the control-normalized single-treatment responses and compared to the observed mixture response. Whenever the mixture effects were assumed to be non-additive the interaction type, strength, and direction were analysed. The results show that both TRAB-DOX and DOX-OXA mixture treatments exhibited lower-than-predicted DNA damage (one-directional antagonism up). The TRAB-OXA mixture showed the opposite (one-directional synergism up), with the exception of the combination of the lowest TRAB and highest OXA concentrations that revealed lower DNA damage than expected (antagonism up). The results of this study highlight the importance of assessing the effects of AA mixtures in the environment rather than solely focusing on their individual effects. Additionally, it provides insights for a better consensus on synergistic or antagonistic operational interactions. The present study was funded by VitroTox (PTDC/CTA?AMB/0126/2020; DOI: http://doi.org/10.54499/PTDC/CTA-AMB/0126/2020) supported by the FCT, in its State Budget component (OE). Daniel Bruno received funding (BI/UI88/10456/2022) via the VitroTox project. Thanks are due for the financial support to CESAM (UIDB/50017/2020+UIDP/50017/2020+LA/P/0094/2020), to FCT/MEC through national funds.

2.01.P-Mo117 Disentangling the Web: The Impacts of Binary Chemical Mixtures on Consumer-Resource Feeding Interactions

Dylan Asbury[1]*, Amy Rose Ockenden*[2]*, Lorraine Maltby*[2] *and Andrew Beckerman*[2]*, (1)University of Sheffield, United Kingdom, (2)School of Biosciences, University of Sheffield, United Kingdom*

Current evaluation of the impacts of chemicals and their mixtures on freshwater ecosystems relies heavily on single- and multi-chemical effects on individual species. However, species do not exist in isolation, and a mechanistic understanding of how chemicals and their mixtures impact species interactions is essential if we are to extrapolate from single-species single-chemical studies to assessing the impact of multiple chemicals on multispecies assemblages in ecosystems. Consumer-resource interactions, which represent fundamental building blocks of the food webs that drive biodiversity, may be impacted by chemicals through changes in abundance (e.g., lethal effects) or through sub-lethal effects such as changes in feeding behaviour, escape response or mobility. The chemicals in a mixture may affect consumer-resource interactions by affecting either the resource, the consumer, or both the resource and the consumer to the same of different extents. Here we demonstrate the use of a consumer-resource system to begin to disentangle the complex effects of chemical mixtures on ecological communities. We present the results from a series of crossed-design binary-chemical consumer (grazer)-resource (primary producer) interaction experiments using the freshwater snail, Potamopyrgus antipodarum and the freshwater diatom, Nitzschia palea. The chemical mixture consisted of a biocide (copper) and insecticide (azoxystrobin) and the experiments addressed three questions: (1) How are the impacts of binary mixtures altered depending on whether they are acting directly on an organism or indirectly through the consumer-resource interaction? (2) What are the consequences of differential sensitivity to binary mixtures for consumer-resource interactions? (3) Do the combined effects of individual chemicals within binary mixtures exert their impacts additively or otherwise in the case of consumer-resource interactions? This studentship is funded by the United Kingdom Natural Environment Research Council (NERC) and Unilever.

2.01.P-Mo118 First Analysis of the Application of Health Impact Assessment in Italy: The Role of Effect-Based Methods in Mixtures Assessment

Mario Carere*, Ines Lacchetti, Aurora Mancini, Walter Cristiano and Laura Mancini, Italian National Institute of Health, Department of Environment and Health, Italy*

The Health Impact Assessment (HIA) as defined by WHO is a practical approach used to systematically judge the potential health effects of a policy, strategy, plan, programme or project on a population. In Europe, the Environmental Impact Assessment (EIA) Directive 2014/52 foresaw that an estimate of the potential public health impacts of the implementing project must be carried out in every EIA procedure. In Italy the HIA has been applied to new plants belonging to the categories of large combustion plants, crude oil refineries, re-gasification and liquefaction plants or for plants that can have strong impacts in relation to their production activity. These plants can release in air, soil and waterbodies several chemical contaminants in low quantities. However their interaction can generate mixtures whose effects can be synergistic with possible impacts for ecosystems and human health. The use of Effect-based Methods (EBM) represents a key aspect for the evaluation of the effects of mixtures in the ecosystems. In this work a first 5 years analysis of the application of HIA in Italy has been carried out. Specifically, 42 industrial projects were analysed, distributed as follows: 50 % in the Northern, 9% in the Central and 41% in the Southern Italy. The projects examined included 81% Thermoelectric Power Plants, 17% Regasification plants and 2% Biorefineries. In this context EBM have been applied mainly to surface inland waters, transitional and marine waters and soils. The bioassays applied covered different trophic levels and also endpoints such as genotoxicity and embryotoxicity. They are mainly in vivo bioassays acute and chronic (e.g., test with earthworms, algae, crustaceans, fish embryos); eco-genotoxicological assays such as the Ames test, Comet assay and the Micronucleus test have been carried out. When effects such as genotoxicity and embryotoxicity have been detected, specific actions have been applied: an extensive chemical monitoring plan of the area and a trend analysis to investigate the causes and apply risk reduction measures. The results of this 5 years analysis showed that the inclusion of effect-based methods in the HIA procedure will contribute to apply the appropriate preventive measures needed to reduce the impacts on the population of the industrial chemical emissions and releases.

2.01.P-Mo119 Assessing the Toxicity of a Mixture of Benzotriazole Ultraviolet Stabilizers to Zebrafish (*Danio rerio*): Insights into Embryotoxic and Molecular Effects

Luis Terrazas Salgado[1]*, Justin Dubiel*[1]*, Lauren Zink*[2]*, Zhe Lu*[3] *and Steve Wiseman*[1]*, (1)Department of Biological Sciences, University of Lethbridge, Canada, (2)University of British Columbia, Canada, (3)Institut des Sciences de la Mer de Rimouski, Universite du Quebec Rimouski, Canada*

Benzotriazole ultraviolet (BUV) stabilizers are a group of industrial chemicals used in industrial (e. g. textiles, plastic, building materials) and personal care products (e.g. sunscreens, body lotions, hair dyes) to protect materials or skin from damage against harmful UV-radiation. They are considered a class of emerging environmental contaminants, although they have been around for nearly six decades and they can absorb UV rays from sunlight (within the 280-400 nm spectrum). BUVs (e.g., UV-P, UV-326, UV-327, UV-328, and UV-329) have been detected in different marine compartments worldwide, such as marine waters and sediments A variety of marine animals, from small crustaceans to large mammals, have accumulated BUVs. BUVS have been detected in aquatic environments at concentrations ranging from 0.05 to 99,200 ng/L; however, there are few studies on the effects of BUVS mixtures on aquatic organisms. Studies show that BUVS can affect behavioral responses and acetylcholinesterase activity, indicators of neurotoxicity. Additional studies support the hypothesis that BUVSs induce oxidative stress and neuroinflammation in fish. The objective of this study was to evaluate the embryotoxicity of a mixture of BUVS and to use whole transcriptome sequencing to link toxicities with effects. We selected 5 UVBs including UV-326, UV-327, UV-328, UV-329, and UV-P for toxicological analysis, as these are among the most frequently detected in aquatic environments. Using microinjection, freshly fertilized embryos were exposed zebrafish embryos to 3 different doses of the BUVS mixtures before gastrulation, and effects on mortality, hatch success, heart rate, and malformations were evacuated until 14 days post-fertilization. We observed an increase in mortality dependent on the dose of BUVS, for the control group mortality was 2%, and 15, 23, and 33 % for the groups treated with BUVS. Likewise, BUVS caused a decrease in heart rate at 48 hours post-fertilization, the control group presented an average of 161 beats per minute (bpm), while the treated groups averaged 159, 157, and 156 bpm. Also, the larval size, eye area, yolk area, and melanophores in the head area in the treated groups decreased compared to the control group. Whole transcriptome (mRNA, non-coding RNAs) analysis is currently being performed to determine the molecular basis of the observed effects. This study provides new insight into the toxicity and hazards of aquatic organisms.

2.01.P-Mo120 Response of Freshwater Periphyton to Pesticides, their Mixture and Transformation Products: New Insight from Untargeted Metametabolomics

Melissa Eon[1]*, Chloe Bonnineau*[2]*, Christelle MARGOUM*[2] *and Nicolas Creusot*[2]*, (1)AQUA, INRAE, France, (2)INRAE, France*

Pesticides are widely used in agriculture and ends up into aquatic environment where they may affect exposed organisms. All along this transfer process from field to river, pesticides can be degraded by abiotic processes and generate transformation products (TPs) for which the identity and the ecotoxicity is mostly unknown. Among these organisms, aquatic periphytons are complex assemblages of microorganisms with a short life cycle (e.g. microalgae, bacteria, etc.) playing a key role in aquatic ecosystems (e.g. primary production). Thus, they are relevant to investigate the impact of chemical contamination at the community level. Despite increasing knowledge on the impact of chemical stress, there is a still of paucity information about the effect of mixture of pesticides and their TPs on these communities. To such an end, metabolomics appears as choice method by prodiving a comprehensive picture of the molecular phenotype. In this context, our study aims to evaluate the toxicity of the herbicide terbuthylazine (TBA) and its transformation products on periphyton through the implementation of a multi-descriptors approach. To do so, periphyton was exposed during 4 weeks to TBA, to one of its commercially available degradation product (TBA-desethyl), both at 5 and 150 µg/L and to weathered TBA (wTBA, homemade by photodegradation from TBA at 5 and 150 µg/L). To enhance the environmental realism, periphyton was exposed to TBA-desethyl in mixture with 2 ubiquitous contaminants, glyphosate and AMPA (GA) at environmental concentrations (0.1 and 0.3 µg/L, respectively). A control (without any contaminants) and GA conditions were also set-up to allow comparison between conditions. First, most descriptors (photosynthetic yield, biomass, heterotrophic enzymatic activities) were strongly affected by TBA and not or slightly by the transformation products, being the TBA-desethyl or the wTBA or the mixture with glyphosate. Controversy, multivariate analyses (PCA and HCA) showed discrepancies in the metabolomics profile between each conditions, TBA 150µg/L being the most discriminated while both 5 and 150 µg/L of TBA-desethyl and wTBA were also separated from the controls. Nevertheless, all conditions with GA had a similar metametabolome profile suggesting no mixture effect. Overall, this study confirms the higher sensitivity of the metametabolome to micropollutants and so its relevance to highlight potential impact of TPs and mixtures on aquatic microbial communities.

2.01.P-Mo122 Screening of mixture toxicity of major biocides in Allivibrio fischeri

***Sunmi Kim**, Kyoung Hee Kang, Myungwon Seo and Chaeun Park, Korea Research Institute of Chemical Technology, Korea, Republic of*

In order to obtain authorisation for a biocidal product, it is necessary to conduct a mixture toxicity assessment of the active ingredients and co-formulations in biocidal products. Regarding the interactions between substances in mixtures, case-by-case testing is necessary, however, given the considerable variety and number of mixtures, appropriate toxicity data is rare. In this study, we selected a range of substances commonly used in wood preservatives and related biocidal products. Then we evaluated their mixture toxicity using the luminescent bacterium Allivibrio fischeri. In total, 26 individual biocides and 50 mixtures were selected for toxicity tests. The combinations most commonly used in wood preservatives were included in the study, as well as those ranked in order of toxicity. Two of the tested substances were found to act as synergists, while the majority of the mixtures followed a concentration addition (CA) model. In some cases, the synergistic effects were as high as 20-fold, indicating that appropriate assessment factors should be set when evaluating biocidal products or mixtures containing these substances. The results of this study need to be validated at a higher level in the future. This study was funded by National Institute of Chemical Safety through the Development of Environmental Risk Assessment Methodology of Biocidal mixtures, Korea Research Institute of Chemical Technology (KRICT) through the Development of Chemical Safety-by-Design Platform Technologies (Project No. KK2552-10), and Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE) (Grant No. RS-2023-00215857).

2.01.P-Mo123 Development of Strategy for Mixture Toxicity Screening in Consumer Products: A Case Study on 1,2-Benzisothiazol-3(2H)-one

***Gaeul Yang**, Yongmin Jung and Jinhee Choi, University of Seoul, Korea, Republic of*

Exposure to chemical mixtures through consumer products is a pervasive aspect of modern life, yet our understanding of the toxicity of such mixtures remains limited. In this study, we developed a strategy to identify chemical mixtures present in consumer products and to screen their potential systemic toxicity, focusing on 1,2-Benzisothiazol-3(2H)-one (BIT) as a case study. We gathered data, including the characteristics of components in products containing 1,2-Benzisothiazol-3(2H)-one (BIT), from Ecolife, a Korean consumer product database. To enable a component-based analysis, binary, ternary, and quaternary mixtures present in these products were identified. Mixtures for toxicity screening were selected with a focus on preservatives and chemicals known to induce allergic reactions. Equal-proportion mixtures were prepared and screened for cytotoxicity using four human cell lines (Beas-2b, E6-1, HepG2, and SH-SY5Y). Simultaneously, parameters derived from the dose-response curves of the individual chemicals constituting each mixture were applied to predict cytotoxicity of mixtures using the concentration addition (CA) model and the independent action (IA) model. The effects of the mixtures were assessed by comparing predicted values with experimental results through the model deviation ratio (MDR). For combinations exhibiting synergistic effects, the mixture ratios were varied to further verify whether the synergistic effects persisted across different compositional proportions. Ultimately, specific combinations of mixtures derived from consumer products containing BIT that demonstrated synergistic effects were identified. This case study demonstrates a strategy for identifying combinations of complex mixtures in consumer products that are likely to exhibit synergistic effects. These findings underscore the importance of accounting for mixture toxicity in consumer product risk assessments. Moreover, the proposed approach, incorporating in vitro screening, is expected to enable more efficient and comprehensive toxicological evaluations. This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products, funded by Korea Ministry of Environment (MOE)(RS-2023-00215309)

2.01.P-Mo124 Evaluation of Wastewater Treatment Plant Outfalls as Attractive Habitats for Fish and Invertebrates

***Lea Lovin**[1], Daniel Cerveny[1], Marcus Michelangeli[1], Jerker Fick[2], Petter Lundberg[1], Mladen Avramovic[3], Aneesh Bose[1], Sara Gronlund[4] and Erin McCallum[1], (1)Swedish University of Agricultural Sciences, Sweden, (2)Umeaa University, Sweden, (3)University of South Bohemia, Czech Republic, (4)Roskilde University, Denmark*

Wastewater treatment plant (WWTP) effluents are often loaded with pollutants that can cause harm to wildlife. However, these effluents can simultaneously host a seemingly advantageous environment with a stable temperature, excess nutrients, and attractive neuroactive chemicals. Previous work in North America has shown that there some species occur in greatest abundance near WWTP outfalls compared to up- and downstream sites, even though this may lead to greater uptake of contaminants. There is a need to understand if fish and invertebrates are attracted to these outfalls in Northern Europe, how these communities change along an effluent gradient, and how these patterns relate to chemical exposure. To this end, rivers around five Swedish WWTPs were sampled for fish using electrofishing and netting as well as invertebrates by kick-net sampling. Water and tissue samples were also taken to measure contaminant concentrations using an analytical suite of pharmaceuticals, personal care products, and pesticides. Preliminary results show that overall most fish were caught upstream of the WWTPs, however, there were species-specific differences of abundance with some species, such as burbot and tench, being more common near outfalls. Preliminary data from one WWTP shows that the total number of invertebrates were higher near the outfall compared to up- and downstream sites. These were largely highly pollutant tolerant taxa, such as chironomid midges and oligochaete worms. Here we show that certain species, especially those which are tolerant of pollution, appear to be attracted to WWTP outfalls. We will then combine these data with contaminant water and tissue concentrations to determine what is the exposure cost of inhabiting these areas. This research highlights the importance of understanding the effects of WWTP on receiving communities, which can help management strategies in these areas including whether tertiary treatment methods in WWTPs should be implemented. This work was funded by the Carl Trygger s Foundation and Swedish Research Council (FORMAS).

2.01.P-Mo125 Linking Aquatic-Terrestrial Ecosystems: Effects of Wastewater and Warming on Aquatic Insects

Iva Kokotovic[1]*, Vojtech Kolar*[2]*, Alberto Scotti*[3]*, Mourine Yegon*[4]*, Marko Ro man*[5]*, Ana Previsic*[1] *and Simon Vitecek*[6]*, (1)University of Zagreb, Faculty of Science, Croatia, (2)University of South Bohemia in ceske Bud?jovice, Faculty of Science; Biology Centre of the Czech Academy of Sciences, Institute of Entomology, Czech Republic, (3)Apem, Stockport, United Kingdom, (4)WasserCluster Lunz, Austria, (5)Ru?er Boskovic Institute, Croatia, (6)University of Innsbruck; WasserCluster Lunz, Austria*

Urbanization and wastewater discharges contribute to introduce complex mixtures of contaminants into freshwater ecosystems. These stressors in combination with the effects of climatic change (e.g. increasing water temperature), affect the ecological balance of aquatic ecosystems, and threaten their biodiversity. All these stressors influence each other and cross ecosystem boundaries through emerging aquatic insects. Emerging aquatic insects are key bioindicators in assessing how contaminants and climate change impact ecosystem health, as they are vectors of nutrients, contaminants, and energy across aquatic-terrestrial boundaries. Accordingly, the aim of the current study was to investigate single and combined effects of wastewater treatment plant effluent and increased water temperature on several community descriptors of aquatic insects. A two-month mesocosm experiment was conducted with a simplified freshwater food web containing aquatic bryophytes and insects, consisting of Ephemeroptera, Plecoptera and Trichoptera, feeding as shredders and grazers. Larvae and pupae were collected at the end of the experiment, whereas emerging insect taxa were collected daily. Changes in overall biomass, community survival, and emergence rates were analysed across different treatments. Additionally, analyses such as total lipid content and lipidome profiling are ongoing. The highest emergence rates were observed in the multiple stressors treatment (increased water temperature and presence of wastewater) and the increased temperature treatment, suggesting that temperature had a dominant influence on insect emergence. Although there were no statistically significant differences in community biomass across treatments, a trend of decreased biomass was observed for certain species exposed to increased temperature. Survival rates did not differ significantly between treatments. This study will provide novel insights into how aquatic insect communities respond to single and combined anthropogenic stressors while also outlining the implications for aquatic-terrestrial nutritional subsidies.

2.01.P-Mo126 Impact of Environmental Matrix Effects on Toxicity-driving Compounds in Wastewater Effluent

Yan Wang[1]*, Kristoffer Kilpinen*[2]*, Selina Tisler*[1]*, Jan H. Christensen*[1] *and Nina Cedergreen*[1]*, (1)Dept. of Plant and Environmental Sciences, University of Copenhagen, Denmark, (2)BIOFOS A/S, Denmark*

Wastewater effluents contain micropollutants, such as pharmaceuticals and PFAS, posing risks to ecosystems and human health. Identifying key toxicity drivers is challenging due to environmental matrices(e.g., humic acids (HA), fulvic acids (FA), and a wealth of organic degradation products), which can mask or alter pollutant toxicity in concentrated samples, underestimating their impact at lower, more prolonged environmental exposures. This study used Raphidocelis subcapitata to assess the toxicity of wastewater effluents screened for over 300 target pollutants. In a subset of more than 250 samples, approximately 60 compounds were detected with an average detection frequency of 80%. By combining

EC50 values from algal growth inhibition tests with the quantified chemical data, we calculated toxic units (TUs) to evaluate the contribution of each compound to overall toxicity. In samples exhibiting toxicity, the biocide terbutryn and the pharmaceutical furosemide, explained 0.72%-143.66% of the total toxicity; however, over 50% of the toxicity remained unexplained in 154 samples. Notably, 23 samples that showed no detectable toxicity contained compounds at concentrations that should yield toxic effects (TU > 1), suggesting the potential for antagonistic effects or matrix interference. To further investigate the effects of matrix components on toxicity expression, we spiked azithromycin, melitracen, and terbutryn (log D at pH7.4 = 0.78, 3.29 and 3.30, respectively) into two non-toxic wastewater samples with different chemical loads, testing at a concentration corresponding to a relative enrichment factor 30 in the highest concentration. The results showed that matrix effects had minimal impact on the toxicity of azithromycin, with only a slight increase in its EC50. In contrast, the matrices significantly suppressed the toxicity of melitracen and terbutryn, with melitracen s EC50 increasing by over ten-fold and terbutryn s by approximately three-fold, when added to the matrix. Absorption and fluorescence scans showed that dissolved organic matter (DOM) in wastewater, mainly HA and FA, suppressed pollutant toxicity, confirmed by spiking experiments with soil extracts. This study reveals the substantial impact of complex environmental matrices on toxicity expression. The fraction of unexplained toxicity may be underestimated, as bioassays with concentrated samples likely underrepresent toxicity in more dilute, bioavailable conditions.

2.01.P-Mo127 Assessing the Environmental Ecotoxicity of Wastewater Effluents Contaminated with Illicit Drugs and Benzodiazepines: Insights from Zebrafish Liver Cell Exposure

*Natalia Melones-Pena, **Paloma de Oro-Carretero**, Jon Sanz-Landaluze and Emma Gracia-Lor, Department of Analytical Chemistry, Complutense University of Madrid, Spain*

The presence of emerging pollutants in aquatic environments has generated significant environmental health concerns, particularly with the increasing detection of pharmaceuticals and illicit drugs in surface and wastewater. Wastewater treatment plants are often unable to effectively eliminate these compounds leading to their continuous release into rivers, lakes, and oceans. This study aims to simulate real-world exposure conditions to assess the impact of illicit drugs and benzodiazepines on Zebrafish Liver Cells, which are the primary site of metabolism for many xenobiotics. The findings provide valuable insights into the potential risks these contaminants pose to aquatic life. This research focuses on the impacts on aquatic organisms and proposes a simpler, less costly method of analysis compared to Effect-Directed Analysis (EDA). To achieve this goal, two sample preparation methods were applied. The first method was based on Solid-Phase Extraction (SPE), and the second involved freeze-drying of the sample. SPE was employed to reduce sample complexity, enabling the establishment of the effects of illicit drugs and benzodiazepines on cells, as well as facilitating the pre-concentration of analytes. Freeze-drying provided a complementary approach to further concentrate contaminants without reducing sample complexity, allowing for a more accurate assessment of toxicity. Detection and quantification of illicit drugs and benzodiazepines with high sensitivity, even at trace levels, were conducted using HPLC-MS/MS. Meanwhile, cellular toxicity was determined using MTT and flow cytometry assays. The results indicate that the mixture of illicit drugs and benzodiazepines tested accounts for approximately 10% of the toxicity observed in the wastewater samples. This suggests that other compounds or synergistic effects between contaminants may also contribute to cytotoxicity. Additionally, the effect of filtration prior to cell exposure was studied and, in general, a decrease in sample toxicity was observed because of this process. In conclusion, these findings improve our understanding of the potential risks raised by the presence of benzodiazepines and illicit drugs in wastewater effluents. They highlight the ecological risks associated with these pollutants and emphasize the need to address this issue in the wastewater treatment processes. These insights can inform policy decisions and environmental management strategies aimed at protecting aquatic ecosystems.

2.01.P-Mo128 Effects of Urban Wastewater Effluents Containing Antibiotics Treated by an FBBR Reactor on the Aquatic Insect *Chironomus sancticaroli*

*Mayara Caroline Felipe[1], Juliano Corbi[2] and **Rodrigo Braz Carneiro**[1], (1)University of S o Paulo, Brazil, (2)University of S o Paulo, Brazil*

Antibiotics are particularly significant among emerging contaminants because they can alter microbial communities, leading to increased antimicrobial resistance. Fluoroquinolones and sulfonamides represent two major classes of antibiotics that are widely utilized in human and veterinary medicine across the globe. This study assessed the ecotoxicological effects of effluent from an anaerobic fixed bed biofilm reactor (AnFBBR) that treats urban wastewater containing seven antibiotics: sulfamethoxazole, sulfadimethoxine, sulfamerazine, ciprofloxacin, pefloxacin, enrofloxacin, and ofloxacin. The evaluation focused on two phases of operation (control and spiked concentrations of antibiotics) and examined the impact on a native Brazilian aquatic insect species, Chironomus sancticaroli, Strixino e Strixino, 1981. Acute ecotoxicity tests were conducted over a duration of 96 hours, during which organisms were exposed to five dilutions of the test solutions: influent I, influent II, effluent I, and effluent II, at concentrations of 60, 120, 250, 500, and 1000 mL/L. A control solution of demineralized water was also used. Since the species being tested spends most of its life cycle in the sediment, 50 grams of defaunated sand were added per triplicate. The results demonstrated that the treatment of urban wastewater effluent performed significantly better than the influent. A reduction in the toxicity of the effluents was observed in both phases across all concentrations tested. At the lowest concentrations (60 and 120 mL/L), the mortality rate was 6.6%. In contrast, the influent at a concentration of 1000 mL/L resulted in 100% mortality of the organisms, while the effluent at the same concentration showed an average mortality of 60%. In the Two-way ANOVA statistical analysis, the 60 mL/L dilution was found to be statistically equivalent to the control group (p-value = 0.1368). Additionally, the influents I and II displayed statistical similarity with a p-value of 0.3609. Based on the results obtained, we can conclude that ecotoxicity tests are valuable tools when combined with biomonitoring in reactors used for the degradation of emerging pollutants, such as antibiotics found in urban wastewater treated in anaerobic reactors. However, it is essential to implement complementary technologies alongside An FBBR to reduce the environmental impact of antibiotics, particularly concerning the spread and development of antimicrobial resistance genes.

2.01.P-Mo129 Application of Mixture Assessment Factor in South Korea's Chemical Regulation
Dawoon Jung*[1] *and Sunmi Kim*[2]*, (1)Korea Environment Institute, Korea, Republic of, (2)Korea Research Institute of Chemical Research, Korea, Republic of
In Korea, risk assessment of chemicals is overseen by two major acts; ?Environmental Health Act? and ?Act on Registration and Evaluation of Chemical Substances? (K-REACH). ?Guideline on Procedures and Methods for Risk Assessment of Environmental Hazards? provides detailed methodology for conducting risk assessments for human health, ecology, and children s products for the execution of the laws. However, the methodology in which cumulative effects of mixtures is not thoroughly described. Therefore, in practice, risk assessment of mixtures is hardly conducted, and mixture risk assessment of unintentional mixtures in the environment has become one of the most pressing measures in which regulation must be implemented. Mixture assessment factor (MAF) is a tool developed to take into account the cumulative effects of mixtures in risk assessment. This concept allows for the risk assessment of multiple chemicals, and can allows the risk assessor to identify potential risk of the mixture even when the level of individual chemicals in the mixture is below the threshold for safety. Recently, the European Commission has proposed the incorporation of MAF into Europe s chemical regulatory framework, and is examining the potential value and utility of MAF in the context of EU REACH. In this study, we explored the possibility and the value of incorporating MAF in Korea s chemical regulation. We conducted literature search to identify studies that conducted risk assessment of mixtures in three different settings in Korea, and examined the data for the possibility of applying the MAF approach. Next, we conducted risk assessment using the MAF concept for examining the mixture effect of mixtures in the selected ecological studies. Our results demonstrate the utility of MAF in conducting ecological risk assessment of unintentional mixtures in the regulatory context, specifically the management of Korea s watersheds. This study was conducted with the generous support of KEITI (RS2024-002-15309).

2.01.P-Mo130 CheOSmix - A Data-Reuse Approach to Determining Chemical Mixture Risk Driver Heterogeneity in European Freshwater
Jana Schor[1]*, Tobias Schulze*[2]*, Nadin Ulrich*[1]*, Ilhan Mutlu*[1]*, Kazi Nafiul Hassan*[1]*, Martin Krauss*[3]*, Werner Brack*[3]*, Triet Doan*[4]*, Sven Bingert*[4]*, Jan Bumberger*[1]*, Wibke Busch*[5] *and* ***Joerg Hackermueller***[1]*,*
(1)Helmholtz Center for Environmental Research, Germany, (2)German Environment Agency, Germany, (3)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research, Leipzig, Germany, (4)Gesellschaft fur wissenschaftliche Datenverarbeitung mbH Gottingen, Germany, (5)Helmholtz Center for Environmental Research, Leipzig, Germany
Chemical pollution of aquatic environments involves complex combinations of substances. Mixture exposure can provoke combined effects even if the concentrations of individual substances remain below their effect thresholds. Therefore, efforts are ongoing to better consider mixture effects in chemical safety regulation. A debate accompanies these efforts on whether only a few substances drive the aquatic mixture risk and, thus, whether more strictly regulating these individual substances would be sufficient or whether a large heterogeneous set of driver substances needs to be considered. Here, we employed a data-reuse strategy to investigate the heterogeneity of drivers of chemical mixture risk to aquatic species. We initially demonstrate that drivers are heterogeneous using data from a single measurement campaign that enables comparing drivers between sites due to a set of consistently measured substances. Subsequently, we extended our analysis to an extensive collection of chemical monitoring data from the NORMAN

network. These data originate from different measurement campaigns that focused on diverging sets of substances at various time points. We, therefore, aggregated the data quarterly and per quarter cluster sites according to the set of measured substances. Our study concludes that an extensive list of substances drives chemical mixture risk across Europe and that these substances were highly heterogeneous between locations. Notably, the drivers of mixture risk were species-specific and exhibited variability over time. Also, we established that lacking monitoring data hindered a more precise analysis, particularly regarding temporal variability. We have stored all collected and curated data in a graph database. We present a chatbot that builds on a graph database - grounded large-language AI model to translate between the researcher and our database and, therefore, allows querying this knowledge for non-computer science experts.

2.01.P-Mo131 The Use of Ecological Modelling in System-based Environmental Risk Assessment: Investigating the Influence of Landscape Heterogeneity and Pesticide Mixtures

Dana Bashkir[1]*, Louise Wipfler*[1]*, Paul van den Brink*[2] *and Bas Buddendorf*[1]*, (1)Wageningen Environmental Research, Netherlands, (2)Aquatic Ecology and Water Quality Management Group, Wageningen University, Netherlands*

The current environmental risk assessment paradigm is limited to silos-based approaches that poorly represent the environmental complexity of pesticide exposure and effects and is in need of revision. To be able to assess the effects of chemicals in a holistic way, not only individual toxicity responses have to be linked to population responses, but also other factors influencing exposure, toxicity, and population dynamics and distribution should be considered. To support the shift towards such system-based approach, this research project uses mechanistic population models to investigate (i) the influence of landscape heterogeneity on populations of the non-target arthropod species Orius laevigatus and (ii) the impact of chemical mixtures on earthworm populations. The first part of the project takes an existing (unpublished) agent-based model in NetLogo as a basis, adding more ecological realism. The model will be translated into Python to better deal with the high computational demands of complex landscapes. The effects of landscape complexity on O. laevigatus population endpoints and the pest control ecosystem service will be investigated at two spatial scales: off-crop margins of variable age and structure of a single arable field in the UK, and multiple vineyards with surrounding areas (500m radius) along a gradient of increasing heterogeneity in Portugal. The environmental scenarios will be based on two case studies within the SYBERAC project, that will also provide collected sampling data with which the modelled population responses will be compared. The second part of the project focuses on the impact of exposure to pesticide mixtures on earthworm population endpoints and the provision of soil related ecosystem services, e.g., nutrient cycling, water regulation, and crop production. Spray application series of multiple pesticides will be included (with concentration addition assumptions) into the existing (open access) earthworm model and population responses will be compared to the sampling data collected within SYBERAC. Additionally, the extent to which functional redundancy can be expected will be determined by comparing the sensitivity of O. laevigatus and earthworms to other service providing units observed in the case studies. The results of this project are expected to provide insights and tools required for the shift towards a more holistic environmental risk assessment in terrestrial ecosystems. This research is part of the SYBERAC project (www.syberac.eu) has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No. 101135213.

2.01.P-Mo132 Modelling Effects of Multiple Stressors – A Case Study with Imidacloprid and Aquatic Insects

Evridiki Klagkou[1]*, Andre Gergs*[2]*, Christian Baden*[2] *and Dina Lika*[1]*, (1)University of Crete, Greece, (2)Bayer AG, Germany*

Mayflies and other aquatic insects due to their high sensitivity to neonicotinoid insecticide exposure serve as important non-target indicators in environmental risk assessments. Acute toxicity testing primarily focuses on lethality; however, sublethal endpoints such as feeding, growth and reproduction are of additional importance when assessing toxicity at chronic timescales. Moreover, the interactions of chemical stressors with environmental stressors (e.g., temperature increase and food reduction) are underexplored. To enhance our understanding of the impact of neonicotinoid insecticides and of their interactions with environments stressor on aquatic insects, a Dynamic Energy Budget (DEB) based toxicokinetic-toxicodynamic (TKTD) model was developed. The model was parameterized for two insect species, Chironomus riparius and Cloeon dipterum, based on experimental data on feeding inhibition and immobility. The models were subsequently used to explore the combined effects of multiple stressors, specifically, imidacloprid exposure, temperature and food availability, under constant and time variable exposure scenarios. Model simulations predict EC50 (50% effect concentration) values for mobility and food consumed, larval/nymphal duration, and survival to pupation/emergence. The timing of exposure initiation during larval/nymphal development is a more significant factor compared to the duration of the duration of constant toxicant exposure, whereas under conditions of time-variable exposure, assuming an exponential decrease of the toxicant, the rate of decrease is more important than the timing of exposure. Temperature has a larger effect on larval/nymphal duration than the food availability, while survival to pupation/emergence was affected mostly by the toxicant concentration, with C. riparius exhibiting sharp responses to changes in toxicant concentration, whereas C. dipterum showing a more gradual effect. However, the EC50 value for mobility of C. dipterum is, by a factor 2, lower compared to the one of C. riparius, indicating the species greater sensitivity.

2.01.P-Mo133 Probabilistic Risk Characterisation for Chemical Mixtures: Hierarchical Integration of Models for Similar and Different Mode of Action

Knut Erik Tollefsen, Sophie Mentzel, Samuel Welch, Merete Grung, Elisabeth Støhle Rødland and ***Jannicke Moe****, Norwegian Institute for Water Research, Norway*

Risk assessment for chemical mixtures has been subject to much research and method development in the last decade, but many challenges remain. Probabilistic risk methodologies are becoming more common in both human and environmental risk assessment (ERA), and can offer new approaches to fundamental challenges in ERA, such as the characterisation of mixtures risk. For pragmatic reasons, the Concentration Addition (CA) concept is regularly used in so-called deterministic risk assessment (e.g., sum of risk quotients). However, the Independent Action (IA) concept lends itself more easily to probabilistic risk calculation (e.g., joint probability of threshold exceedances). Here, we explore a combination of these two concepts in a hierarchical probabilistic model (object-oriented Bayesian network OOBN). First, probabilistic risk quotients (RQ) are calculated for individual chemicals, as probability distributions of environmental concentrations divided by a predicted no-effect concentration). Next, the CA concept is applied within groups of chemicals (e.g., with similar mode of action) by summing the RQ distributions. Finally, the IA concept is applied across the different chemical groups, to combine RQ distributions by joint probability calculation (OR expressions). This model is applied to case studies from the EU-funded project MULTISOURCE (ModULar Tools for Integrating enhanced natural treatment SOlutions in URban water CyclEs; https://multisource.eu/). This project is based on a set of seven technical pilots for improved wastewater treatment by nature-based solutions, across European countries and in USA. The aims of this poster presentation are: (1) to introduce a novel probabilistic approach to mixture risk characterisation, which integrates the CA and IA concepts in a hierarchical BN model; (2) to demonstrate the usefulness of the model to a real-life case study (a MULTISOURCE technical pilot) as a proof-of-concept; and (3) to evaluate the applicability of this approach for environmental risk assessment in more general contexts and at larger scales. The MULTISOURCE project has received funding from the European Union s Horizon H2020 innovation action programme under grant agreement 101003527.

2.01.P-Mo134 Bush Encroachment Coupled with Climate Change and Variability in Protected and Communal Areas: A Species Distribution Modelling Approach

Thabang Maphanga[1]*, Cletah shoko*[2]*, Mbulisi Sibanda*[3]*, Corli Coetsee*[4] *and Timothy Dube*[3]*, (1)Cape Peninsula University of Technology, South Africa, (2)University of the Witwatersrand, (3)University of the Western Cape, (4)South African National Parks, Scientific Services, South Africa*

Savanna rangelands have experienced widespread degradation due to bush encroachment, raising significant concerns among conservationists and rural communities. In the context of climate change, these ecosystem shifts are likely to intensify, especially in South Africa s semi-arid regions. Understanding the impacts of climate variability and change on species distribution within these rangelands is crucial for mitigating further ecosystem disruption. Environmental factors, along with climatic variables, can accelerate the process of bush encroachment, threatening both biodiversity and land use. Early identification of areas vulnerable to invasion is key to developing effective and cost-efficient management strategies. This study aims to model the distribution of invasive species across protected and communal landscapes under long-term climate change projections. The current and future bioclimatic variables, as well as environmental and Sentinel-2 Multispectral Instrument satellite data, were used to fit the models and predict areas at risk of bush encroachment in the Kruger National Park and surrounding communal areas. The combined variables explained over 90% of the habitat suitability model under the current climate with Bio 2 being the most important variable (95%-53.5%) for RF and MaxEnt respectively. The future projections have also shown that slope, precipitation and temperature some of the key climatic variables were good predictors for the suitable areas for encroachment for both RCP 2.6 and RCP 8.5. Moreover, the overall predictions using the ensemble model demonstrated an increase in areas suitable for encroachment under RCP 8.5 but a decrease in the bush encroachment rate under RCP 2.6. These findings underscore the critical need for proactive management strategies to mitigate bush encroachment, particularly under high-emission scenarios, ensuring the sustainability of semi-arid savanna rangelands in the face of climate change.

2.01.P-Mo135 Evaluation of the Population-level impacts of Chemical Exposures on Pacific Salmon in the Puget Sound, Washington, USA - Part 1 - Model Development and Legacy Contaminants

***C. Andrew James**[1], Maya Faber[1], Ruth Sofield[2], John Best[3], Sandra O'Neill[3], Molly Shuman-Goodier[3] and Andrea Carey[3], (1)University of Washington Tacoma, United States, (2)Western Washington University, United States, (3)Washington Department of Fish and Wildlife, United States*

Pacific salmon (Oncorhynchus spp.) are a culturally and economically important fish, found along the northwest coast of North America. They have a complex life history that includes stages in the freshwater, estuarine, and marine environments, with long migration routes. Population levels have declined markedly due to anthropogenic pressures including habitat loss, river dams, over exploitation, and exposures to chemical contaminants including polychlorinated biphenyls (PCBs). The effects of some of these contaminants have been well studied for individual fishes, yet this evaluation has not been widely applied to populations. The objective of this project was to understand the population level impacts of exposures to PCBs on different salmonid populations in the Puget Sound, WA, USA. To do so, we developed a set of life-history models, each representing a distinct population. These models provide the framework to understand the extent, duration, and range of chemical exposures, and to quantify the potential, population-level impacts. Chemical exposures in each life stage were estimated for populations, and some life stages, based on monitoring data collected in the region by the Washington Department of Fish and Wildlife. The effects of chemical exposures on population-relevant endpoints, including growth, survival, and reproduction were informed by published exposure-response relationships and/or developed from the literature. These effects were used to adjust the probability of survival of key life-stage transitions in the population model. The results indicated that there was a significant effect on the population specifically associated to chemical exposures, limiting the success of salmonid recovery and restoration activities. This highlights the need to improve our management of anthropogenic chemical loading to receiving waters. This population level effect was apparent based on an analysis of exposures to a single chemical group; environmental monitoring data indicates that salmonids are exposed to mixtures. Ongoing and future work will focus on developing and applying relationships for individual chemicals and mixtures.

2.01.P-Mo136 Probabilistic Modelling of Pharmaceutical Pollution in a Scottish Meso-scale Catchment

***Miriam Glendell**[1], Mads Troldborg[1], Kerr Adams[1], Zisis Gagkas[1], Pat Cooper[1], Alison Brown[2], Anna Doeser[3], Linda May[3], Camilla Negri[1], David Oliver[2], Philip Taylor[3], Nigel Willby[2], Zulin Zhang[1], Adrian Bass[4], Lindsay Beevers[5], Lydia Niemi[6], Eulyn Pagaling[1], Amy Pickard[3], Marian Scott[4] and Andrew Tyler[2], (1)The James Hutton Institute, United Kingdom, (2)University of Stirling, United Kingdom, (3)UK Centre for Ecology and Hydrology, United Kingdom, (4)University of Glasgow, United Kingdom, (5)University of Edinburgh, United Kingdom, (6)University of Highlands and Islands, United Kingdom*

Understanding how hydro-climatic interactions affect the movement of pollutant mixtures through the environment and how these interact with riverine ecosystems is a major research challenge. Riverine environments are affected by multiple combinations of physical, biological and chemical stressors. Although concentrations of some regulated pollutants have been reduced in recent decades, the increasing diversity of emerging contaminants of concern has resulted in a wide array of pollutant mixtures from a range of sources. These include wastewater treatment systems including combined sewer overflows (CSOs), rural septic tanks, agricultural and urban runoff and legacy pollutants from past practices. Simultaneously, climate driven shifts in water flows and temperatures are likely to influence how freshwater ecological communities function, with changes in exposure likely to magnify effects on biota. However, the combined effects of these pollutant mixtures and multiple stressors are poorly understood. Here, we develop a probabilistic model based on Bayesian Belief Networks to simulate contaminant inputs to the River Almond, Scotland, UK (369 km2), from its catchment. Pharmaceutical pollution from sewage treatment works (STWs), storm overflows, septic tanks and diffuse sources (veterinary prescribing, agricultural land use) will be simulated on a monthly time-step. Data on river flow, pharmaceutical prescription rates, the number, size and type of STWs, pharmaceutical-specific excretion rate and removal within STWs are integrated to simulate contaminant concentrations and loads at 20 sampling points. The model simulations for a set of selected pharmaceuticals showed reasonable agreement with measured concentrations. Ecological risk quotients (ERQs) using predicted environmental concentrations and no-observed-effect concentrations (NOEC), coupled with a probabilistic Precautionary Factor (as in Mentzel 2022), will be used to assess the impact of pollutant mixtures on stream macro-invertebrates, making the assumption that the stressor-response relationship is additive. A simplified version of the model will be upscaled to Scotland-wide to map pollution risk on an annual time-step to identify pollution hot-spots and inform prioritisation of mitigation strategies. This research is funded by the UKRI Natural Environment Research Council Freshwater Quality Program (MOT4Rivers project), with in-kind contribution from the Scottish Government Strategic Research Program 2022-2027.

2.01.P-Mo137 Predicting Cellular Level Vulnerability to Combined Stress of a Non-Chemical Stressor and Chemical Toxicity Using the Stress Additional Model (SAM)

Syarifatun Nisa Nurdhy*, Jonas Groning, Naeem Shahid, Matthias Liess and Jo Nyffeler, UFZ Helmholtz Center for Environmental Research, Germany*

In the environment, organisms face simultaneous chemical and non-chemical stressors. The Stress Addition Model (SAM) enables to predict the effect of combined stresses and has been applied to survival studies in vertebrates and Daphnia. Typically, non-chemical stress enhances chemical toxicity while reducing the steepness of dose-response curves. So far, studies on combined stress effects at the cellular level remain limited. This study investigates the impact of starvation (a non-chemical stress) combined with chemical stressors on the human lung cancer cell line A549. In this experiment, A549 cells were plated in 384-well plates in Dulbecco s Modified Eagle Medium with 10% fetal bovine serum. After 24 hours, starvation was induced by replacing the medium with a mix of medium and phosphate-buffered saline (PBS) at 0%, 20%, 40%, 60%, 80%, or 100% PBS. Cells were then exposed to test chemicals for 24 hours: 3,4-dichloroaniline (nonspecific toxicant), staurosporine (a protein kinase inhibitor, inducing apoptosis), docetaxel (inhibitor of microtubule polymerization, disrupting proliferation), and saccharin (negative control). Three independent experiments were conducted with two technical replicates per condition and six concentrations per chemical. After 24 h of exposure, cells were live-labeled with Hoechst, Calcein-AM, and propidium iodide for 30 minutes, followed by fluorescent imaging. Viability was defined as calcein-positive cells relative to solvent controls, and cytotoxicity as propidium iodide-positive cells relative to total cells per well. Complete starvation resulted in significant cytotoxicity. In non-starved cells, staurosporine exhibited a steep concentration-response curve with a potency of 100 nM. However, in fully starved cells, the curve was less steep, with excess cytotoxicity observed at concentrations below 10 nM. In contrast, docetaxel induced cytotoxicity at concentrations above 10 nM in non-starved cells, but this effect was absent under starvation conditions. We hypothesize that under starvation, cells cease proliferating, thereby rendering docetaxel ineffective in inducing additional cell death.

In conclusion, these findings indicate that the Stress Addition Model (SAM) is applicable at the cellular level. However, its applicability appears to depend on the mode of action of the chemical stressor. A strong reduction in food was required to observe effects; consistent with studies in invertebrates and vertebrates.

2.01.P-Mo138 Linking Micropollutants Toxicity and Macroinvertebrate Communities in German Rivers Using AI-Based Toxicity Predictions

Ariane Moulinec*[1], Fabian G. Weichert[2], Sarah Johann[2], Henner Hollert[2] and Andrea Sundermann[1], (1)Senckenberg Research Institute and Natural History Museum Frankfurt, Department of River Ecology and Conservation, Germany, (2)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany*

Understanding the impact of chemical pollution on benthic invertebrate communities in streams and rivers is critical for assessing ecosystem health. However, linking chemical monitoring data with communities health remains challenging; chemical pollution rarely occurs alone but rather act in concert with other stressors, such as water scarcity or increasing temperatures, that might hinder that evaluation of chemicals toxic effects. Moreover, each individual compound has a its very own toxic effect that might be difficult to disentangled in the wide array of chemicals present in the system. In our study, we employed the recently developed AI-based ecotoxicological prediction model TRIDENT providing robust toxicity estimates for a wide range of micropollutants. We linked the chronic toxicity predictions of approximately 1100 compounds with monitoring data from German federal states at over 100 sampling sites. Using predicted EC10, we calculated different sets of toxic units (TUs) to estimate the overall toxicity of the water samples and the toxicity of several groups of micropollutants (e.g. pharmaceuticals, biocides). These estimates were subsequently integrated with data on benthic invertebrate community structures from sites near the location of the chemical samples. By linking chronic toxicity predictions with multimetric index and community assemblages, we derived valuable insights into the role of micropollutants in shaping benthic invertebrate communities. We also highlighted micropollutants with the most detrimental effects on the communities health. This approach not only enhances our ability to assess the ecological impacts of chemical pollution but also highlights the utility of AI-based methods in environmental monitoring and management. Our findings emphasize the need for integrating advanced predictive tools to better understand and mitigate the effects of micropollutants on aquatic ecosystems.

2.01.P-Mo140 Multistress in a Changing World: Impacts of Pollutant Mixture and Temperature on Gene Expression of the Freshwater Gastropod Physella acuta

Ahlam Mohamed-Benhammou *and Jose-Luis Martinez-Guitarte, National University of Distance Education, Spain*

Aquatic ecosystems are highly vulnerable to climate change and pollution. Individual pollutants and combinations of anthropogenic compounds, including microplastics, pesticides, and heavy metals, impact these ecosystems. Diverse chemicals lead to complex interactions often overlooked while rising temperatures from climate change add stress to aquatic life. Due to the intricate nature of environmental conditions, typical toxicity assessments may not effectively capture the impacts and interactions of these factors that could affect aquatic invertebrates, ultimately putting their populations at risk. Therefore, to mimic closer environmental conditions, we exposed the freshwater gastropod Physella acuta to mixtures of three pollutants Bisphenol A (BPA), Endosulfan, and Cadmium. Exposure mimicked the warming scenario 3 proposed by IPCC (middle of the road: 2.7 ºC by 2100), so control (18 ºC) and warming scenario (20.5ºC) were used. The animals were collected for gene expression analysis at 24 hours, 7 days, and 21 days. The effects were evaluated using retrotranscription and Real-Time PCR with genes related to stress response, endocrine system, and detoxification mechanisms. This study aims to collect data on temporal responses and elucidate the putative impact that global warming can have on the ability of aquatic invertebrates to respond to toxicity. The information gathered will also benefit other species, helping to know biomarkers that are helpful in this analysis. Changes in the genes are observed, and the results are discussed, considering the toxicants and temperature since both factors are relevant to the future of the populations. In addition, the experimental design will provide insights into the standardization of molecular studies for toxicity analysis in complex scenarios involving different factors that can be affected by the progress of global change. This work has been funded by Ministerio de Ciencia e Innovación (PID2022-136669OB-I00). A.M-B is a recipient of a fellowship from Ministerio de Ciencia e Innovación (PRE2022- 000781)

2.01.P-Mo141 Sublethal Chemical Exposure Alters Thermal Tolerances of Freshwater Fish and Invertebrates

Helena Soraya Bayat*, Verena Schreiner and Ralf Bernhard Schaefer, Research Center One Health Ruhr, University Alliance Ruhr & Faculty of Biology, University Duisburg-Essen, Germany*

Chemicals not only exert direct effects on the growth, survival, and reproduction of organisms, but can also indirectly affect an organism s ability to confront shifting abiotic conditions, potentiating or moderating dire consequences in a multi-stressor world. Climate change, industrial effluents, and hydromorphological changes contribute to increasing temperatures, along with their fluctuations and extremes, in freshwater ecosystems. The thermal tolerance of freshwater organisms dictates their ability to handle these stressful temperatures . Chemical exposure can decrease the thermal tolerance of an organism by diverting energy towards detoxification processes or maintaining homeostasis, or increase thermal tolerance by activating a protective general stress response. Whether chemicals generally lead to higher or lower thermal tolerances in organisms, and how the concentration and characteristics of a chemical influence the effect, remains unknown.

To investigate the interaction between chemicals at sublethal concentrations and thermal tolerance, studies investigating thermal tolerance under chemical exposure were collated from the literature. The relationship between 15 substances, including heavy metals and organic chemicals, and thermal tolerances of freshwater fish and invertebrates (36 species-substance combinations) was compared. Most chemical exposures led to a reduction in thermal tolerance, with notable exceptions. Funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) SFB 1439/1 2021 426547801

2.01.P-Mo142 How Does Copper Alter the Thermal Tolerance of Calanus Copepods in Oslo Fjord?

Aase Gressetvold Finstad*, Khuong V. Dinh, Mathieu Lutier and Josefin Titelman, Section for Aquatic Biology and Toxicology, Department of Biosciences, University of Oslo, Norway*

Fjord ecosystems are commonly found in Arctic and subarctic regions. These unique landscapes feature long, narrow sea inlets with steep cliffs or slopes, shaped by glacial activity. Their distinctive morphology and strategic locations have historically made fjords hubs for human settlements. However, they are increasingly affected by climate change and human activities, including shipping and aquaculture. This is particularly true for Norwegian fjords such as Oslofjord where both warming and pollutants such as copper have been major issues for key fjord species such as Calanus copepods. Copper and warming have been known to interact synergistically to intensify their cumulative effects on exposed copepods. Furthermore, pronounced seasonal changes in the fjord environmental conditions and physiology of Calanus copepods in Oslofjord may affect their sensitivity to warming and copper, but this remains to be tested. The objective of this study is to disentangle the role of seasonality with two contrasting seasons:

winter and summer on the vulnerability of Calanus copepods in the Oslofjord to copper and elevated temperatures. Here we exposed Calanus copepods collected from Oslofjord to 5 temperatures (5, 10, 15, 20 and 25°C) in combination with 4 different copper concentrations (0, 20, 40, 60 and 120 ?g/L). The daily survival was then monitored over 4 days. Lipid sack and size were measured as an indication of energy consumption during the exposure. To explore the genotoxic effects of warming and copper, we analyzed DNA damage of surviving individuals. We are analyzing the data and will provide the main findings at the conference. Results of this study might provide mechanistic insights into the vulnerability of Calanus copepods to warming and pollutants with applications for ecological risk assessments of fjord ecosystems.

2.01.P-Mo143 Comparing the Thermal Tipping Point of the Overwintering and Summer Arctic Calanus Copepods in Response to Copper Pollution

Milla Mona Sophie Albertsen*, Mathieu Lutier and Khuong V. Dinh, Section for Aquatic Biology and Toxicology, Department of Biosciences, University of Oslo, Norway*

One of the main threats for arctic species is ocean warming, which is approximately 4 times faster than the other seas and oceans. The Arctic warming is intensified by the influence of the warm Atlantic water, particularly during the winter while several Arctic zooplankton are overwintering. In the summer, a great concern is marine heatwaves, i.e. sudden peak in maximal temperatures, that can last several weeks and should increase in intensity, duration and frequency. It is unknown if the Arctic warming may approach the thermal tipping points (TTPs) of Arctic copepods, a tolerance threshold beyond which the survival copepods is impacted is primordial to project on their fate. Furthermore, Arctic zooplankton are increasingly exposed to pollutants from human activities such as copper from increasing shipping and aquaculture. Copper exposure has been known reduce the tolerance of polar copepod to warming, therefore, it is predicted to lower their TTPs. It has never been tested 1) whether exposure to copper may reduce TTP of the dominant Arctic copepods from the genus Calanus and, if yes, 2) how changes in TTP of Calanus copepod differ between winter and summer due to differences in the copepod physiology. The objective of this study is to determine the effect of copper on the survival of copepods at elevated temperatures by assessing survival over a wide range of temperatures and estimating thermal tolerance threshold, with a focus on how seasonality and extreme winter conditions may influence these effects. Sixteen individuals were individually placed in 50 ml flasks with different copper conditions (0, 20, 60, 120 ?g/L) at different temperatures (0°C, 5°C, 10°C, 15°C, 20 °C) in incubators. The survival was checked daily over four and six days. Survival was modelled as a function of temperature and copper conditions using Cox proportional-hazards model, and Kaplan-Meier survival curves. Preliminary analyses showed that the tolerance threshold for copper was identified between 0 and 20 ?g/L, while the thermal tipping point was found between 15°C and 20 °C. Above 20 ?g/L, the effect of copper dominated and masked the effect of temperature on survival. Seasonality did not seem to affect the sensitivity to temperature and copper.

2.01.P-Mo144 Chronic Toxicity of Methoxyfenozide to Aquatic Macroinvertebrates at Two Different Temperatures

***Iim Imroatushshoolikhah**[1], Ayesha Siddiqa[1] and Paul van den Brink[2], (1)Wageningen University and Research, Netherlands, (2)Wageningen University and Research, Wageningen, Netherlands*

Methoxyfenozide, a diacylhydrazine insect growth regulator, has become a globally popular insecticide due to its high specificity for lepidopteran pests. As an ecdysone agonist, methoxyfenozide mimics the molting hormone and triggers premature molting, leading to developmental arrest and mortality. However, its environmental persistence and potential to disrupt endocrine systems in non-target organisms raise concerns. Furthermore, temperature an environmental stressor amplified by climate change can modulate pesticide toxicity, potentially increasing its risks to aquatic ecosystems. The acute toxicity of methoxyfenozide has been studied in Aedes aegypti, Culex quinquefasciatus, Anopheles gambia for 10 day period and in Chironomus tentans for 5 days in the endpoint point of mortality. Moreover, a developmental study highlighted the significant potency of methoxyfenozide against C.tentans, showing activity comparable to its high efficacy observed in lepidopteran larvae. In this study, we evaluate the chronic toxicity of methoxyfenozide at different temperatures to bridge a critical knowledge gap in understanding the ecological risk of long-term effects of methoxyfenozide, especially under climate change. We tested insect and crustacea as the models because they have homologous endocrine pathways. We exposed Gammarus pulex and Cloeon dipterum juveniles to methoxyfenozide in 7 concentrations ranging from 0 to 100 µg/L under 10 and 18 °C. We assessed survival, immobility, and food consumption during the chronic test of 28 days. Results revealed that the 28d, EC50 of C.dipterum at 10 and 18 °C were 126 and 75 µg/L, respectively, indicating an increased toxicity at higher temperatures. The 28d, EC50 of G.pulex were much higher than the highest concentration tested. C.dipterum showed a lower EC50 than

G.pulex, consistent with the mode action of methoxyfenozide. Survival probability in all treatments was lower with higher temperatures. These findings emphasize the need for integrated assessments considering multiple stressors. Follow-up experiments will investigate mechanistic processes by including bioaccumulation and multi-generation to evaluate cumulative long-term- effects on non-target species, especially insect larvae. These studies would enhance understanding of the long-term impact of methoxyfenozide for guiding sustainable pesticide use.

2.01.P-Mo145 Impact of Increasing Temperature Fluctuations on the Toxicity of λ-Cyhalothrin to *Chironomus riparius*

Maren Dill[1]*, Guido Gonsior*[2]*, Sara Cuellar*[3] *and Gundula Gonsior*[1]*, (1)GG BioTech Design, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design, Germany, (3)Algae Research, GG BioTech Design, Germany*

Ongoing global warming and the associated increase in water temperature will have a variety of effects on freshwater habitats. The threat posed to non-target organisms by plant protection products may increase as a result. Temperature is an important factor in ecotoxicological studies, it acts as a stress factor and can influence the physiological state of organisms. Rising average temperatures can lower toxicological endpoints of risk assessment. In addition to average temperatures, the intensity and frequency of daily temperature fluctuations will also increase in the future. Ecotoxicological studies have already shown that the increase in daily temperature fluctuations has a greater impact on organisms than the increase in the average temperature. This might be crucial for evaluating the toxicity of plant protection products and thus could play a relevant role in future risk assessment. Our aim is to record the effects of plant protection products on non-target organisms in the event of (increasing) daily temperature fluctuations. We present data of acute ecotoxicological studies with Chironomus riparius and ?-Cyhalothrin (according to OECD 235) with three different temperature scenarios where the daily fluctuation is either 0, ± 5 or ± 10°C.

2.01.P-Mo146 Influences of Sertraline on the Activity Patterns of the Phantom Midge Larvae Chaoborus Under Varying Temperature Conditions

Frida Pallapies*, Roman Epping and Linda C. Weiss, Ruhr-University Bochum, Department of Animal Ecology, Evolution and Biodiversity, Germany*

Global change significantly impacts freshwater ecosystems, contributing to biodiversity loss and ecosystem instability. Among various anthropogenic influences, rising temperatures and micropollutants, such as antidepressants, are major stressors. Selective serotonin reuptake inhibitors (SSRIs), like sertraline, are increasingly found in freshwater due to rising prescription rates and low removal efficiency in wastewater treatment plants. These neuroactive substances affect serotonergic pathways in invertebrates, often linked to feeding behavior and activity patterns. Simultaneously, elevated temperatures accelerate metabolic rates, potentially altering behavior and interaction dynamics in freshwater organisms. Behavioral adaptations are critical for survival in the context of predation. Prey often reduce activity to avoid detection, while ambush predators, like the phantom midge Chaoborus, rely on motionless stealth to capture prey. These strategies may be compromised under stress from elevated temperatures or exposure to neurostimulants. Furthermore, Chaoborus, a key species in freshwater food webs, preys on zooplankton and serves as prey for fish, transferring energy up the food chain. Stressor-induced behavioral changes, such as reduced predation rates on zooplankton and increased vulnerability to fish predation, could destabilize these ecosystems. In this study, we investigated the effects of sertraline and elevated temperatures on Chaoborus larvae activity and predation patterns. Larvae were exposed to sertraline under ambient and elevated temperature conditions. Results showed that both stressors reduced overall activity and predation rates. Reduced predation by Chaoborus could lead to increased zooplankton populations, such as Daphnia, altering community composition and improving water clarity through enhanced phytoplankton grazing. These changes may disrupt trophic dynamics, reducing energy transfer to higher predators, such as fish, and shifting nutrient cycling processes. Understanding how combined stressors impact predator-prey dynamics is crucial for predicting and mitigating global change effects on aquatic ecosystems. This study highlights the importance of addressing multiple anthropogenic pressures to preserve freshwater ecosystem health and functionality.

2.01.P-Mo147 Interactive effects of mixtures of Copper and Pendimethalin to Microalgae – Temperature Matters!

Micael Mendes Neves[1]*, Fatima Jesus*[1]*, Fernando J M Goncalves*[1] *and Ana Marta Goncalves*[2]*, (1)Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, CFE Centre for Functional Ecology: Science for People & Planet, Marine Resources, Conservation and Technology, Department of Life Sciences, University of Co, Portugal*

Climate changes are linked to extreme weather events affecting various activities and ecosystems. The growing world population and food consumption demand intensive use of fertilizers and pesticides. Among pesticides, copper and pendimethalin have been commonly used. Copper is widely used in biological agriculture and is component of several other pesticides. Although it is an essential metal, it becomes toxic in high amounts. Pendimethalin is a widely used herbicide of the dinitroaniline family, used to control annual grass and broadleaf weeds in various crops. When these contaminants enter in aquatic systems, they can harm non-target organisms like microalgae, which are similar to other plants and become unintended targets of herbicides. Therefore, it's crucial to determine if climate changes influence the combined toxicity of pesticides on microalgae. This study evaluates how temperature affects the toxicity of copper and pendimethalin mixtures on microalgae, using Raphidocelis subcapitata as a model, at environmentally realistic concentrations. Growth inhibition assays were performed at 15ºC, 20 ºC and 25ºC, and the obtained yield data were modelled using the mixture models Concentration Addition (CA) and Independent Action (IA), accounting for possible deviations. Both models fit the experimental data similarly, with the IA model performing slightly better at 15ºC and 25ºC. Considering the distinct modes of action of both compounds, the IA model was chosen to describe and predict the interactive effects of both contaminants. At 15ºC, the baseline IA model described better the obtained data (R2 = 0.8837). At 20ºC, the model that best described the data was IA with a Dose Ratio deviation (R2= 0.9345), showing antagonistic effects, most likely caused by copper. At 25ºC, the IA model with a Dose Level deviation was the model which best explained the data (R2= 0.9544), showing antagonistic effects at low concentrations but predicting synergetic effects at higher concentrations. These results indicate that rising temperatures could alter the interactive effects of both contaminants on freshwater microalgae. At higher temperatures, there was a trend for antagonistic interactions at environmentally realistic concentrations, suggesting that the combined toxicity of these contaminants might be lower than predicted based on their individual toxicity at low temperatures. These findings enhance our understanding of climate change's effects on microalgae.

2.01.P-Mo148 Effects of Altered Metamorphosis on the Population Maintenance of Amphibians - A Systematic Review

Adam Jonas[1]*, Lucie Ctverackova*[2] *and Tomas Novotny*[2]*, (1)Regartis, Praha 6-Břevnov, Czech Republic, (2)EcoMole, Czech Republic*

The Regulation 2018/605 laying down the scientific criteria for the identification of pesticides having endocrine disrupting (ED) properties on humans and non-target organisms was published in 2018. To reach a conclusion on ED properties for wild species according this regulation, amphibians are considered the model species based on the available knowledge and test methodology. For amphibians, any effect on metamorphosis is considered adverse. However, a better understanding of the extent to which metamorphosis have to be altered to produce an impairment on populations is needed. Protocols and search strategies were developed for this project. Consequently, an extensive review of the literature was done to identify effects of altered metamorphosis on the population maintenance of amphibians. For the systematic review a search strategy was developed to identification of 2342 papers based on a research question. The relevance analysis of the documents according to the eligibility criteria did not identify any articles which would answer the initial question. Nevertheless, articles focused on metamorphosis change or population strategies of various amphibians were identified. Findings showed the complexity of populations, interactions and complexity of environmental interactions and various species life and reproduction strategies of orders Anura and Urodela. Based on this review a research which investigates effects on metamorphosis assessed in AMA and simultaneously investigate consequence of such effects on population maintenance does not exist. However, there are several technics used in the ecology research present in examined studies which could allow to conduct future population study for linking the laboratory experiments such as AMA with the in situ population research. Question in such study would be the extra species extrapolation as species use different life strategies, but at least as a proof of concept of metamorphosis effects on population maintenance a study could be designed.

2.01.P-Mo149 Oxidative Status In Two Populations of the Invasive Asian Clam in a Major Estuary in South America

Florencia Liquin[1]*, Tatiana Noya Abad*[2]*, Henrique Knack de Almeida*[2]*, Stephanie Beraldo Pissinis*[3]*, Paolucci Esteba*[3]*, Sebastian Sabatini*[2] *and Francisco Sylvester*[4]*, (1)Facultad de Ciencias Naturales, Instituto para el Estudio de la Biodiversidad de Invertebrados, Universidad Nacional de Salta, Argentina; Faculty of Biological Sciences, Goethe University Frankfurt, Frankfurt am Main, Germany, Argentina, (2)Laboratorio de Enzimolog a, Estres Oxidativo y Metabolismo, Departamento de Qu mica Biologica, IQUIBICEN-CONICET, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Argentina, (3)Museo Argentino de Ciencias Naturales Bernardino Rivadavia , CONICET, Argentina,*

(4)Facultad de Ciencias Naturales, Instituto para el Estudio de la Biodiversidad de Invertebrados, Universidad Nacional de Salta, Argentina; Faculty of Biological Sciences, Goethe University Frankfurt, Frankfurt am Main, Germany; Consejo Nacional de I, Argentina
Invasive species face multiple environmental stressors within the ecosystems they colonize. In aquatic habitats, these stressors include pollution, parasites, and variations in water temperature, which can significantly affect the competitive abilities of these species and potentially restrict their expansion. The present study evaluated two populations of the invasive clam Corbicula fluminea in the Río de la Plata estuary, one of Argentina s most significant waterbodies. These populations are exposed to varying levels of anthropogenic impact: Parque de los Niños (PN), in the northern part of the estuary, is heavily impacted by urban pollution, whereas Punta Lara (PL), situated 74 km to the south, is away from this influence. Between October and November 2023, we collected clams and water samples from both sites. Live clams were transported to the laboratory to assess their gill oxidative status and examine the potential influence of the gill parasite Chaetogaster limnaei at two different temperatures: 21°C (the water temperature at the time of sampling) and 12℃ (the average water temperature during the winter). The infection prevalences were also determined. Oxidative stress biomarkers analyzed included the antioxidant activities of reduced glutathione (GSH), glutathione S-transferase (GST), and catalase (CAT), as well as thiobarbituric acid reactive substances (TBARS), as indicator of lipid peroxidation. Metal concentrations (Cd, Co, Cr, Cu, Fe, Ni, Pb, and Zn) were analyzed in the water. Significant differences ($P<0.05$) in cobalt (Co), iron (Fe), and lead (Pb) were observed between the two sites, with higher levels detected in PN. Parasite prevalence was 6% and 4% in PL and 43% and 40% in PN at 12°C and 21°C, respectively. While temperature and parasite prevalence significantly affect all the studied variables (CAT, GST, GSH, and TBARS) of clams collected at PN, these two factors only affect GSH and TBARS activities of the studied clams at PL. These findings suggest differences in the oxidative stress status of the two C. fluminea populations, possibly influenced by the biotic and abiotic conditions of the two sites in the Río de la Plata estuary. Clams from PL demonstrated potentially higher fitness, characterized by lower infection prevalence and reduced metal concentrations. These factors may play a role in determining the survival and spread of this highly invasive species to novel habitats.

2.01.P-Mo150 Evaluation of the Population-Level Impacts of Chemical Exposures on Pacific Salmon in the Puget Sound, Washington, USA. - Part 2 – Emerging Contaminants and Sublethal Effects

Maya Faber[1]*, C. Andrew James*[1]*, Ruth Sofield*[2]*, John Best*[3]*, Sandra O'Neill*[3]*, Andrea Carey*[3] *and Molly Shuman-Goodier*[3]*, (1)University of Washington Tacoma, United States, (2)Western Washington Tacoma, United States, (3)Washington Department of Fish and Wildlife, United States*
In the western United States, several wild Chinook salmon (Oncorhynchus tshawytscha) populations have been listed as either threatened or endangered under the U.S. Endangered Species Act. Declining populations have been attributed to salmon habitat quantity and quality, including the presence of anthropogenic contaminants. Chinook salmon are particularly susceptible to contaminant exposures during critical early life stages spent rearing and foraging in rivers and estuaries where contaminants enter the environment from multiple sources. Polybrominated diphenyl ethers (PBDEs) are a group of contaminants that have been widely used as flame retardants in consumer products such as electronics, textiles, and plastics. While the production of many PBDE mixtures has been phased out due to human health concerns, certain congeners, including BDE-47 and BDE-99, remain prevalent, and continue to be detected in Chinook salmon tissue in Puget Sound, WA, USA. Despite emerging concerns regarding the adverse effects of PBDE exposure on individual salmon health, their population level impacts have not been investigated. This study aims to evaluate the impacts of PBDE exposure on Chinook salmon populations, focusing on the interactive effects of PBDE mixtures, particularly BDE-47 and BDE-99, on host-susceptibility to disease. Using the population model developed for legacy chemicals with field-collected PBDE exposure data and Listonella anguillarum as a model pathogen, this work estimates the incidence of delayed disease-induced mortalities in juvenile Chinook salmon populations in Puget Sound. This work improves our understanding of how sublethal effects, such as immunosuppression, contribute to population-level impacts, underscoring the potential benefits of pollution remediation efforts in promoting salmon recovery in the Pacific Northwest.

2.01.P-Mo151 Chemical Stressors and Their Impacts on Edaphic Organisms: The Role of MPs and Pesticides

Amanda Araujo[1] *and Evaldo Espindola*[2]*, (1)LEEA/SHS, S o Carlos Engineering School, University of S o Paulo, Brazil, (2)LEEA/SHS and PPGSEA, S o Carlos Engineering School, University of S o Paulo, Brazil*
Terrestrial ecosystems are increasingly subject to simultaneous exposure to multiple chemical stressors, such as pesticides and microplastics (MPs), whose interactions can cause impacts are still unknown. MPs, due to their high persistence, can adsorb pesticides and release plastic additives, altering the degradation,

transport, and ecotoxicity patterns of these compounds in the soil. In countries with a strong presence of agribusiness, such as Brazil, MPs from agricultural plastic materials are one of the main sources of this type of pollutant, contributing significantly to the contamination of various ecosystems. In this regard, this study aims to investigate the ecological and toxicological impacts of the interaction between polyethylene microparticles and the pesticides imidacloprid and tebuconazole in natural soil, considering the coexistence and interaction of these contaminants. Experiments include conventional level I ecotoxicological tests and intermediate multispecies systems, focusing on survival, reproduction, biochemical changes, and changes in soil community composition. The edaphic species used include Sinella curviseta, Proisotoma minuta, and Enchytraeus crypticus, while parallel trials with Eruca sativa and Allium cepa will evaluate the effects on plants. The experimental design reflects environmentally relevant conditions, such as precipitation simulations and repeated applications of contaminants, to investigate the cumulative effects of these residues and their impacts on soil organisms. We start from the hypothesis that the interaction between MPs and the soil alters the bioavailability of MPs to organisms, interfering with the fate and toxicity of pesticides. Furthermore, toxicity to edaphic species may vary according to their position in the soil layers (euedaphic and epedaphic). This study is expected to provide unprecedented data on the interactions between MPs and pesticides, contributing to a more realistic and in-depth risk analysis. To our knowledge, this study is the first to address the toxicity of MPs associated with pesticides in multispecies systems, significantly expanding knowledge about the impacts on soil organisms. Therefore, the study can support public environmental management policies and effective strategies for mitigating ecological risks in tropical soils. A.P.C.A. thanks the Laboratory of Ecotoxicology and Applied Ecology EESC/USP (University of São Paulo) for the research opportunity and wants to express her gratefulness to the São Paulo State Research Foundation (process: 2024/12350-0).

2.01.P-Mo152 Ecotoxicological Assessment of Anti-Tuberculosis Medications in Aquatic Environments: Occurrence, Reproductive Effects and Ecological Risks

***Wei-Yu Chen**, Cong-Wei Li, Yi-Jie Wang, Yi-Ying Li, Xiang-Rong Huang and Chung-Hung Chen, Department of Ecology and Environmental Resources, National University of Tainan, Taiwan*

Antituberculosis medications have the potential to elicit a range of adverse effects, such as neurotoxicity, and reproductive toxicity, in terrestrial organisms. Limited knowledge exists about the potential consequences of chronic exposure in aquatic ecosystems. This study aims to assess the reproductive toxicity of isoniazid (INH), rifampicin (RMP), and ethambutol (EMB) and exposure risk in aquatic organisms. We conducted reproduction tests on Daphnia magna, and measured residues of antituberculosis medication in aquatic environments to assess the ecotoxicological risks. Except for EMB, INH and RMP exposures did not affect number of broods and did not delay the time to the first bro od at high concentration exposures in daphnia. However, three antituberculosis medications caused a significant decrease in the total number of neonates. We used the Benchmark dose to determine the thresholds for 2.80 mg/L of INH, 1.37 mg/L of RMP, and 22.14 mg/L of EMB in aquatic environments. For environmental residues, EMP has the highest frequency detection of 92% in rivers, while INH has the highest environmental residue level ranging from 81.01 to 547.88 ng/L, with RMP shows the lowest residue level and detection rate in rivers. Although there are no ecotoxicological risk concerns, INH has the highest exposure risk with a risk quotient of 0.03 (95%CI: 0.0018 0.1630). Here, these findings contribute to the ecotoxicological impacts of antituberculosis medications in aquatic environments and highlights isoniazid as a potential concern due to its highest residues and exposure risk.

2.01.P-Mo153 The Practical Application of Toxic Pressure and Bioassays for the Micropollutants Measurement Network HHNK 2023

*Feline M. Smits and **Chantal K.E. van Drimmelen**, HHNK, Netherlands*

Hoogheemraadschap Hollands Noorderkwartier (HHNK) has been investigating the topic of micropollutants since 2014. The micropollutant monitoring aims to gain insight into the situation in our water management area and to develop knowledge about the role of sewage treatment plants (WWTP) in the removal and transport of pharmaceutical residues. The Key Factor Toxicity uses several methods to determine the toxicity of substances. One of them is to calculate the toxic pressure via the species sensitivity distribution (SSD) per substance. From these SSD curves the percentage of potentially affected fraction (PAF) per concentration of the substance can be read. When this is done for each substance, all PAF results can be added together to arrive at a more substances (ms)PAF. In addition to calculating toxic pressure (TP) the response of living organisms can also be looked at through bioassays. HHNK sampled effluent from WWTPs and surface water taken in June and September of 2023. The following bioassays were conducted: Daphniatox, Microtox, PAH-Calux, ER-Calux, PXR-Calux, and GR-Calux, P53-Calux (-S9). Overall, September scores can be seen to be somewhat worse than June. The GR-CALUX and the

P53-CALUX score relatively well. In contrast, the PXR-CALUX stands out as it scores poorly in almost all samples. This bioassay measures toxicant conversion and is sensitive to a wide range of substances. The Microtox, PAH-Calux and ERa-Calux score moderately. In all bioassays, more frequent and/or higher effects were observed in effluent than in surface water. The TP calculations give a good picture for the selected list of substances. However, this underestimates the actual toxic pressure. Not all substances are measured and included in the TP even though they may be present in the sample, and the SSD curves are also not available for all substances. The results of the TP and bioassays are broadly similar. For example, both results show that higher effect and toxic pressures were observed in effluent than in surface water. HHNK recommends continuing monitoring this monitoring network and annually update the analysis with the via data. This will provide insight into trends but also give a better picture of the toxic effects and pressures within the area. As more and more substances come onto the market, it will eventually become impossible to monitor them all through chemical analysis. Bioassays can be a valuable addition to that. HHNK is a Dutch government agency.

2.01.P-Mo154 Assessing the Reproductive Status of Fathead Minnows (*Pimephales promelas*) Exposed to Frank Lake, AB, Canada Effluent as a Bio-indicator of Ecosystem Health

Rayen Morales Urrutia[1]*, Jaden Griffiths*[1]*, Blake Hunnie*[2]*, Markus Brinkmann*[2] *and Steve Wiseman*[1]*,*
(1)University of Lethbridge, Canada, (2)University of Saskatchewan, Canada

Municipal and industrial wastewaters are complex chemical cocktails, including personal-care products, pharmaceuticals, and pesticides, many of which are endocrine disrupting chemicals. Frank Lake (FL) is a multi-basin wetland in southern Alberta, Canada, that was restored to stable water levels in 1990 with the addition of a combined effluent from the town of High River and the Cargill beef processing facility. At high precipitation levels, water from FL drains into the Little Bow River that ultimately drains into the Twin Valley Reservoir, Alberta s newest reservoir. The biological effects that input of largely uncharacterized chemicals might be causing in the wetland, river, and multi-use reservoir are unknown. The study objective was to assess the reproductive physiology of fathead minnows exposed to the combined effluent from High River and Cargill. Standard 96-hr and 21-day assays were performed to assess reproductive toxicity, with the 96-hr assays being completed three times over the summer season of 2024 to quantify temporal variation in effluent toxicity. Fecundity and health indices (female condition factor, gonadosomatic index, hepatosomatic index) were not affected with exposure. Males exposed to high (75%) effluent concentration had a 25% decrease in condition factor (p=0.0441) and a 16% decrease in fertilization success (p=0.0247). Additionally, the tubercle score of males was increased by 55% with high effluent concentration (p=0.0068). Plasma concentrations of sex steroids and vitellogenin, expression of genes along the hypothalamus-pituitary-gonad-liver axis, and histological assessment of testes are being used to determine molecular and biochemical mechanisms of reproductive impairment in male fish. To complement laboratory assays, the same analyses of plasma and tissues are being assessed in male and female fathead minnows captured from Frank Lake and from a reference lake that does not receive effluent. This research will expand the understanding of industrial and municipal effluent impact on aquatic ecosystems, including health of exposed biota, and inform future management decisions regarding Frank Lake.

2.01.P-Mo155 Co-occurrence of Microplastics and Contaminants of Emerging Concern in River Water, Sediment and Fish: The Case Study of Júcar River Basin (Spain)

Vasiliki Soursou[1]*, Julian Campo*[2]*, Jacopo La Nasa*[3]*, Francesca Modugno*[4] *and Yolanda Pico*[5]*,*
(1)University of Valencia, Valencia, Spain, (2)CSIC, Spain, (3)University of Pisa, Italy, (4)Department of Chemistry and Industrial Chemistry, University of Pisa, Italy, (5)University of Valencia, Moncada, Valencia, Spain

There is rising concern about the environmental pollution by microplastics (MPs), especially about their ability to accumulate various types of contaminants on their surface. These contaminants include pesticides, pharmaceutical and personal care products (PPCPs), per-/ poly-fluoroalkyl substances (PFASs) and polycyclic aromatic hydrocarbons (PAHs). The co-occurrence and combined toxicity of MPs and organic pollutants needs to be studied. Thus, the presence of MPs, pesticides, PFASs, PPCPs and PAHs in water, sediment and fish samples from the Júcar River basin (Spain) was determined. The Júcar River flows through three different provinces, being one of the most important rivers in E Spain. The extraction was optimized for each matrix and contaminant. Density separation and digestion were combined for MPs extraction from water and sediment, while a microwave-assisted digestion was performed for MPs present in the fish gastrointestinal track. For the organic pollutants, solid-phase extraction and microwave-assisted extraction were adapted for each matrix. For MPs, ?FTIR and Pyrolysis coupled with Gas Chromatography-Mass Spectrometry (Py-GC-MS) were utilized, while the PAHs were analysed using GC-MS and the rest of the contaminants were analyzed by High Pressure Liquid Chromatography-High

Resolution Mass Spectrometry (HPLC-HRMS/MS), in both target and non-target modes. ?FTIR indicated the presence of MPs in all water samples (0.1- 6.9 MPs L-1), whereas 73% of the sediment samples and 66% of the fish samples were polluted by MPs (sediments: 20- 140 MPs Kg-1, fish: 6.7- 26.7 MPs g-1). The main polymer types were polyethylene (water and sediments) and polyvinyl chloride (fish). Tebuconazole and difenoconazole were the most abundant pesticides in water. Perfluorobutane sulfonate and the painkillers ibuprofen and tramadol, were found in all water samples. The initial water analyses points to correlations between MPs and pesticides (i.e. propazine, imazalil, thiabendazole) and the flame retardant tris(chloropropyl) phosphate, particularly at two sampling points (highest MP amounts). Completing all analyses of sediment and fish samples will provide a better understanding of MPs and emerging contaminants co-occurrence. The risk assessment that is currently being performed, allows the estimation of the environmental toxicity that multiple anthropogenic pressures cause to wildlife and human health in a basin representative of the Mediterranean. This work has been supported by the Generalitat Valenciana (GV) through the Prometeo Programme CIPROM/2021/032. V. Soursou also acknowledges her pre-doctoral contract ACIF/2021/408 and the grant CIBEFP/2023/154, both funded by the GV. The latter allowed her to work at the University of Pisa, Italy for 3 months.

2.01.P-Mo156 Vulnerability of Groundwater Species to Wildfire Ashes

Nelson Abrantes[1], *Maria Dias*[2], *Carlos Gravato*[2] *and Ana Sofia P. S. Reboleira*[2], *(1)Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal, (2)Faculdade de Ciencias, Universidade de Lisboa, Portugal*

Subterranean ecosystems possess unique characteristics and host specialized organisms critical for maintaining groundwater quality. Despite their ecological stability, cave habitats are increasingly threatened by contamination from anthropogenic and natural sources, including wildfires. Wildfires are diffuse sources of water pollution, impacting surface and groundwater systems. Wildfire ashes contain harmful organic and inorganic compounds, such as polycyclic aromatic hydrocarbons and metals, which pose significant environmental risks due to their toxicity and bioaccumulation potential. This study assessed, for the first time, the effects of wildfire-related compounds on two groundwater-adapted crustaceans (stygobionts), Proasellus lusitanicus and P. assaforensis (Isopoda: Asellidae), differing in their adaptation to subterranean habitats. Organisms were exposed to ash dilutions, followed by biomarker analyses targeting detoxification, antioxidant defenses, oxidative damage, metabolism, and neurophysiology. Biomarkers included glutathione S-transferase, total glutathione, catalase, lipid peroxidation, electron transport system activity, lactate dehydrogenase, acetylcholinesterase, and total protein. Results revealed elevated lipid peroxidation in both species, indicating oxidative stress. P. assaforensis, the less groundwater-adapted species, showed increased lactate dehydrogenase activity at 1.25 g/L ash concentration, producing sufficient energy to counteract oxidative damage. However, this mechanism failed at higher concentrations. Conversely, P. lusitanicus, the more specialized species, experienced significant catalase inhibition across all tested concentrations and heightened ventilatory activity at the highest concentrations. This response suggests energy-seeking behavior, as P. lusitanicus lacks anaerobic energy production capacity, likely due to its adaptation to the stable subterranean environment. This specialization makes P. lusitanicus more vulnerable to stressors compared to P. assaforensis. These findings highlight the susceptibility of groundwater communities to wildfire-derived stressors, potentially disrupting ecosystem functioning and water quality. The loss of these species could impair subterranean ecosystems, triggering cascading ecological imbalances and affecting the water quality. Preventive conservation measures are critical to protect these organisms and preserve the ecological integrity of subterranean habitats.

2.02 Evolutionary and Mechanistic Insights to Improve Ecotoxicology

2.02.T-01 The Use of Ecological Relevant High-Throughput Video-Tracking Behavioral Responses in *Daphnia magna* in Environmental Risk Assessment of Chemicals

Carlos Barata *and Juliette Bedrossiantz, IDAEA-CSIC, Spain*

Recent advances in imaging allow to monitor in real time the behaviour of individuals under a given stress. Light is a common stressor that alters the behaviour of fish larvae and many aquatic invertebrate species. The water flea Daphnia magna as many other zooplanktonic species show anti-predatory behavioural responses to light to avoid visual predators like fish. Antipredator behavioural responses include scape responses to light such as increase motility under light and diel vertical migration characterized by swimming towards deep and dark waters during daylight and towards surface waters during night to feed on alga. It is also known that many of those species used particular light wavelengths to trigger their migratory movements and other ones to search for food. The aim of this talk is to show recent developments using commercial and custom made high-throughput video-tracking devices that have been use to study how neuro-active chemicals affect cognitive responses phylogenetically conserved such as those belonging to short term non associative learning to repetitive stimuli (sensitization, habituation), visual motor responses and phototaxis including colour preference. We also provide omic data anchoring those responses with known neurological molecular pathways. Examples include how illicit drugs such as cocaine, methamphetamine, MDMA and ketamine disrupt serotonergic and dopaminergic signalling routes and habituation and visual motor responses to light in a similar way as they do in humans, how fish kairomonesand other drugs affect phototaxis across D. magna clones and their underlayer molecular mechanisms and how UV filters modify the light colour preferences and its ecological implications. Our results indicate that automated imaging enriched methods are promising high-throughput New Aproach Methodologies (NAMS) to screen the toxicity of chemicals using ecological and human relevant health responses

2.02.T-02 Data-Driven Characterization of Chemical Impacts on the Genetic Diversity of Wild Populations: A Case Study

Marissa B Kosnik, *Tiffany Scholier and Daniel Guignard, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Chemical pollution threatens within-species genetic diversity, and understanding the potential impacts of chemicals is essential to determine the resilience and adaptation potential of different species. However, methods for assessing chemical impacts on the genetics of wild populations are limited, and primarily depend on sequencing large numbers of organisms in a given population/geographic region, which is impractical for all species/populations. Further, finding connections between the genetics of wild populations and chemical exposures is challenging and difficult to do prospectively. We propose that data-driven approaches are essential to help fill the knowledge gap for chemical impacts on the genetics of wild populations. As a proof of concept, we conducted a case study of pesticide impacts on wild boar in Europe to see whether we could identify a link between pesticide concentrations in the environment and differences in wild boar genetic variation. We chose to focus on single polynucleotide polymorphisms (SNPs) as this is the most common type of genetic variation. We collected data on wild boar SNP variation at different sampling sites in Europe (e.g., studies originally conducted to assess wild boar population structure) and maps of modelled soil pesticide concentrations for Europe from the literature. We used a landscape genomics approach to assess the potential relationship between pesticide exposure and wild boar genetic variation. Of the 40,700 SNPs included in the analysis, 2,228 were significantly associated with one or more pesticides, and 702 were intragenic covering 396 unique genes (66 total pesticides were associated with these SNPs/genes). To assess if the SNPs/genes associated with pesticides in the analysis made biological sense, we identified enriched Gene Ontology (GO) terms and found 29 GO terms enriched, including several nervous system-related phenotypes (e.g., neuron to neuron synapse). Because many pesticides are known to have neuronal activity (e.g., malathion, diquat), this provides some support for our predicted associations. To provide further support to the Pesticide SNP/gene associations from our landscape genomics approach, we looked at reported associations from the literature and found external support for pesticides altering gene activity in wild boar. This analysis demonstrates the value of repurposing existing datasets to assess the potential impact of chemicals on genetic variation in populations.

2.02.T-03 Evolutionary Adaptation to Predation Mediates Microplastics Sensitivity in *Daphnia Magna*: The Critical Role of Gut Microbiota

Jingzhen Li[1], Wencheng Xu[1], Haoxun Zhang[2], Protopopov Mikhail[3], Mengjie Chang[2] and ***Chao Zhang**[1]*, *(1)Shandong University, China, (2)China, (3)Russian Federation*

Microplastic pollution and predation pressure are two key stressors in aquatic ecosystems, but their interactive effects, especially from an evolutionary perspective, are poorly understood. Furthermore, the role of gut microbiota in mediating these combined stressors remains underexplored. This study examines how historical fish predation (pre-fish and high-fish periods) shapes Daphnia magna's tolerance to combined predation and microplastics stressors and explores the role of gut microbiota in modulating these effects. Our findings show that microplastics strongly disrupt the inducible defenses of Daphnia, with populations from high-fish environments displayed stronger adaptive responses to predation, which in turn enhanced their tolerance to microplastics when exposed to both stressors. Moreover, gut microbiota were proved crucial in modulating the resilience of Daphnia to these combined pressures. High-fish period Daphnia exhibit a more resilient gut microbiota, which is characterized by minimal alterations in gut microbial diversity and enhanced functional attributes under stress. This study highlights the importance of evolutionary perspective and the complex interplay of environmental pressures in assessing the ecological risks of microplastics, emphasizing the pivotal role of gut microbiota in mediating these interactions.

2.02.T-04 Determination of Immuno-ecotoxic Effects and Evaluation of their Relevance for Chemical Hazard Assessment

Kirsten Germing[1]*, Elke Eilebrecht*[1]*, Sebastian Eilebrecht*[2]*, Martina Ross-Nickoll*[3]*, Joachim Kurtz*[4] *and Christoph Schafers*[5]*, (1)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (3)RWTH Aachen, Germany, (4)University of Munster, Germany, (5)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany*

Climate change, invasive species and habitat fragmentation pose major challenges for the stability of ecosystems. It is assumed that in stressed ecosystems, pathogens in particular exert strong pressure on populations. In addition, the organisms in the environment are exposed to a large number of directly or diffusively released environmental pollutants such as pesticides or drugs. The ecotoxicological hazard and risk assessment of chemicals currently does not include the identification of effects regarding the immunocompetence of organisms. However, studies indicate that chemicals can induce various effects on immune related parameters of organisms. In relation to the increasing pressure from pathogens, immunotoxic effects of chemicals that impair the immunocompetence of organisms could influence host-pathogen-interactions and could pose a significant threat to the stability of ecosystems. Thus, the regulatory authorities claim that methods must be developed to identify immunotoxic modes of action (MoA) of chemicals. The presented project aims at the establishment of standardized methods to identify immunotoxic MoA of chemicals in Danio rerio (Zebrafish) and Tribolium castaneum (Red flour beetle). Challenge experiments are performed using pathogen-associated-molecular patterns (PAMPs) to induce an activation of the immune system. The test organisms are exposed to selected chemicals with known MoA like drugs with immune suppressive or stimulating properties and are PAMP-challenged after exposure. Molecular fingerprints for immunosuppressive and immunostimulating MoA in the challenged immune system are identified using transcriptomics and proteomics. To add on to the weight of evidence for immunotoxicity, effects on immune related parameters are investigated. In a last step of the project, substances that are suspected to influence the immunocompetence of organisms, for example RNAi pesticides, are tested using the established methods. Furthermore, the effect of these substances on population relevant endpoints are examined in extended ecotoxicological tests and host resistance assays are conducted. The results of the study will contribute to the development of Adverse Outcome Pathways (AOP) for immunotoxicity.

2.02.T-05 Does Thermal Evolution Influence Thermal Performance Curves Under Pollutant Exposure?

Ying Dong[1]*, Julie Verheyen*[2] *and Robby Stoks*[3]*, (1)KU Leuven, Belgium, (2)Biology, KU Leuven, Belgium, (3)KU Leuven, Belgium*

While it is well-known that natural populations can evolve higher thermal tolerance in response to global warming, less attention has been given to how this thermal evolution might influence responses to additional stressors, such as pollution. Although thermal performance curves (TPCs) are valuable and conceptual tools for predicting organismal and population responses to global warming, they have barely been applied to deepen our understanding of population dynamics in a world increasingly stressed by both warming and pollution. In this study, we tested the impact of pollutant exposure (three zinc concentrations) on the thermal performance curve of the water flea Daphnia magna, and examined how this was influenced by thermal evolution. To do so, we used clones from two D. magna subpopulations (old: 1955 1965 vs recent: 1995 2005) that have different levels of heat tolerance and have been resurrected from the resting bank of a single lake which has experienced an average temperature increase and more frequent heat waves in the recent decades. Overall, both low and high zinc concentrations reduced survival, acute heat tolerance (critical thermal maximum, CTMAX) and body size in both D. magna subpopulations. In the absence of zinc, thermal evolution in the recent subpopulation improved performance at the highest temperature (30 °C), with the recent subpopulation showing higher survival and CTMAX compared to the older subpopulation. However, the survival advantage due to thermal evolution was reduced and for heat tolerance, entirely offset by zinc exposure, with the recent subpopulation exhibiting lower survival and CTMAX than the older subpopulation under the combined stress of the highest temperature and zinc exposure. These findings emphasize that the benefits of thermal evolution were weakened for chronic heat tolerance and fully offset for acute heat tolerance under the most stressful combination of warming and zinc exposure. In conclusion, this study provides rare evidence that TPCs, which are widely used to evaluate the impact of global warming on organisms, can be significantly affected by metal exposure. Our results suggest that predictions of population responses to future warming based solely on TPCs may be biased if pollutant exposure is not considered. This underscores the importance of investigating pollutant toxicity across a range of temperatures to generate more accurate forecasts for populations facing a warmer and polluted world.

2.02.P Evolutionary and Mechanistic Insights to Improve Ecotoxicology

2.02.P-Tu163 Evolved Differences in Toxicity: Insights from the *Daphnia pulex-Daphnia pulicaria* Complex

***Emily Rose DeTemple**, Craig Jackson, Stephen Glaholt and Joseph Shaw, Paul H. O'Neill School of Public and Environmental Affairs, Indiana University, United States*

Daphnia are keystone species in aquatic ecosystems commonly used to monitor the impact of chemical pollution. Typically, toxicological assessment utilizes a single clonal isolate of a Daphnia species suggesting all Daphnia will respond similarly to chemical stressors. However, Daphnia have adapted to live in varied habitats around the globe, which shape their unique physiological processes and ecological preferences. In North America the predominant species are Daphnia pulex and Daphnia pulicaria which are part of a rapidly, radiating clade. They are phenotypically indistinguishable yet evolved to live in different habitats with D. pulicaria preferring static lakes, and D. pulex preferring ephemeral ponds. These habitat preferences drive important physiological differences of toxicological importance including life span, and reproductive and metabolic rates. A recent study from our lab has shown that only 30% of genome differs between species, while the majority (70%) is homogenized through gene flow. These differences are constrained to large, rearranged regions that persist on each chromosome and harbor genes under selection of these ecological forces. We hypothesize that the fixed differences found within these divergent regions, when probed with a variety of chemical stressors, will reveal the mechanisms controlling the differences in toxicity between the species. Our lab has determined that the triazine herbicide, Atrazine, produces differential acute and chronic responses between these species. Acute exposures revealed D. pulex are more sensitive to atrazine when compared to D. pulicaria. Chronic atrazine exposures revealed that D. pulex experience greater negative impacts on total reproduction in comparison to D. pulicaria. Individual responses support our hypothesis; but remain unclear if these responses are linked to the divergent regions. Therefore, this research presents the dissection of the molecular responses in the fixed differences that exist in the divergent genome regions in these species following exposure to atrazine. We hypothesis that these genes and processes that have evolved to prefer different habitats (ephemeral ponds, lakes) such as reproduction, formation reactive oxygen species, antioxidant defense, and lipid peroxidation will respond differently when exposed to Atrazine. This research will provide an example of how evolutionarily driven aspects of the genome can influence toxicological responses.

2.02.P-Tu164 Non-Invasive Automated Approach for Evaluating the Size of Small Aquatic Organisms: *Daphnia magna* Case Study

***Sizenando Nogueira Abreu**[1], Fatima Jesus[1], Amadeu M.V.M. Soares[1], Rui Escadas Martins[2] and Miguel Oliveira e Silva[2], (1)Centre for Environmental and Marine Studies, University of Aveiro, Portugal, (2)IEETA-Univ. Aveiro, TekenBio, Portugal*

In Ecotoxicology, there is an increasing demand for the measurement of sensitive sublethal endpoints, including developmental time, body length and growth rate. The evaluation of body length and subsequent growth rate in small aquatic organisms enables the inference of developmental time, which represents a sublethal endpoint with implications in the life-history of the model organisms. Assessing the body size of aquatic organisms is particularly relevant for Daphnia and similar model organisms, fulfilling the requests of chronic toxicity assays, according to OECD guidelines. Currently, the evaluation of the body size of neonates and adults often requires a stereomicroscope observation, either through direct measurement or subsequent measurement of previously captured images. Hence, the objective of this study was to assess the feasibility of using a non-invasive automated computer approach for evaluation of the body length of small aquatic organisms, with Daphnia magna at different life stages serving as a case study. The automated computer device (EP3214426B1), besides counting number of organisms, estimates the body size of D. magna neonates and adults , from the gravity-driven passage time (intercepting the light path of the sensors), regarding each individual organism that passes the sensors. The accuracy of the computer estimation of D. magna body length was obtained by comparing direct measurements (performed under a stereomicroscope, mm) to the device s indirect estimation, which is given by the corresponding passage time (duration of light interference induced by the same organism (µs)), showing a linear correlation ($y=0.74x$; $r2>0.92$). Subsequently, a linear high correlation ($y=1.0x$; $r2>0.92$) was also obtained between the conventional and the new computer-assisted approach for assessing the body length of D. magna. Results indicate that the computer assisted evaluation of body length is more straightforward and faster, thus, reducing the high costs and labor intensity associated with following the body length of aquatic small organisms. As a consequence, assessing the body length of an organism can be performed more easily, allowing the measurement over longer timescales, including multiple generations, which are considered to represent natural exposure scenarios more realistically.

2.02.P-Tu165 Sex-specific Vulnerability of Marine, Freshwater and Terrestrial Animals to Pollutants: A Meta-analysis Study

Eira Ronneberg[1]*, Khuong V. Dinh*[2] *and Susanne Claudia Schneider*[3]*, (1)Norwegian University of Life Sciences, Faculty of Environmental Sciences and Natural Resource Management, Norway, (2)Section for Aquatic Biology and Toxicology, Department of Biosciences, University of Oslo, Norway, (3)Norwegian Institute for Water Research, Section for Freshwater Ecology; Norwegian University of Life Sciences, Faculty of Environmental Sciences and Natural Resource Management, Norway*

Chemical pollution is ubiquitous and impacts animals across all realms, marine, freshwater and terrestrial ecosystems. However, chemical pollution may influence males and females differently, which may have consequences for populations, communities and ecosystems. To the best of our knowledge, no systematic reviews or meta-analyses have compared the effect of chemical pollution on females and males. Using the Web of Science Core Collection we conducted a systematic search for relevant publications on this topic in the last decade, from 2010 to 2022. Our search yielded 321 papers after duplicates were removed, and 125 primary research papers after title and abstract screening. Our aim was to explore sex-specific stress responses of exposed males and females. We studied species in different phyla and realms to chemical pollutants such as pesticides, flame retardants, hydrocarbons and microplastics. We further investigated the gene, hormonal and behavioural mechanisms underlying the different sensitivities between the sexes. Preliminary findings show that most of the studies are from the global North and China. Most studies are from the freshwater and marine realm, with most of the organisms tested being a few species of fish, crustaceans, and molluscs. Preliminary results suggest females have higher LC50/LD50, and underlying mechanisms vary between the sexes and species. Moreover, sex ratios can change towards more female or male dominance compared to the control. Our results suggest that pooling the sexes in ecotoxicological studies may confound the results, also because stress responses that alter sex ratios are likely to have long-term consequences for population fitness. We suggest that sex-specific vulnerability to pollutants should be included in ecotoxicological studies whenever possible to improve ecological risk assessments.

2.02.P-Tu166 Decades of E-Waste Recycling Activities Reshaped Local Mosquitofish by Adaptation to AhR Agonists

Huizhen Li *and Jing You, Jinan University, China*

Anthropogenic activities, such as electronic waste (e-waste) recycling, have led to severe pollution in aquatic environments with various aryl hydrocarbon receptor (AhR) agonists such as dioxin-like compounds (DLCs). However, the adaptive phenotypes of organisms in these polluted ecosystems remain largely unknown. Here, we identified a mosquitofish population (Gambusia affinis) that has resided for over 40 years at an e-waste recycling site and has developed adaptation to an AhR agonist, phenanthrene. This population exhibited a two-fold increase in resistance compared to a mosquitofish population from a reference site, in both F0 adult fish and F1 juvenile fish. The adapted G. affinis displayed elevated CYP1A induction both in vitro and in vivo, indicating an alternative adaptive strategy compared to previous studies. This adaptation involved increased biotransformation, rapid toxicant dynamics in vivo, and enhanced swimming behavior, suggesting a link to increased bioenergetic functions. These functions allow for higher energy allocation towards both behavioral activities and phenanthrene detoxification. Our findings underscore the importance of considering multiple levels of organismal effects to predict population and ecological consequences. This distinct DLC adaptation in a freshwater fish species offers valuable insights into forecasting the impacts of radical environmental changes resulting from long-term industrial activities.

2.02.P-Tu167 Sensitivity of Fishes to Aryl Hydrocarbon Receptor Activation by Polycyclic Aromatic Hydrocarbons Follows Phylogenetic Relationships

Justin Dubiel[1]*, Cameron Hunter Collins*[2]*, Vann Lynne Boyte*[2]*, Lauren Eagon*[2]*, Andreas N.M. Eriksson*[1]*, Danielle Philibert*[3]*, Benjamin Patrick de Jourdan*[4]*, Jonathon Doering*[2] *and Steve Wiseman*[1]*, (1)University of Lethbridge, Canada, (2)Louisiana State University, United States, (3)Huntsman Marine Science Centre, St. Andrews, NB, Canada, (4)Huntsman Marine Science Centre, Canada*

Polycyclic aromatic hydrocarbons (PAHs) are structurally diverse organic chemicals known to induce toxicity in fishes by activating the aryl hydrocarbon (AhR). The AhR is a ligand activated transcription factor responsible for regulating a large battery of genes involved in diverse physiological processes. Species sensitivity distributions have been developed for sensitivity to activation of the AhR by the prototypical AhR agonist TCDD, benz[a]anthracene (BAA) and 8-methylbenz[a]anthracene (8-MBAA) that varied by 167-, 141-, and 561-fold, respectively. However, while species can vary dramatically in sensitivity, most research has been performed on a small number of model test species that may not be representative of native species of concern. Currently, no methods for predicting species sensitivity to PAHs have been developed. However, such tools would greatly facilitate risk assessment due to differences in sensitivity across species, and practical limitations of performing traditional toxicity tests across numerous species. This research aims to 1) continue expanding species sensitivity distributions for sensitivity to AhR activation in additional species and 2) determine whether differences in species sensitivity follow phylogenetic relationships which could then be used to make predictions. This research utilized a standardized in vitro luciferase reporter gene assay to develop species sensitivity distributions based on species-specific half maximal effect concentrations (EC50s) for transactivation of the AhR by TCDD, BAA, and 8-MBAA in 18 species. Phylogenetic signals were then calculated for each compound using Pagel's Lambda (?) and Blomberg's K method for each chemical. Each chemical showed a phylogenetic signal of differing strength. The phylogenetic signal for TCDD was the strongest (? = 0.99, p = 0.004; K = 0.69, p = 0.048) while BAA (? = 0.99, p = 0.01; K = 0.59, p = 0.176) and 8-MBAA (? = 0.99, p = 0.003; K = 0.67, p =0.418) showed phylogenetic signals that were weaker and did not reach the level of significance using both methods. These results suggest that species that are more closely related phylogenetically can be expected to be similar in sensitivity to AhR activation by each compound which could facilitate predictions for species of unknown sensitivity. However, additional research is needed to generate data from additional species to strengthen this data set and ensure that closely-related species are available for comparison.

2.02.P-Tu168 Exploring the Applicability of the OECD TG 249 Fish Cell Line Acute Toxicity Assay in Environmental Hazard and Risk Assessment of Cosmetic and Personal Care Product Ingredients

*Kyle Roush[1], Bruno Campos[2], Iain Davies[3], Alexandra Rachel Evans[4], Giacomo Grassi[5], Beta Montemayor[6], Takahiro Suzuki[7], Michael Walter[8], **Ryan Heisler**[9] and Amelie Ott[9], (1)Proctor & Gamble, United States, (2)Unilever, Bedford, United Kingdom, (3)PCPC, United States, (4)Croda, United Kingdom, (5)L Oreal, France, (6)Science, Regulation and Market Access, Cosmetics Alliance Canada, Canada, (7)Kao Corporation, Japan, (8)BASF, Germany, (9)ICCS, United States*

Significant efforts are being made to advance the adoption of animal-free safety assessments. However, acute fish toxicity data are currently a component of environmental hazard and risk assessments and often an explicit requirement in global chemical regulations. To minimize animal use while ensuring the environmental safety of chemicals and products, it is necessary to consider alternative methods for assessing acute fish toxicity that will enable robust and regulatory-compliant animal-free approaches to decision making. One alternative that has shown utility for assessing acute fish toxicity is the OECD TG 249, rainbow trout gill cytotoxicity assay. Although this assay has shown a good correlation with historical standard acute fish toxicity (e.g., OECD TG 203) test data, there have been calls for further data generation with TG 249 to better define the?chemical applicability domain and identify potential assay limitations before full implementation within regulatory schemes. To further explore the suitability of this assay and identify best use cases, a project is underway by the not-for-profit science organization ICCS (International Collaboration on Cosmetics Safety) to evaluate the OECD TG 249 against a diverse set of cosmetic and personal care product ingredients. This presentation will serve as an overview of the planned multi-phase approach for the project, provide an update on the status and an opportunity for stakeholders to provide feedback or share relevant findings in either testing or conducting environmental safety assessments using OECD TG 249 data especially with cosmetic and personal care product ingredients. Ideally, this will ensure efficient, appropriate, and strategic use of resources in building a high-quality dataset to support the?best use of this assay in NAM (new approach methodology) frameworks for environmental safety assessment and will help expedite broader regulatory acceptance of approaches leveraging this assay. This reach is funded by the International Collaboration on Cosmetics Safety.

2.02.P-Tu169 Comparing Evolutionary AhR2-Activation in Transfected COS-7 Cells Exposed to the Benzotriazole UV-stabiliser UV-P

***Andreas N.M. Eriksson**[1], Justin Dubiel[1], Cameron Hunter Collins[2], Hunter Johnson[1], Jonathon Doering[2] and Steve Wiseman[1], (1)University of Lethbridge, Canada, (2)Louisiana State University, United States*

Benzotriazole UV-stabilizers (BUVSs) are a class of chemicals added to various consumer products (e.g. lotions, cosmetics, plastics, etc) and utilized in industrial processes. Functionally, BUVSs extend the lifespan of plastics by absorbing light in the UV-A and UV-B spectra. Produced since the 1950s, BUVSs are now be found in every strata across the world as it accumulates (logKow typically > 6) in soil, sediment, and tissue. Due to their ability to accumulate, the European Union completed the phaseout of several BUVSs as of 2023, and in the same year, one BUVSs (UV-328) was added to the Stockholm Convention. However, little is known about these chemicals (66 hits on Sciencedirect); although it is known that some BUVSs, including UV-P, can cause toxicity by activating the Aryl Hydrocarbon Receptor 2 of fishes (AhR2). In this study, we investigated activation of the AhR2 of 19 phylogenetically diverse marine and freshwater fish species. COS-7 cells, which lack an endogenous AhR pathway, were transfected with species specific ahr2 and activation of the receptor was quantified using a luciferase assay. In parallel, activation of the AhR2 by the prototypical AhR agonist TCDD, was characterized in each species. This study investigates the inverse relationship between the sensitivity of fishes to AhR activation by UV-P and TCDD (based on data from 9 freshwater fishes). Species that were on the sensitive end of the species sensitivity distribution for AhR2 activation by TCDD were on the insensitive end of the species sensitivity distribution for UV-P (Japanese medaka, Oryzias latipes; TCDD: 0.3 nM compared to 30000 nM for UV-P) and vice versa (white sucker, Catostomus commersonii: TCDD 1 nM compared to 300 nM for UV-P). Additionally, we will compare the sensitivity of each species with their evolutionary relatedness to draw conclusions on how evolution predicts taxa specific sensitivity to AhR2 activation. This research has implications for risk assessment as species thought to be tolerant to UV-P due to their tolerance to TCDD might be at greater risk of AhR2 mediated toxicity than previously thought.

2.03 Linking Lab and Field Evidence on Pesticide Effects on Biodiversity and Ecosystem Functions

2.03.T-01 Revealing the Cascade of Pesticide Effects from Genes to Communities

*Ayesha Siddique, **Naeem Shahid** and Matthias Liess, Helmholtz Center for Environmental Research, Germany*

Agricultural pesticides, even at concentrations below regulatory thresholds, are significant drivers of biodiversity loss, altering ecosystems from genetic to community levels. Freshwater ecosystems are particularly vulnerable due to proximity to agricultural runoff. This study investigates the cascading effects of pesticide exposure on Gammarus pulex, a dominant freshwater crustacean, and its associated macroinvertebrate communities across streams in central Germany. Pesticide exposure was quantified, and genetic diversity in Gammarus pulex populations was assessed using molecular techniques. Laboratory experiments measured fecundity and tolerance to neonicotinoid pesticides, while community-level impacts were evaluated through field surveys of macroinvertebrate diversity and composition. Results reveal that populations exposed to higher pesticide contamination exhibited reduced genetic diversity and altered allele frequencies, indicating strong selective pressure. These genetic adaptations were linked to increased pesticide tolerance but incurred fitness trade-offs, such as reduced fecundity in pesticide-free environments. At the community level, pesticide exposure reduced the abundance of sensitive species, such as Ephemeroptera, Plecoptera, and Trichoptera, and reshaped macroinvertebrate composition. This loss of competition allowed pesticide-tolerant Gammarus pulex populations to dominate, despite their reduced fitness. Streams closer to uncontaminated refuges retained higher genetic diversity and lower frequencies of pesticide-tolerant alleles, demonstrating the protective role of refuge areas. This research underscores the need to integrate genetic and ecological perspectives into chemical risk assessments, which often overlook the sublethal and long-term impacts of low-level pesticide exposure. By linking genetic changes to ecosystem-level consequences, this study highlights the broader implications of chemical contamination on biodiversity and ecosystem functionality, urging a more comprehensive approach to pesticide regulation.

2.03.T-02 A Streamlined Approach to Pesticide Risk Assessment that Aligns Prediction and Reality

***Matthias Liess**, UFZ - Helmholtz Centre for Environmental Research, Leipzig, Germany*

The environmental risk assessment is initially carried out by using standardised acute or chronic test systems and deriving endpoints to which assessment factors were added in order to protect communities in the field. However, it became clear that effects at ecosystem level are also determined by a large number of other ecological factors and processes. These are better addressed in higher tier effect assessment such as in model-ecosystems. With the expanded knowledge of the effect-determining factors and mechanisms, it became clear that a practicable and predictive risk assessment taking into account the entire complexity of the cause-effect relationships not feasible for prospective regulatory contexts based on predictive approaches is not possible. The EU Partnership for the Assessment of Risks from Chemicals (PARC), activity 6.4.4 aims to advance chemical risk assessment to protect human health and the environment. Here we suggest a new approach for a protective ERA with reduced complexity and resources required while keeping it as information-rich as necessary under Regulation (EU) 546/2011. We compare a common Effect-Cascade Prediction approach and the novel Effect-Adaptation Prediction. Effect-Cascade Prediction: The common approach in ecological prediction to identify effect assessment at ecosystem level. Here, the effects of various environmental factors and stressors on an individual are predicted. This can then be extrapolated to populations or communities Effect-Adaptation Prediction: This approach enables a prospective effect assessment at ecosystem level. The pesticide toxicity information is revealed with standard laboratory experiments. The prediction of the effect in the field is based on pesticide-specific indicators, generally based on ecological traits. The link between results from laboratory test systems and the effects at ecosystem level is initially established through exposure and effect monitoring of some widely used pesticides. I will present these different approaches and discuss their respective

advantages and disadvantages. The author thank the EU PARC regulatory core group for intensive discussion. This work was supported by the German Helmholtz Research (POF IV, Topic 9 Healthy Planet) and the European Partnership for the Assessment of Risks from Chemicals (PARC), supported by European Union s Horizon Europe research and innovation programme under grant agreement no. 101057014.

2.03.T-03 Benthic Diatoms as Indicators of Pesticide Pollution in Swiss Watercourses
***Sarah Descloux**[1], Ahmed Tlili[1], Kristin Schirmer[2], Soizic Morin[3] and Nele Schuwirth[2], (1)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Eawag, Swiss Federal Institute of Aquatic Science and Technology; Federal Institute of Technology Zurich, Switzerland, (3)National Research Institute for Agriculture, Food and the Environment, France*
Protecting aquatic ecosystems from pesticide pollution and other micropollutants is a critical regulatory task. Benthic diatoms, commonly used to indicate nutrient pollution, exhibit variable species sensitivities to pesticides. Therefore, we assess if they could also serve as effective bioindicators for pesticide pollution. To identify potential benthic diatom taxa that are sensitive or tolerant to pesticides, we conducted a laboratory study using flow-through chambers for periphyton colonisation in a closed and controlled system. We continuously exposed the periphyton to 44 treatments, consisting of combinations of environmentally relevant pesticide levels (36 levels of Toxic Unitmix ranging from 0 to 4.6) and three environmental factors (i.e., light intensity, temperature, and nutrient levels) over a 23-day colonisation period. Following colonisation and exposure, we examined the diatom community composition and structure using both morphological and molecular techniques to address discrepancies between the two approaches. The similarities in diatom community composition assessed using ordination techniques revealed no significant correlation with pesticide stress, while light intensity and temperature showed a significant impact. A multivariate beta regression model was used to quantify the effect of pesticide stress and the other environmental factors on the relative abundance of diatom species, highlighting both similar and distinct patterns of tolerance and sensitivity for a set of species observed across the two identification techniques (morphological and molecular). Community-level periphyton functions and structure (i.e., effective photosynthetic activity, chlorophyll-a content, ash-free dry weight, and bacterial abundance) were assessed using a linear model where pesticide treatments showed no significant impacts. This could be due to functional redundancies within the diatom communities that may prevent significant impacts on functions at environmental pesticide concentrations. These findings suggest that certain diatom species could be promising bioindicators for pesticide pollution. Further research at the community level and with single species are required to validate this hypothesis. Ultimately, this project could aid in developing diatom-based indicators, improving pesticide impact assessment and ecosystem management, while addressing discrepancies between morphological and metabarcoding approaches for diatom identification.

2.03.T-04 Behavioural Effects of Pesticide Mixtures and Caffeine on *Hyalella azteca*
*Andrea Belamaric[1], **Kathrin Fisch**[2] and Stefan Lorenz[2], (1)University of Zagreb, Croatia, (2)Julius Kuhn-Institut, Federal Research Centre for Cultivated Plants, Germany*
Residues of agricultural and urban contaminants occur frequently in freshwater bodies. They cause negative impacts on the freshwater organisms by altering their reproduction, food consumption, behaviour and, consequently, their ecological interactions. Mixtures of substances can lead to even more severe damage. At the same time, the individual effects are difficult to assess. In this study, the epibenthic crustacean specie Hyalella azteca was used to observe changes in activity behaviour using the Multispecies Freshwater Biomonitor. The response of H. azteca to the pesticides tebuconazole, nicosulfuron, chlorpyrifos and clothianidin, as well as their combinations was tested. Furthermore, pesticide interaction with the urban contaminant caffeine were of particular interest because of its ubiquity in the aquatic environment. Our results indicate that all pesticides, as well as their mixtures, have a statistically significant effect on the activity of H. azteca. The observed variation in response to contaminants results from different mode of action, which range from escape behaviour to a complete reduction in swimming rates. Contrary to the effect observed on humans, caffeine lowered the activity level of H. azteca up to 17% in single substance treatments. However, further studies are needed to truly understand the mode of action of the tested substances and their impact on the activity behaviour of crustacean. This study was part of the German Academic Exchange Service schloarship no. 57725695.

2.03.P-We046 Behavioural Response of a Native and Invasive Amphipod to Sublethal Pesticide Exposure
***Darragh Melaugh**[1], Gareth Arnott[1], Archie Murchie[2], Jaimie Dick[3] and Gary Hardiman Prof[3], (1)School of Biological Sciences, Queen's University Belfast, United Kingdom, (2)Agri-Food and Biosciences Institute, United Kingdom, (3)School of Biological Sciences, Queen's Marine Laboratory, Queen's*

University Belfast, United Kingdom
Aquatic ecosystems are subject to a multitude of environmental pressures simultaneously, including chemical toxicants and biological stressors. In freshwater habitats, chemical contamination and invasive species are often considered prominent drivers of biodiversity decline. However, the ecological consequences can potentially be more pronounced when these stressors interact. Therefore, this study aimed to assess the combined effect of pesticide inputs and invasive species on ecosystem resilience and functioning. Behavioural endpoints were used to assess the impact of pesticide exposure on two amphipod species, the native Gammarus duebeni celticus and the invasive Gammarus pulex. Each species was subject to sublethal concentrations (1, 5 & 10 ?gL-1) of the phenoxyacetic acid herbicide, 2-methyl-4-chlorophenoxyacetic acid (MCPA) for 96h to investigate the acute effects of exposure. Despite their widespread and extensive use, phenoxyacetic acid herbicides remain understudied with respect to their toxicological effects. Species differences were assessed by employing the comparative functional response (CFR) metric, which quantifies resource use as function of prey density. FR trials were conducted using live chironomid prey (Chironomus sp.). Given the status of G. pulex as an established invader in this instance, a greater FR in comparison to G. duebeni was expected. The CFR is an effective means by which to determine species response to contaminant exposure and ecosystem impacts of invaders. Incorporating indirect effects, such as species interactions, in the assessment of chemical contaminants provides a more holistic understanding of ecosystem level impacts.

2.03.P-We052 Effects of the Fungicide Tebuconazole with Endocrine Acting Potential on a Macroinvertebrate Community in Stream-Lake Mesocosms

***Silvia Mohr*[1]*, Erik Sperfeld*[2]*, Ulrike Scholz*[1]*, Ronny Schmiediche*[3] *and Valeska Contardo Jara*[4]*, (1)IV 2.5, German Environment Agency, Dessau-Rosslau, Germany, (2)German Environment Agency, Dessau-Rosslau, Germany, (3)German Environment Agency, Germany, (4)Zentrum für Wasser- und Chemikalienforschung, German Environment Agency, Dessau-Rosslau, Germany*
Understanding the consequences of increased pesticide use in agriculture is crucial to protecting terrestrial and aquatic ecosystems from harm. Tebuconazole (TBZ) is a triazole fungicide that inhibits the biosynthesis of ergosterol in fungal cell membranes and thus fungal growth. In addition, TBZ blocks the biosynthesis of cholesterol as an important precursor of sexual steroid hormones in animals, and can therefore act as endocrine disruptor. As part of a comprehensive indoor mesocosm study, aimed at revealing effects of TBZ on fungal biodiversity and functioning, we also investigated the effects of TBZ on the macroinvertebrate community and insect emergence in stream-lake mesocosms over a 7-month period. Three and one month prior to TBZ application, macroinvertebrates from an unpolluted stream were transferred into the freshwater mesocosms for acclimatization, using attraction devices consisting of organic straw. The mesocosms were dosed once with six concentrations of TBZ using the formulation Folicur® (5, 50, 100, 500, 100, 5000 ?g/L TBZ). Two mesocosms served as controls. The macroinvertebrate community showed community response (principle response curve analysis) at concentrations higher than 100 µg/L TBZ. Gammarids and snails were the most sensitive taxonomic groups in the systems, while species of chironomid sub families differed strongly in their sensitivity. For the endpoint emergence, number of male chironomids decreased after TBZ application, whereas the number of females even increased in the 500 and 1000 µg/L TBZ treatments. This result may be attributable to the endocrine acting potential of TBZ. Transferring field macroinvertebrate communities into mesocosms seems to be a suitable method for investigating TBZ effects on benthic organisms. We could identify direct and indirect effects of TBZ on macroinvertebrates, underlining the added value of mesocosm studies for risk assessment of pesticides in aquatic environments.

2.03.P-We061 Evaluation of Triazole Fungicide Exposure to the Development of *Tenebrio molitor*

***Paula Bolívar*[1]*, Rafael Mateo*[2]*, Claudia Santamaria Cervantes*[3]*, Manuel Ortiz Santaliestra*[3] *and Ricardo Sanchez de la Nieta*[3]*, (1)University of Castilla-La Mancha, Spain, (2)Institute of Enviromental Assessment and Water Research, Spain, (3)Instituto de Investigacion en Recursos Cinegeticos, Spain*
The use of pesticides, in particular triazole fungicides, contributes significantly to biodiversity loss in agroecosystems. These fungicides affect fungal cell wall formation by inhibiting ergosterol synthesis, and in arthropods they can disrupt the production of ecdysteroids, key hormones in moulting and reproduction. Since invertebrates are essential for ecosystem balance, this study evaluated the effects of triazoles on the mealworm (Tenebrio molitor) by simulating exposure scenarios through the ingestion of cereal seeds treated with prothioconazole and tebuconazole. Physiological variables (size, weight and development) and changes in gene expression linked to ecdysteroidogenesis were measured. Three exposure treatments were carried out: seeds treated with the labelled dose of Raxil® Plus, 50:50 and 25:75 mixtures of treated and untreated seeds, and a control with untreated seeds. Sixty larvae per treatment were exposed for 10 days, ingesting only the allocated seeds. Subsequently, they were offered oats, wheat bran and vegetables,

and their development was monitored until the adult stage. Weight, mortality, malformations and development time were recorded. For molecular analysis, total RNA was extracted from larvae, pupae and adults and converted into cDNA for qRT-PCR. Gene expression was assessed using specific primers and relative differences from the control were calculated. Mealworm showed rejection of treated seeds, especially in the intermediate treatment. A decrease in weight was also observed in the higher treatments. No significant differences in development time were observed. Gene analysis revealed a lower expression of the enzymes Spo, Sad, Shd and the transcription factor HR3 in the highest treatment. In the intermediate treatment, a reduction of Spo and HR3 was detected, as well as an overexpression of the regulator E75. These changes suggest that fungicides interact with key elements of the ecdysteroidogenesis pathway, which could compromise essential functions in exposed arthropods. In conclusion, exposure to triazole fungicides may affect both physiological parameters and genetic regulation of hormonal processes in Tenebrio molitor, highlighting the need to assess their impact on biodiversity and agroecosystem functioning.

2.03.P Linking Lab and Field Evidence on Pesticide Effects on Biodiversity and Ecosystem Functions

2.03.P-We042 Effects of the Antimicrobial Triclosan on Community Structure and Ecosystem Functioning in Sub-tropical Freshwater Ecosystems

***Kai-Sheng Yao*[1]*, Pei-Liang Zhou*[2]*, Hua-Qiao Yang*[3]*, Li-Juan Tan*[2]*, Lu-Kai Qiao*[2]*, Guangguo Ying*[2] *and Paul van den Brink*[1]*, (1)Aquatic Ecology and Water Quality Management Group, Wageningen University & Research, Netherlands, (2)Environmental Research Institute, Guangdong Provincial Key Laboratory of Chemical Pollution and Environmental Safety, MOE Key Laboratory of Theoretical Chemistry of Environment, South China Normal University, China, (3)Institute of Hydrobiology, Chinese Academy of Sciences, China*

Triclosan, a synthetic broad-spectrum antimicrobial agent, is commonly used in personal care products, household goods, and industrial items. Its extensive use and subsequent release have led to frequent detections in aquatic ecosystems worldwide, potentially harming ecosystem health. Here, an outdoor mesocosm experiment was conducted to assess the effects of triclosan on community structure (microbes, phytoplankton, zooplankton, and macroinvertebrates) and ecosystem functioning in freshwater ecosystems under sub-tropical conditions. Triclosan was applied daily in pulses at nominal concentrations of 0.05, 0.5, 5, and 50 μg/L over a three-week treatment period, followed by a five-week recovery period. Triclosan significantly affected the structure of microbial (NOEC of 0.5 μg/L), phytoplankton (NOEC of 5 μg/L), and zooplankton (NOEC of 5 μg/L) communities. Within the microbial community, the phyla Cyanobacteria and Bacteroidetes consistently showed significant responses to triclosan exposure, with taxa in the Cyanobiaceae family being the most adversely affected. Among phytoplankton taxa, Cylindrospermopsis sp. had the lowest consistent NOEC (< 0.05 μg/L), while the lowest NOEC (0.5 μg/L) among zooplankton taxa was observed for nauplii and Mesocyclops leuckarti. Piecewise structural equation modelling revealed that triclosan exposure resulted in significant direct and indirect effects across multiple trophic levels via cascading interactions, ultimately influencing ecosystem functioning related to carbon and nitrogen cycling. Hence, our study highlights the threat posed by environmentally relevant concentrations of triclosan to both community structure and ecosystem functioning in sub-tropical freshwater ecosystems.

2.03.P-We043 Towards the Integration of Periphyton in Pesticide Biomonitoring to Assess Ecological Impacts on Agricultural Streams

***Alina Koch*[1]*, Danny C.P. Lau*[2]*, Mikaela Gonczi*[3]*, Ove Jonsson*[4] *and Natalia Corcoll Cornet*[5]*, (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Uppsala, Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (4)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Sweden, (5)University of Gothenburg, Sweden*

In agricultural streams aquatic biofilms (hereafter periphyton) are exposed to several stressors including a wide array of pesticide residues. This study investigated the temporal variations and site differences in pesticide concentrations accumulated in periphyton over the course of three months. In addition, we assessed if changes in the structure of the algal community and the fatty acid content as proxy of periphyton nutritional value were linked to pesticide exposure in periphyton. Field experiments were conducted in two agricultural streams and one reference stream in Sweden during summer 2022. Artificial substrata (tiles) were deployed in each stream to facilitate periphyton colonization for three months. Periphyton samples were collected once per month. Surface water was collected with weekly time-integrated sampling. Analysis included residue of 109 pesticides, in surface water and in periphyton, 37 fatty acids, ash-free dry mass, and 11 photosynthetic pigments in periphyton. In periphyton, up to 31 pesticides were detected, with distinct chemical profiles observed in the two agricultural streams. The pesticide composition in periphyton differed from that in the water. Water profiles showed greater variability over time and were dominated by water-soluble substances. In contrast, periphyton accumulated more hydrophobic compounds, some of them banned for years, suggesting longer-term, chronic exposure. Pigment analyses revealed high algal biomass, predominantly composed of diatoms, but lower diversity in the agricultural streams compared to the reference stream. Diatom biomass was strongly correlated with the polyunsaturated fatty acids EPA and DHA concentrations, markers of high nutritional value produced mainly by diatoms. Linear regression revealed a general, though not significant, negative relationship between pesticide concentrations in periphyton and diatom biomass or EPA levels. We hypothesize that at low pesticide concentrations, other stressors, such as high nutrient load, are more prominent. However, beyond a certain threshold, pesticide exposure may become a primary stressor, reducing nutritional quality of ther periphyton and altering algal community. These findings highlight that peripython in agricultural streams acculumate a variety of pesticides, exhibit high biomass and display altered algal community structure and fatty acid profiles.

2.03.P-We044 Investigating the Role of Pesticides and Pharmaceuticals in Riparian Ecosystems: Insights from the RIPARIANET Project

Monika Laux[1]*, Maria Cristina Bruno*[2]*, Jose Barquin*[3]*, Laura Concostrina-Zubiri*[3]*, Luca Gallitelli*[4]*, Micael Jonsson*[5]*, Morgan Hughes*[5]*, Giorgio Pace*[6]*, Massimiliano Scalici*[7]*, Stefano Larsen*[2] *and Ralf Schulz*[1]*, (1)Institute for Environmental Sciences, University of Kaiserslautern-Landau, Germany, (2)Research and Innovation Centre, Fondazione Edmund Mach; National Biodiversity Future Center, Universit di Palermo, Italy, (3)IHCantabria, Instituto de Hidraulica Ambiental, Universidad de Cantabria, Spain, (4)University of Roma Tre, Department of Sciences, Italy, (5)Department of Ecology and Environmental Science, Umeaa University, Sweden, (6)Centre of Molecular and Environmental Biology/Aquatic Research Network Associate Laboratory, Department of Biology, University of Minho; Institute of Science and Innovation for Bio-Sustainability, University of Minho, Portugal, (7)University of Roma Tre, Department of Sciences; National Biodiversity Future Center, Universit di Palermo, Italy*

Riparian zones are natural ecotones that contribute greatly to biodiversity and ecosystem services. As Europe commits to protecting 30% of its land and sea, riparian networks "blue-green arteries" connecting ecosystems across elevation gradients offer critical opportunities for targeted conservation. The RIPARIANET project focuses on six river basins across Europe, covering the boreal (Sweden), continental (Germany), alpine (Trento, Italy), Mediterranean (Rome, Italy), and Atlantic (Northern Spain, Northern Portugal) climatic regions to optimize conservation strategies for these ecosystems. This study investigates how pesticides and pharmaceuticals entering riparian ecosystems through water affect aquatic and terrestrial food webs. By examining contaminant transport and accumulation across water, biofilms, emerging insects, riparian spiders, and bats, we aim to assess ecosystem-level impacts and distribution of contaminants across tropic levels. Our approach combines GIS-based modeling with comprehensive field data collected in 2024. We analyzed a wide range of contaminants in field-collected samples using UHPLC-ESI-MS/MS. Our findings will shed light on how pesticides and pharmaceuticals are transported into aquatic and terrestrial food webs and their potential impacts on biodiversity and ecosystem resilience. As environmental stressors such as chemical pollution interact with broader challenges like climate change, understanding these dynamics is crucial for developing conservation strategies that protect riparian ecosystems under future conditions. Biodiversa+ RIPARIANET project

2.03.P-We045 Effects of Flood-Mediated Pollutant Transfer on Total Polyphenol Content in Riparian Plants

María José Gormaz-Aravena*, Franziska Fiolka, Sven Korz, Katherine Munoz, Franziska Middendorf, Stephane Mutel, Collins Ogbeide, Alessandro Manfrin and Ralf Schulz, Institute for Environmental Sciences, University of Kaiserslautern-Landau, Germany*

Flooding can transfer pollutants from aquatic to terrestrial ecosystems, acting as a contamination pathway for riparian plants. Due to land-use changes and more frequent and intense rainfall events caused by climate change, both flooding frequency and duration are expected to rise over the next decades. This increase will intensify the floods ability to act as an exposure pathway to the riparian vegetation, where agricultural pesticides are transported back to land in riparian zones. This strongly affects the vegetation s stress-mediated response, where polyphenolic compounds are involved in defense mechanisms against biotic and abiotic stressors. Research on contaminants entering riparian lands remains limited, especially regarding their impact on plant resilience. This study investigated the effect of flood-mediated pesticide transfer under different flooding frequencies (after 1 and 4 floods) and durations (0, 3, 7 and 14 days) on the Total Polyphenolic Content (TPC) as a stress biomarker of the stinging nettle (Urtica dioica L.) and a common grass species (Elymus spp) at the Riparian Stream Mesocosm site in Landau, Germany. We hypothesized that prolonged and frequent flooding will increase pesticide concentration in common grass and stinging nettle, showing a positive correlation with TPC levels as a response to the stress. The concentrations of pesticides and their metabolites were quantified using HPLC-ESI-MS/MS, while TPC was measured spectrophotometrically via the Folin-Ciocalteu reagent method. Ten pesticides were frequently detected in both riparian plants, showing a positive trend between flooding frequency and pesticide concentration. TPC concentrations in grass differed significantly from nettle after flooding, with grass exhibiting higher TPC levels. While no correlations were found between overall pesticide exposure and TPC, specific pesticide compounds showed distinct correlations with TPC, indicating compound-specific responses. These findings highlight the complexity of the impact of flooding and pesticide exposure on riparian plants resilience. Our study suggests that individual pesticide compounds may influence plant biochemical stress responses individually.

2.03.P-We046 Behavioural Response of a Native and Invasive Amphipod to Sublethal Pesticide Exposure

***Darragh Melaugh**[1], Gareth Arnott[1], Archie Murchie[2], Jaimie Dick[3] and Gary Hardiman Prof[3], (1)School of Biological Sciences, Queen's University Belfast, United Kingdom, (2)Agri-Food and Biosciences Institute, United Kingdom, (3)School of Biological Sciences, Queen's Marine Laboratory, Queen's University Belfast, United Kingdom*

Aquatic ecosystems are subject to a multitude of environmental pressures simultaneously, including chemical toxicants and biological stressors. In freshwater habitats, chemical contamination and invasive species are often considered prominent drivers of biodiversity decline. However, the ecological consequences can potentially be more pronounced when these stressors interact. Therefore, this study aimed to assess the combined effect of pesticide inputs and invasive species on ecosystem resilience and functioning. Behavioural endpoints were used to assess the impact of pesticide exposure on two amphipod species, the native Gammarus duebeni celticus and the invasive Gammarus pulex. Each species was subject to sublethal concentrations (1, 5 & 10 ?gL-1) of the phenoxyacetic acid herbicide, 2-methyl-4-chlorophenoxyacetic acid (MCPA) for 96h to investigate the acute effects of exposure. Despite their widespread and extensive use, phenoxyacetic acid herbicides remain understudied with respect to their toxicological effects. Species differences were assessed by employing the comparative functional response (CFR) metric, which quantifies resource use as function of prey density. FR trials were conducted using live chironomid prey (Chironomus sp.). Given the status of G. pulex as an established invader in this instance, a greater FR in comparison to G. duebeni was expected. The CFR is an effective means by which to determine species response to contaminant exposure and ecosystem impacts of invaders. Incorporating indirect effects, such as species interactions, in the assessment of chemical contaminants provides a more holistic understanding of ecosystem level impacts.

2.03.P-We047 Effects of Triticonazole on a Simple Freshwater Ecosystem under Elevated Temperature

***Banchiamlak Getnet Admasu**, Wageningen University and Research, Netherlands*

This study investigates the ecological effects of triticonazole on freshwater ecosystem under elevated temperature condition in a microcosm experiment being conducted from September 30 to November 30, 2024. The experimental design comprises 17 microcosms, including 5 controls and 12 treatment microcosms with three triticonazole concentrations (Low, 10 µg/L; Medium,100 µg/L; High, 1000 µg/L). Each treatment concentration is replicated four times, while the control treatment has 5 replicates. All microcosms are maintained at a consistent elevated temperature of 28°C to simulate tropical conditions. Key physico-chemical parameters including temperature, pH, electrical conductivity, dissolved oxygen, and nutrients (nitrate, phosphate, ammonium, particulate organic nitrogen, particulate organic phosphorus, and particulate inorganic phosphorus) are being regularly monitored. Biological assessments include the growth of the macrophyte Myriophyllum spicatum, the zooplankton community, chlorophyll-a (as a proxy for algal biomass), microbes, and the dynamics of the macroinvertebrates Gammarus pulex and Physella spp. Feeding rates of macroinvertebrates and microbial leaf litter decomposition rates are being measured to assess ecosystem functionality under triticonazole stress. Water and sediment samples are being collected regularly to evaluate the persistence and distribution of triticonazole within the microcosms. Multivariate analyses using Canoco software will be employed to investigate relationships among physicochemical and biological parameters under triticonazole exposure. This approach will identify patterns and interactions within the data, offering deeper insights into ecosystem responses to triticonazole. This comprehensive analysis aims to provide critical insights into the effects of triticonazole exposure under tropical conditions.

2.03.P-We048 The effects of commercial 2,4-D herbicide on larval fathead minnows: Natural lake water vs. laboratory system water

***Serena George*[1]*, Gavin Dehnert[2] and Catherine Smith[1], (1)University of Wisconsin-Madison, United States, (2)University of Wisconsin-Madison Sea Grant Institute, United States*

Herbicides with the active ingredient 2,4-Dichlorphenoxyacetic acid (2,4-D) are commonly applied worldwide to control non-native aquatic plants that negatively impact native biodiversity and ecosystem services. Traditional laboratory ecotoxicity studies associate exposure to ecologically relevant concentrations of 2,4-D with decreased survival and sublethal impacts on non-target organisms, including multiple freshwater fish species. Given the diverse water parameters of freshwater aquatic ecosystems globally, it is important to evaluate if controlled laboratory experiments reflect toxicity outcomes under real-world scenarios. To do so, concurrent in situ and laboratory exposure assays were conducted. In-situ systems were established in two Wisconsin lakes (Big Lake and Dutch Hollow Lake) one day prior to whole-lake treatment with DMA®4IVM (46.3% 2,4-D) and four months post treatment for control. Larval fathead minnows (Pimephales promelas; n = 200 per lake) developed for 21 days, then survival, length, and weight were recorded. Laboratory exposure systems were conducted in parallel using water sourced from the respective lake before and after herbicide treatment. For both in situ and laboratory exposures, a statistically significant decrease in survivorship but no differences in morphological parameters of surviving larvae were observed for 2,4-D treatment groups compared to corresponding controls. No statistically significant differences in survivorship between laboratory controls and in-situ controls were detected for either lake; however, a statistically significant decrease in survivorship was observed for Dutch Hollow in-situ treatment compared to laboratory treatment. Results confirm previous findings of decreased larval fish survivorship upon exposure to 2,4-D in controlled laboratory system water environments, demonstrating the ecological relevance of laboratory studies for elucidating toxicity impacts to non-target organisms in natural lake water. While laboratory studies provide useful information for herbicide risk assessment, it is important for management agencies to take location-specific water parameters and environmental factors into account to more accurately predict and minimize health impacts in non-target species.

2.03.P-We049 Weight-of-Evidence Approaches for Interpreting Multiple Mesocosm Studies: A Case Study with *Lambda-cyhalothrin*

***Daniel Bruce Pickford*[1]*, Onofrio Schifanella[2], Klaus Peter Ebke[3], Udo Hommen[4] and Michael Hamer[5], (1)Syngenta, ., United Kingdom, (2)Syngenta, Italy, (3)Mesocosm, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (5)Syngenta, United Kingdom*

Experimental ecosystem (mesocosm or microcosm) studies are a valuable refinement tool in aquatic risk assessment for PPPs, accommodating environmental fate and behaviour of the active substance while addressing ecological processes such as community level effects and recovery. These processes occur in real world edge of field surface waters, and mesocosms therefore act as the surrogate reference tier, supporting prediction of risks to aquatic flora and fauna arising from real-world uses of PPPs. While recovery is recognised as an important factor in assessing risk at population and community level, as provided for in the specific protection goals, at the present time regulatory acceptance of recovery arguments is uncertain. Lambda-cyhalothrin (LCYH) is a pyrethroid insecticide that has been used in Europe for over thirty years, with proven efficacy over a wide range of crop-pest combinations. LCYHs neurotoxic mode of action is targeted to crop pests, but also affects non-target arthropods and crustaceans and in Europe at least, the aquatic risk assessment for LCYH invariably requires higher tier refinement for these groups. LCYH has one of the most comprehensive mesocosm datasets of any AI registered in the EU, with the most recent study conducted in 2018 and can be considered state of the art by reference to current best practice. This database provides an exceptional opportunity to explore weight of evidence approaches where multiple mesocosm studies are available and should provide greater certainty in predicting effects in edge-of-field surface waters.

2.03.P-We050 Short-Term Toxicity of Agricultural Pesticides Imidacloprid and Tebuconazole in Three Freshwater Invertebrates: A Comparative Study

***David Silva Alexandre*[1]*, Thandy Junio da Silva Pinto[2], Diego Gomes Ferreira[1], Vanessa Borges da Costa[1] and Evaldo Espindola[1], (1)Laboratory of Ecotoxicology and Applied Ecology, Department of Hydraulic and Sanitation, S o Carlos School of Engineering, University of S o Paulo, Brazil, (2)Institute of Chemistry, University of Campinas, Brazil*

The widespread use of imidacloprid and tebuconazole has led to their frequent detection in surface waters, where their persistence poses risks to non-target organisms, highlighting the need to assess their ecotoxicological effects on aquatic invertebrates. In this context, short-term toxicity tests were conducted on three species of aquatic crustaceans: Daphnia similis, Ceriodaphnia silvestrii, and Hyalella meinerti.

Toxicity tests were conducted for 48 hours at 24 ± 2 °C with a 12L:12D photoperiod for C. silvestrii, following ABNT 13373 guidelines, and at 20 ± 2 °C with a 12L:16D photoperiod for D. similis, in accordance with ABNT 12713. For H. meinerti, tests were performed over 96 hours at 24 ± 2 °C with a 12L:12D photoperiod, following ABNT 15470 guidelines, with feeding provided at the start and after 48 hours. For each species, five concentrations of imidacloprid and tebuconazole were tested, with stock solution concentrations confirmed by liquid chromatography coupled with tandem mass spectrometry, and at least three independent trials were conducted for each species, ensuring a coefficient of variation of less than 20%. For the pesticide tebuconazole, D. similis exhibited an LC50-48h of 9.4 mg L?¹, with a confidence interval of 8.0 to 10.8 mg L?¹. C. silvestrii showed an LC50-48h of 3.9 mg L?¹, with a confidence interval of 2.8 to 4.9 mg L?¹. For H. meinerti, the LC50-96h was 6.2 mg L?¹, with a confidence interval of 4.1 to 6.1 mg L?¹. Regarding the pesticide imidacloprid, D. similis exhibited an LC50-48h of 4.1 mg L?¹, with a confidence interval of 2.5 to 5.6 mg L?¹. C. silvestrii showed an LC50-48h of 2.5 mg L?¹, with a confidence interval of 2.1 to 2.8 mg L?¹. For H. meinerti, the LC50-96h was 38.6 µg L?¹, with a confidence interval of 21.8 to 44.7 µg L?¹. When comparing the two pesticides, imidacloprid was found to be more toxic than tebuconazole to H. meinerti and C. silvestrii, indicating a greater risk for these species. The varying sensitivity levels among the species highlight the need to use multiple test organisms to better assess the ecotoxicological effects of pesticides. These findings contribute to the field of ecotoxicology by providing new data on the acute toxicity of imidacloprid and tebuconazole to aquatic invertebrates. Such data could contribute to environmental policy, particularly regarding pesticide regulation and the protection of aquatic ecosystems. This research was supported by the São Paulo Research Foundation - FAPESP (grant no. 2022/12104-4). David Silva Alexandre has a doctoral scholarship supported by FAPESP (grant no. 2024/00791-2). Thandy Junio da Silva Pinto and Diego Gomes Ferreira have a postdoctoral scholarship supported by FAPESP (grant no. 2022/14293-9 and 2024/08039-8).

2.03.P-We051 Effect of the Fungicide Tebuconazole With Herbicidal Mode of Action on Plankton and Periphyton Communities in Freshwater Mesocosms

***Erik Sperfeld**[1], Valeska Contardo-Jara[2] and Silvia Mohr[3], (1)German Environment Agency, Dessau-Rosslau, Germany, (2)German Environment Agency, Germany, (3)IV 2.5, German Environment Agency, Dessau-Rosslau, Germany*

The fungicide tebuconazole (TBZ) is used against fungi that are pathogenic for agricultural crop. TBZ is also used as growth regulator in agriculture due to its herbicidal mode of action by inhibiting the sterol 14?-demethylase, which is involved in the synthesis of phytosterols. Therefore, TBZ can potentially have adverse effects on aquatic autotrophs after run-off into freshwater ecosystems. However, there is very limited knowledge on the effects of TBZ on aquatic non-target organisms, such as phytoplankton and periphyton species. In a comprehensive aquatic mesocosm experiment, studying the effects of TBZ on aquatic fungi, we investigated likewise the effects of the fungicide on plankton and periphyton communities. Freshwater mesocosms simulating stream-lakes were inoculated several times with field-sampled plankton and periphyton communities during a 5-month establishing period prior to the fungicide application. The mesocosms were also stocked with macrophytes, aquatic fungi and macroinvertebrates in the establishing period. Using the formulation Folicur®, six concentrations of TBZ (5, 50, 100, 500, 100, 5000 ?g/L) were applied once in the mesocosms and plankton and periphyton communities were sampled regularly after the application for up to 8 months. Principal response curve analyses revealed that the communities of phytoplankton, zooplankton and periphyton responded to the TBZ application gradient. We did not observe an immediate dose-response relationship on community composition. Instead, communities in the mesocosms with TBZ concentrations >100 µg/L tended to show increasingly different species compositions over time, suggesting indirect effects playing a role in driving community responses. Some species were more sensitive to the TBZ treatment than others from the same taxonomic group, indicating inter-specific differences in the response to pollutants and demonstrating the added value of mesocosm studies for risk assessment of chemicals in aquatic environments.

2.03.P-We052 Effects of the Fungicide Tebuconazole with Endocrine Acting Potential on a Macroinvertebrate Community in Stream-Lake Mesocosms

***Silvia Mohr**[1], Erik Sperfeld[2], Ulrike Scholz[1], Ronny Schmiediche[3] and Valeska Contardo Jara[4], (1)IV 2.5, German Environment Agency, Dessau-Rosslau, Germany, (2)German Environment Agency, Dessau-Rosslau, Germany, (3)German Environment Agency, Germany, (4)Zentrum für Wasser- und Chemikalienforschung, German Environment Agency, Dessau-Rosslau, Germany*

Understanding the consequences of increased pesticide use in agriculture is crucial to protecting terrestrial and aquatic ecosystems from harm. Tebuconazole (TBZ) is a triazole fungicide that inhibits the biosynthesis of ergosterol in fungal cell membranes and thus fungal growth. In addition, TBZ blocks the biosynthesis of cholesterol as an important precursor of sexual steroid hormones in animals, and can therefore act as endocrine disruptor. As part of a comprehensive indoor mesocosm study, aimed at revealing effects of TBZ on fungal biodiversity and functioning, we also investigated the effects of TBZ on the macroinvertebrate community and insect emergence in stream-lake mesocosms over a 7-month period. Three and one month prior to TBZ application, macroinvertebrates from an unpolluted stream were transferred into the freshwater mesocosms for acclimatization, using attraction devices consisting of organic straw. The mesocosms were dosed once with six concentrations of TBZ using the formulation Folicur® (5, 50, 100, 500, 100, 5000 ?g/L TBZ). Two mesocosms served as controls. The macroinvertebrate community showed community response (principle response curve analysis) at concentrations higher than 100 µg/L TBZ. Gammarids and snails were the most sensitive taxonomic groups in the systems, while species of chironomid sub families differed strongly in their sensitivity. For the endpoint emergence, number of male chironomids decreased after TBZ application, whereas the number of females even increased in the 500 and 1000 µg/L TBZ treatments. This result may be attributable to the endocrine acting potential of TBZ. Transferring field macroinvertebrate communities into mesocosms seems to be a suitable method for investigating TBZ effects on benthic organisms. We could identify direct and indirect effects of TBZ on macroinvertebrates, underlining the added value of mesocosm studies for risk assessment of pesticides in aquatic environments.

2.03.P-We053 Functional and Behavioral Responses of *Physa acuta* Snails Exposed to Fungicide Tebuconazole

***Thandy Junio da Silva Pinto**[1], Vanessa Borges da Costa[2], Evaldo Espindola[2] and Cassiana Carolina Montagner[1], (1)Universidade Estadual de Campinas, Brazil, (2)Universidade de S o Paulo, Brazil*
After being applied to crops, pesticides can be carried to aquatic environments, affecting indigenous organisms. This is the case of tebuconazole, a triazole fungicide that, despite being used to control fungi, may endanger non-target species. In this way, this study investigates how short and prolonged exposure to environmentally relevant concentrations of tebuconazole impairs functional and behavioral responses in Physa acuta snails. Chronic and subchronic assays were carried out with five concentrations of tebuconazole (25, 50, 100, 200, and 400 µg/L). The subchronic assays (10 days) were carried out with newborns (1-24 hours life) to assess the effects on the initial growth. The chronic assay (21 days) was initiated with sexually mature individuals (30-32 days live) and investigated responses in reproduction (fertility and fecundity). The displacement behavior (distance traveled and maximum velocity achieved) was assessed at the end of both experiments. All experiments were carried out at 25 ºC and 12h:12h (light: dark) light regime and data were evaluated by Generalized Linear Models. In none of the assays, tebuconazole exposure impaired snails survival; thus, sublethal responses were assessed. In the subchronic assay, the fungicide reduced the initial growth of P. acuta neonates at all tested concentrations (NOEC < 25 µg/L, p <0.05) relative to control (26 to 90% reduction). Regarding reproductive output from chronic tests, exposure to all tebuconazole concentrations reduced the number of ovigerous masses (46 to 62%) and total of eggs produced (40 to 70%) compared to control individuals (NOEC <25 µg/L, p < 0.05). Also, the egg hatchability was reduced in these same concentrations. To the behavioral responses, newbo rns were most susceptible to tebuconazole exposure. While the distance traveled and maximum speed was impaired in individuals from all tested concentrations (NOEC <25 µg/L) in subchronic exposure, only adults from the three highest concentrations (NOEC = 50 µg/L) had these parameters reduced (p < 0.05). Despite the action mechanisms of tebuconazole being described to fungi, results demonstrate that exposure to this fungicide at concentrations already reported in aquatic environments impacts functional and behavior traits of neonates and adults of P. acuta with several consequences to the maintenance of species in the environment and their ecological interactions at population and community levels. T.J.S.P. would like to thank the São Paulo Research Foundation Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) for the post doctorate grant (Process number: 2022/14293-9). Financial support was also provided by FAPESP (thematic project 2022/12104-4).

2.03.P-We054 Use of a Native Amazonian Ostracod in the Evaluation of the Sublethal Effects of Tebuconazole and Imidacloprid

***Diego Ferreira Gomes**[1], Thandy Junio da Silva Pinto[2], David Silva Alexandre[1], Cassiana Carolina Montagner[2] and Evaldo Espindola[1], (1)Engineering School, University of Sao Paulo, Brazil, (2)University of Campinas, Institute of Chemistry, Brazil*
The excessive use of pesticides currently poses a risk to the health of aquatic biota, since different pesticides inevitably end up reaching aquatic ecosystems. Therefore, this study aims to evaluate the chronic effects of environmentally relevant concentrations of imidacloprid and tebuconazole on a native species of ostracod, Strandesia rondoniensis. S. rondoniensis cultures were maintained following recommendations adapted from the ABNT protocol for tropical cladocerans, No. 13373. Feeding

consisted of 20 mL of Tetramin® fish food (5 g solution in 1 liter of distilled water) and 20 mL of Raphidocelis subcapitata suspension (? 10? cells L?¹). The experiments were carried out at 25 ± 1°C with a 12L:12D photoperiod. Each pesticide had 8 replicates per concentration, with one juvenile individual per replicate, and a duration of 20 days. The concentration ranges used in the tests were: 0 / 22.5 / 45 / 90 / 180 / 360 µg L?¹ and 0 / 0.25 / 0.5 / 1.0 / 2.0 / 4.0 µg L?¹ for the commercial formulations Tebuco 430SC (fungicide) and Imidagold 700WG (insecticide), respectively. To estimate growth rates, individuals were measured individually at the beginning and end of the experiment, on a hollowed-out slide under a stereomicroscope with 50x magnification, being handled with Pasteur pipettes. The effects were analyzed using Generalized Linear Models (GLM). The results showed that the growth rates for tebuconazole were 28.92 ± 3.87; 26.42 ± 4.76; 28.92 ± 5.80; 27.85 ± 4.51; 25.00 ± 5.66 and 23.92 ± 4.81 µm/day, while for imidacloprid the rates were 28.92 ± 3.87; 31.07 ± 4.43; 29.28 ± 4.25; 26.07 ± 5.16; 25.71 ± 2.85 and 20.00 ± 2.64 µm/day. Both pesticides caused a significant decrease ($p < 0.05$) in the growth of S. rondoniensis individuals at the highest concentrations. The change in the growth pattern of S. rondoniensis individuals is worrying, since studies show the occurrence of high concentrations of both pesticides in Brazil, ranging from 2,579 to 90.7 µg L?¹ for imidacloprid and up to 180 µg L?¹ for tebuconazole. Therefore, it is essential to strengthen public policies aimed at environmental monitoring, aiming to deepen the understanding of the real effects caused by the widespread occurrence of pesticides in aquatic ecosystems. This research was supported by the São Paulo Research Foundation - FAPESP (grant no. 2022/12104-4). Diego Ferreira Gomes and Thandy Junio da Silva Pinto have a postdoctoral scholarship supported by FAPESP (grant no. 2022/14293-9 and 2024/08039-8). David Silva Alexandre has a doctoral scholarship supported by FAPESP (grant no. 2024/00791-2).

2.03.P-We055 Imidacloprid: Spatial Avoidance and Behavioral Impacts on the Organism *Poecilia reticulate*

***Teresa Paiva**[1], Flavio Silva[1], Annah Carneiro[1] and Daniel Silva[2], (1)University of S o Paulo, Brazil, (2)Federal University of Itajuba, Brazil*

Imidacloprid is a neonicotinoid insecticide widely used in agriculture due to its high efficiency in controlling insects that cause damage to various types of crops. This pesticide has been found in freshwater ecosystems worldwide, including Brazilian water bodies. The present study evaluated the spatial avoidance and behavioral impacts of the commercial formulation of imidacloprid (ICF) Galeão® on the Brazilian non-target aquatic organism Poecilia reticulate in an ecologically relevant concentration range. The Multi-Habitat Assay System (HeMHAS) was selected for avoidance and colonization tests with the organism Poecilia reticulata. The system was constructed with PVC boxes, formed by 12 square compartments (arranged in 3 columns and 4 rows), with a volume of 900 mL in each chamber, interconnected by 2 cm tubes allowing the exposure of the organisms to a concentration gradient of a chemical substance and free movement of the organisms between them. In this study, the length, width and height of the HeMHAS used were 1000 mm, 1000 mm and 100 mm, respectively. After filling the chambers (900 mL with different concentrations of the compound), 3 fish were inserted into each of the 4 compartments, totaling 12 fish per system. The tests were carried out for 90 min, under natural light conditions and were filmed with a suspended camera, avoiding interference from the human presence. The distribution of P. reticulata fish in the control occurred randomly, demonstrating that there was no interference from the system or the location on the organisms ($p>0.05$). When exposed to imidacloprid, a significant difference was observed between the control and the 3 treatments with the compound ($p>0.05$). The percentage data of the P. reticulata population within the system showed a clear tendency for the organisms to move to the less contaminated regions. It was found that after the 90-minute exposure, more than 70% of the population was concentrated between the control and the lowest concentration of imidacloprid, demonstrating that the compound has the potential to cause repellency in the organisms, directly interfering in the habitat selection process, and may lead to a great risk of loss of biodiversity of aquatic organisms. The authors thank to CNPq for financial support.

2.03.P-We057 Acute Toxicity of the *Bacillus thuringi*ensis Commercial Bio-Insecticide for Aquatic Invertebrates

***Marina Tenório Botelho**, Adria C Oliveira and Gisela de Aragão Umbuzeiro, Universidade de Campinas, Brazil*

The use of biopesticides has been increasing annually and worldwide. Their formulations derived from natural sources such as bacteria, animals, plants, or minerals. Today, about 90% of microbial biopesticides are derived from Bacillus thuringiensis (Bt). During sporulation, Bt strains synthesize crystal (Cry) and cytolytic (Cyt) toxic proteins, which have potential be used as pesticides in several crops. Insecticides containing B. thuringiensis are considered safe bioproducts and are commonly used in organic agriculture. Studies on Bt toxicity to non-target organisms have demonstrated that some commercial products were not toxic, but some were, especially showing sublethal effects. Data from literature also suggest a synergy effect between the formulation compounds (spores, cleaved toxins, additives), which might increase the toxicity. Some additives used in commercial formulations might be even be more harmful than the active ingredients. Therefore, the aim of this work was to evaluate the acute toxicity of a commercial formulation from Bt in the freshwater microcrustean Daphnia similis and the marine amphipod Parhyale hawaiensis. Bt (HizoBio) acquired from the market claimed to contain water, non-toxic additives and 5 x 108 CFU/mL of Bt. Aiming to also evaluate the effect of the formulation, we centrifuged the product 3 times for 20min at 2500rpm to remove Bt spores. After the last centrifugation, no pellet formation was observed. Acute toxicity tests were performed for the commercial product and the supernatant. Test with D. similis was carried out for 48h with photoperiod of 16:8h at 22ºC in concentrations ranging from 0 to 0.1%. Test with P. hawaiensis was performed for 96h with photoperiod of 12:12h at 24ºC in concentrations ranging from 0 to 10%. Data was analyzed applying generalized logistic models. Bt was toxic to D. similis (EC50 0.014%) and P. hawaiensis (LC50 0.37%). The supernatant was responsible for the toxicity detected in both organisms (EC50 0.012% and LC50 0.38%). Thus, we believe the toxicity is due to the formulation and not to the Bt spores. We aim to test more commercial compounds to evaluate the effect that the formulation/additives might cause in these aquatic species. The authors thank FAPESP (2022/04482-9)

2.03.P-We058 Ecotoxicological Sensitivity Mapping of the Province of Buenos Aires to Agrochemical Use

Walter D. di marzio*, Maria Elena Saenz, jose alberdi and santiago martinez, PRIET DCB UNLU CONICET, Argentina*

The Province of Buenos Aires is one of the most agriculturally productive regions in Argentina. Dominated by the cultivation of genetically modified soybeans, corn, and wheat, among other crops, it exerts constant environmental pressure due to the use and application of pesticides, growth enhancers, and fertilizers. The dominant aquatic environments are shallow lagoons and low-flow streams, which are often temporary. There is a gradient in the physical and chemical conditions across the province's different watersheds. This study focuses on the variation in suspended solids concentration and salinity/conductivity and how these factors can influence the capacity to buffer the impact of agrochemicals. Two widely used pesticides were selected for analysis: those containing chlorpyrifos and glyphosate-based herbicides. Ecotoxicity was evaluated on algae and cladocerans using water samples from various environments within the Province of Buenos Aires. For this purpose, the province was divided into four sectors, and the watersheds associated with these sectors were sampled over a year. An ecotoxicological sensitivity map was created, taking into account the results of the bioassays and the gradients of conductivity and suspended solids.

2.03.P-We059 Pesticide Residues in Bio-Based Fertilizer Products – Assessing Product Safety by Bioassays

Salla Kristiina Selonen*[1], Anne Relander[2], Johanna Jarvisto[1], Mikko Lehtonen[2], Matti T. Leppanen[1] and Liisa Maunuksela[2], (1)Finnish Environment Institute, Finland, (2)Finnish Food Authority, Finland*

The increased use and development of bio-based fertilizer (BBF) products supports the circular bioeconomy and sustainable food production by reducing dependency on mineral fertilizers and enhancing food security. However, fertilizer product raw materials may contain pesticide residues, such as pyralids (e.g., clopyralid and aminopyralid) and glyphosate. Pyralids can significantly inhibit plant growth even at very low concentrations, with sensitivity varying between plant species. Pyralids in crop residues that are further processed into fertilizers or growing media may eventually pose negative implications to crops or soil biota. Glyphosate, in turn, when introduced through feeding on fodder crops with glyphosate residues, can accumulate in manure, leading to reduced plant growth when manure is applied to fields. This study aims to promote the safety of BBFs. This includes increasing knowledge on BBF pesticide residue concentrations and the effects on plants and soil biota. In addition, the aim is to provide better tools for fertilizer product manufacturers and regulators to evaluate pesticide residue impacts on plants and ensure the safety of the fertilizer products, including growing media. The suitability of bioassays for assessing fertilizer product safety are evaluated by studying the effects of clopyralid and glyphosate on various plant species using e.g. standardized germination and shoot growth tests, and photosynthesis inhibition tests under controlled conditions. BBF products with known pesticide residue concentrations are also tested. Results from the study, expected in early 2025, will provide information that can be utilized in guidelines for the safe use of BBF products in agriculture and horticulture. This study is funded by Agri-food Research and Development funding of Ministry of Agriculture and Forestry of Finland (Makera)

2.03.P-We060 Non-target Arthropod Testing Under Extended Study Conditions: How to Handle Study Validity?

*Thomas Schmidt[1], **Stephen Vinall**[2], Russell Vaughan[3] and Stefan Josef Hoeger[1], (1)IES Ltd., Switzerland, (2)Mambo Tox, United Kingdom, (3)Mambo-Tox, United Kingdom*
Non-target arthropod (NTA) species on plants are used for the risk assessment of plant protection products. The required studies follow the test procedures for worst case laboratory studies according to guidelines to evaluate side-effects of plant protection products to non-target arthropods from Candolfi et al. (2000). These guidelines are related to eight arthropod species but according to ESCORT 2 workshop (2000) the parasitoid wasp species Aphidius rhopalosiphi and the predatory mite species Typhlodromus pyri were identified as sensitive indicator species in worst-case laboratory studies. One of the requirements on the validity of this study type is the use of a toxic standard substance for the verification that the respective arthropod species is sufficiently susceptible to potential effects of the test substance. Candolfi el al. (2002) present recommendations for the type and application rate of a toxic substance to be used in a worst-case laboratory test. However, this worst-case laboratory test design differs from natural conditions and is therefore often supplemented by studies under extended laboratory conditions, e.g. exposure to treated leaves, treated plants or aged residues on treated leaves and plants. Unfortunately, for these extended laboratory studies a reliable and conclusive information on the type and rate of a toxic standard is not generally available. This poster presentation compiles data on toxic substances from extended studies in the scientific literature and the publicly available draft assessment reports from registration dossiers and gives recommendations for different types of extended NTA studies.

2.03.P-We061 Evaluation of Triazole Fungicide Exposure To The Development of *Tenebrio molitor*
***Paula Bolívar**[1], Rafael Mateo[2], Claudia Santamaria Cervantes[3], Manuel Ortiz Santaliestra[3] and Ricardo Sanchez de la Nieta[3], (1)University of Castilla-La Mancha, Spain, (2)Institute of Enviromental Assessment and Water Research, Spain, (3)Instituto de Investigacion en Recursos Cinegeticos, Spain*
The use of pesticides, in particular triazole fungicides, contributes significantly to biodiversity loss in agroecosystems. These fungicides affect fungal cell wall formation by inhibiting ergosterol synthesis, and in arthropods they can disrupt the production of ecdysteroids, key hormones in moulting and reproduction. Since invertebrates are essential for ecosystem balance, this study evaluated the effects of triazoles on the mealworm (Tenebrio molitor) by simulating exposure scenarios through the ingestion of cereal seeds treated with prothioconazole and tebuconazole. Physiological variables (size, weight and development) and changes in gene expression linked to ecdysteroidogenesis were measured. Three exposure treatments were carried out: seeds treated with the labelled dose of Raxil® Plus, 50:50 and 25:75 mixtures of treated and untreated seeds, and a control with untreated seeds. Sixty larvae per treatment were exposed for 10 days, ingesting only the allocated seeds. Subsequently, they were offered oats, wheat bran and vegetables, and their development was monitored until the adult stage. Weight, mortality, malformations and development time were recorded. For molecular analysis, total RNA was extracted from larvae, pupae and adults and converted into cDNA for qRT-PCR. Gene expression was assessed using specific primers and relative differences from the control were calculated. Mealworm showed rejection of treated seeds, especially in the intermediate treatment. A decrease in weight was also observed in the higher treatments. No significant differences in development time were observed. Gene analysis revealed a lower expression of the enzymes Spo, Sad, Shd and the transcription factor HR3 in the highest treatment. In the intermediate treatment, a reduction of Spo and HR3 was detected, as well as an overexpression of the regulator E75. These changes suggest that fungicides interact with key elements of the ecdysteroidogenesis pathway, which could compromise essential functions in exposed arthropods. In conclusion, exposure to triazole fungicides may affect both physiological parameters and genetic regulation of hormonal processes in Tenebrio molitor, highlighting the need to assess their impact on biodiversity and agroecosystem functioning.

2.03.P-We062 Assessing Seed Coating Pesticide Risk to Honey Bee (*Apis mellifera anatoliaca*) Populations: A Study on Toxicity, Residue Levels, and Ecotoxicological Implications in Turkish Maize Fields
***Cafer Turgut**, Melis Yalcin, Mustafa Kösoğlu and Nalan Turgut, Aydin Adnan Menderes University, Turkiye*
This study investigates the potential risks associated with thiamethoxam and clothianidin, neonicotinoid insecticides, on honey bees (Apis mellifera anatoliaca) in Turkey. The research focuses on honey bees foraging water from guttation fluid, exploring the toxicity of clothianidin and thiamethoxam, and assessing their residue levels in guttation fluid from maize plants. Ecotoxicological tests were conducted to evaluate the impact of guttation fluid on honey bee populations. In bee toxicity tests with guttation fluid collected from plants grown from seeds treated with thiamethoxam, one of the neonicotinoid insecticides, 80% mortality was observed as early as 4 hours during the first 5 days of guttation fluid. In the following days, the mortality rate initially decreased but remained above 50% until the 10th day, with fluctuations

observed. Counts made at 24 and 48 hours of the trials indicated that all the bees in the trials died by the 9th day. Although guttation fluid collected on subsequent days showed an effect of about 50% at 48 hours, when the experiment was extended to 72 hours, gut fluid collected on all days caused more than 50% mortality. Thiamethoxam caused very high mortality from 24 h in the collected gut fluid trials, and at 72 h, it caused over 80% mortality on almost all days gut fluid was collected. Similar results were found in the experiments with clothianidin, which resulted in mortality rates between 80% and 100% during the experiments. Further research and regulatory measures are warranted to address and mitigate the risks posed by these pesticides to pollinator populations and the overall health of ecosystems.

2.03.P-We063 Nationwide Monitoring and Risk Assessment of Neonicotinoid Insecticides in Korean River Basins: A Species Sensitivity Distribution Approach
Daeho Kang *and Junho Jeon, Changwon National University, Korea, Republic of*
Neonicotinoid insecticides (NNIs) are the most widely used insecticides globally, having replaced organophosphates, carbamates, and pyrethroids due to their higher selective toxicity to pests and lower impact on non-target organisms. However, concerns remain over their high toxicity to pollinators, particularly honeybees, which can disrupt entire ecosystems. This study presents a comprehensive assessment of NNIs in Korean river basins, focusing on their ecological risks and spatial-temporal occurrences. Nationwide monitoring was conducted across four major river basins in Korea. Results indicated that southern basins, such as Yeongsan and Nakdong, exhibited significantly higher NNI concentrations, likely due to extensive agricultural activities. Seasonal variations revealed peak NNI levels during application periods, with significant runoff-driven transport into aquatic ecosystems. Risk assessments were performed using Species Sensitivity Distributions (SSDs), suggesting the sensitivity of aquatic species to NNIs, particularly invertebrates. The SSD-derived Predicted No Effect Concentration (PNEC) values were compared with conventional standards, showing the conservative assessment of SSD-based risk assessment. Our findings emphasize the need for tailored regulatory approaches in managing NNIs in agriculture-intensive regions and urban areas, and indicate the importance of accounting for transformation products in risk assessments. This research contributes to the development of a refined NNI monitoring paradigm, addressing both acute and chronic ecological risks.

2.03.P-We064 Wellness Peeling? Reduced Exposure to Pesticides via Dehusking in Small Mammals
Tina Grimm[1]*, Martin Vallon*[1]*, Anja Quellmalz*[2]*, Felix von Blanckenhagen*[2] *and Severine Platat*[3]*,*
(1)RIFCON, Hirschberg, Germany, (2)Rifcon, Germany, (3)Certis Belchim France, France
Dehusking of seeds before consumption is a well-known behaviour in small granivorous mammals. This behaviour strongly influences the potential uptake of pesticides, either used as seed treatments or applied via overspray on weed and crop seeds (on the plant or ground). In all cases, the greatest amount of pesticide residues is usually located on the outer husk of the seeds; therefore, dehusking can lead to significant exposure reduction for selected species. The recently noted revised EFSA Guidance Document on Risk Assessment for Birds and Mammals, which will be implemented in 2025, highlights dehusking as suitable refinement option and gives advice on specific parameters for conducting dehusking studies. We present an extensive data set obtained from a dehusking study with a cereal seed treatment product, providing data for wood mouse (Apodemus sylvaticus) as well as yellow-necked mouse (A. flavicollis), two common small mammal species known to regularly feed on seeds and both potential focal species in European pesticide risk assessment schemes. The study design followed a semi-field approach with wild-caught animals, which were individually housed in cages, and presented with treated cereal seeds. Dehusking behaviour was observed via video recordings. In addition, actual exposure reduction was quantified via residue analysis to enable derivation of an actual dehusking factor for risk assessment purposes. Our results clearly demonstrate extensive dehusking behaviour in both tested species leading to considerable exposure reduction. This substance-specific approach with a high sample size and a robust quantification method is thus in line with previous data for wood mouse generated in the lab and confirms the suitability of the study setup. In addition, we hereby provide important data for yellow-necked mouse as potential focal species and can demonstrate that exposure reduction via dehusking in this species is in a similar range as in wood mice. While the study design was crop- and substance-specific, the general methods can be adapted and applied for different scenarios or even species to derive dehusking factors, which is now in light of the new Bird and Mammal Guidance Document and the increased importance of granivorous scenarios of even greater importance as refinement option.

2.03.P-We065 Peel, eat, repeat - Monitoring of Bird Dehusking Behaviour
Martin Vallon[1]*, Tina Grimm*[1]*, Anja Quellmalz*[2]*, Silke Laucht*[2]*, Stephanie Tokar*[3] *and Jan-Dieter Ludwigs*[2]*,*
(1)RIFCON, Hirschberg, Germany, (2)Rifcon, Germany, (3)EU MTF, United States
Regardless of the application type (seed treatment on crop seeds or spray application on weed or crop

seeds), the bulk of pesticide residues ends up on the outside of the seed the husk. Thus, the removal of the seed husk prior to ingestion (so-called dehusking) leads to a considerable reduction of the exposure. The revised EFSA Guidance Document on Risk Assessment for Birds and Mammals, set to be implemented in 2025, identifies dehusking as a valuable refinement option and offers recommendations on the key parameters for conducting dehusking studies. In order to estimate the exposure for the use as a dehusking factor in avian risk assessments, it is important to quantify the extent and efficiency of the dehusking behaviour in addition to the analysis of which portion of active ingredients on seed is not ingested by a dehusking bird. Linnets (Linaria cannabina) and serins (Serinus serinus) are two granivorous bird species, widespread in many agricultural landscapes and the only two European bird species that regularly occur in farmland, which exhibit a nearly entirely granivorous diet. Here we present results of a study that aimed to investigate how linnets and serins handle and dehusk six different kinds of weed and crop seeds and to additionally quantify the reduction of exposure to contaminated seeds via this behavioural trait. The study was conducted using a semi-field approach over two years, involving a large number of wild-caught birds, which were individually placed in cages at trapping sites and provided with treated seeds. As proposed by the new EFSA Guidance Document, a non-toxic substance (capsaicin) substituting the pesticide was used to measure the exposure reduction caused by dehusking. Our results support that the two bird species showed different preferences for the offered seed types and an upper limit of seed size included in common serin feed. We could also demonstrate that both species commonly dehusk seeds prior to consumption. The handling of different seed types and the comparison between both species will be presented and discussed.

2.03.P-We066 Effects of Subchronic Exposure to Pyriproxyfen and Fipronil in Zebrafish (*Danio rerio*): Impacts on Thyroidal and Gonadal Axis Disruption and Oxidative Stress Gene Expression
*Gisele Giannocco, Roberta Goes da Silva, Anna Virginia Pike, Mayara Lago Teixeira, Fabio Kummrow and **Bruno Fiorelini Pereira**, Federal University of S o Paulo, Brazil*
Pyriproxyfen, widely used to combat vectors like dengue mosquitoes, and Fipronil, an insecticide and acaricide applied against various pests, are essential tools in pest control. However, their growing use raises concerns about potential impacts on human health, particularly on the endocrine system. Even at low doses, these compounds can mimic hormones, disrupting target organs and interfering with critical physiological functions. To evaluate the effects of chronic exposure to Pyriproxyfen (PPF) and Fipronil (FPN) on endocrine disruption, growth, and oxidative stress in the brain of zebrafish (Danio rerio). Zebrafish were allocated to eight aquariums (n=8 per group) and divided into groups: saline control (CS), DMSO control (CD), and exposure to PPF at 0.01, 0.1, 0.5, 1.0, and 1.5 µg/L or FPN at 0.01, 0.1, 1.0, 10, and 50 µg/L for 15 days. Brain and thyroid tissues were collected for gene expression analysis related to the thyroidal and gonadal axes, as well as oxidative stress markers, using real-time PCR. Data were analyzed with one-way ANOVA and Dunnett's multiple comparison test, with significance set at $p < 0.05$. Endocrine Disruption: PPF exposure at 0.5 and 1.2 µg/L significantly increased tsh gene expression, while FPN exposure at 1.0 and 50 µg/L showed similar effects. FPN also elevated tsh, lh, fsh, kisspeptin expression at 0.01 and 1.0, 1,5 µg/L, suggesting hypothyroidism. Both compounds reduced gh expression across multiple concentrations, likely linked to thyroid hormone activity. Antioxidant enzyme genes (cat, sod) were upregulated at 0.01 µg/L PPF exposure, while sod and gpx showed increased expression at 0.01 and 0.1 µg/L FPN, respectively. Higher FPN concentrations (10 and 50 µg/L) significantly upregulated cat expression. Dio2 expression increased with 0.5 and 1.2 µg/L PPF and 0.1 µg/L FPN exposure. PPF at 0.5 µg/L also upregulated tra expression. These findings suggest an adaptive response to oxidative damage caused by these insecticides. Chronic low-dose exposure to PPF and FPN caused thyroid and gonadal endocrine disruption in zebrafish, evidenced by increased expression of tsh, gnrh, kisspeptin, lh, and fsh, alongside reduced gh expression. Both insecticides also induced oxidative stress in the brain, marked by upregulation of antioxidant enzymes (cat, sod, and gpx). This suggests that brain tissues attempt to counteract oxidative damage caused by these compounds, highlighting their potential as endocrine disruptors. FAPESP Project: 2022/03094-5

2.03.P-We067 Toxic Response of *Danio rerio* Exposed to Two Commercial Formulations of Glyphosate
*Maria Angelica Delgado-Lugo, Miriam Hernandez-Zamora and **Fernando Martínez-Jerónimo**, Instituto Politecnico Nacional. Escuela Nacional de Ciencias Biologicas, Mexico*
Agriculture is the largest production activity consumer of pesticides. Glyphosate is the most consumed herbicide used to protect several crops (soybean, corn, cotton, wheat, fruits, and vegetables) from weeds and is coupled with transgenic crops. This herbicide is known for its effectiveness, accessibility, low cost, and ease of use. In Mexico, it is sold under various brand names (AquaMaster®, Faena®, and Mamba®); these formulations differ in composition, but all contain surfactants to allow even distribution on target

species. Because of its liquid condition, glyphosate can easily be washed into waterbodies, leading to pollution and potential damage to non-target aquatic biota, including protozoa, microalgae, amphibians, insects, and fish. The present study aimed to assess the toxic effects of two glyphosate commercial formulations (Faena Classic® and Faena Fuerte®) on the early life stages of zebrafish (Danio rerio). Bioassays were conducted following OECD protocol 236 to assess the toxic effects. The embryos were exposed to varying concentrations of the formulations for 144 hpf. Glyphosate levels in the formulations were quantified using an ELISA immunoassay. The median lethal concentration (LC50) of each formulation was determined, with Faena Fuerte® showing higher toxicity (LC50: 3.78 mg/L) compared to Faena Classic® (LC50: 4.18 mg/L). In addition to higher mortality, Faena Fuerte® also caused more pronounced sublethal effects, such as coagulation (40%), edema (10%), and scoliosis (15%). The results indicated that Faena Fuerte® is more toxic to zebrafish embryos than Faena Classic®. The quantification of glyphosate showed that both herbicides have 328 g/L of glyphosate in their formulation; however, additives such as emulsifiers, solvents, and surfactants (surfactants) may be different, and these modified the toxicity of the active ingredient. This study reveals that both herbicides produced lethal and sublethal toxic effects in aquatic organisms, so it is essential to establish controls and implement measures to prevent these compounds from contaminating the aquatic environment. Also, more attention and regulation must be given to the inert ingredients in formulations, as they can increase toxicity to non-target species.

2.03.P-We068 Pesticide Mixture Effects on Bioaccumulation and Toxicity in Biofilms

Betty Chaumet[1], *Stella Kohler*[2], *Elena Gorokhova*[2] *and Anna Sobek*[3], *(1)Environmental Science, Stockholm University, Stockholm, Sweden, (2)Stockholm University, Sweden, (3)Environmental Science, Stockholm University, Sweden*

Pesticides threaten aquatic ecosystems, particularly biofilm communities (microalgae, bacteria, and fungi within an extracellular matrix), which underpin food webs and act as sensitive water quality indicators. Pesticides' toxicity and bioaccumulation in biofilms depend on properties like logKow and mode of action, yet studies often overlook the effects of pesticide mixtures, common in the environment. Moreover, bioaccumulation doesn t always correlate linearly with exposure, limiting concentration-based risk assessments. Understanding mixture effects whether competitive, additive, or synergistic is critical as pesticide pollution in aquatic systems continues to rise. This study aims to develop a predictive model to evaluate the impact of pesticide mixtures on bioaccumulation and toxicity in biofilms, based on pesticide properties. Based on existing literature, we hypothesize that pesticides sharing the same mode of action will exhibit additive effects, whereas those with different modes of action may result in synergistic effects, as they target different receptors. To achieve this, we will conduct an experiment exposing biofilms, composed of the picocyanobacterium Synechococcus bacillaris and the diatom Phaeodactylum tricornutum, to various pesticide mixtures and assessing pesticide bioaccumulation and toxicity. Five pesticides diuron, terbuthylazine, tebuconazole, acetochlor, and hexazinone were selected for their diverse and/or similar physicochemical properties. Initially, biofilms will be exposed to each pesticide individually to determine their EC50 values, which will be used to establish the equivalent of 1 Toxic Unit (TU) for each compound. The single-exposure experiment will be used to develop an initial model linking pesticide concentration in water and pesticide properties, with bioaccumulation and toxic effects such as photosynthesis inhibition. Binary mixture exposure data will then be incorporated to account for mixture effects, refining the model further. Subsequently, biofilms will be exposed to all possible binary mixtures, with each pesticide at 1 TU, to evaluate the mixture effect. Pesticide concentrations will be measured in both the medium and the biofilm, while toxicity will be assessed by measuring photosynthesis inhibition in the biofilm. These efforts reveal the complexity of pesticide bioaccumulation, where non-linear relationships make concentration alone an insufficient risk indicator. This project is funded by FORMAS (grant number : 2023-01095)

2.03.P-We069 Histopathological Effects of Commercial Diflubenzuron Formulations on Wild-Type Zebrafish (*Danio rerio*): A Sub-Chronic Exposure Study

Amanda de Azevedo Valle[1], *Rafaella da Silva Brito*[1], *Flavio Tominaga*[1], *Isis dos Santos*[1], *Nuha Dsouki*[2], *Fabio Kummrow*[3] *and Bruno Fiorelini Pereira*[4], *(1)Laboratory of Molecular and Translational Endocrinology, Department of Medicine, Escola Paulista de Medicina, Universidade Federal de S o Paulo, Brazil, (2)Physiology Department, Faculdade de Medicina do ABC, Brazil, (3)Department of Pharmaceutical Sciences - Campus Diadema, Universidade Federal de S o Paulo, Brazil, (4)Department of Biological Sciences - Campus Diadema, Universidade Federal de S o Paulo, Brazil*

In aquatic ecosystems, pollutants like insecticides pose risks to wildlife. Diflubenzuron (DFB), used in agriculture and veterinary practices, may harm non-target species. Despite the widespread application of its commercial formulations, research addressing their toxicity and morphological effects on non-target species remains limited, leaving a comprehensive understanding of their impacts unresolved. Our objective was to assess histopathological alterations in the liver, kidney, and gonads of adult male and female wild-type zebrafish (Danio rerio) following a sub-chronic (14-day) exposure to two commercial DFB formulations, one for agriculture and the other for veterinary use. Ten specimens (?=5; ?=5) of zebrafish per treatment were exposed to six different DFB formulations concentrations (DBF concentrations ranging from 0.025-1.00 mg/L). Dimethyl sulfoxide (DMSO) was used as intermediate solvent. The experimental design included a negative and a solvent control group. Samples were hematoxylin-eosin stained, scanned, and analyzed via Aperio ImageScope 12.4.6 (20x). Quantitative analyses used GraphPad Prism version 10.0.0. Regarding the liver, telangiectasia and peripheral nuclei occurred in all treatment groups, with pronounced severity at 0.125-0.5 mg/L. Steatosis, altered hepatocyte nuclear morphology, and fibrosis were most evident at 0.065-0.25 mg/L treatments. For the kidney, all exposed specimens exhibited progressive dilation of the capillaries, and degeneration of the distal and proximal tubules and glomeruli, often accompanied by a reduction in Bowman's space. Moreover, extravasation of inflammatory exudate primarily occurred in specimens exposed to the highest concentrations of veterinary formulation. All treated males exhibited spermatogonia, spermatocytes, spermatids, and spermatozoa, with regions of pyknosis observed starting at 0.065 mg/L. Concerning the ovaries, most of the treated females showed the five stages of maturation (primary growth, pre-vitellogenic, early vitellogenic, mid-vitellogenic, and complete vitellogenesis), although no significant differences occurred compared to the control group. Fused vitellogenin granules appeared even at 0.025 mg/L. Furthermore, necrotic areas appeared in all treatment groups across the three focal organs. The findings demonstrate that commercial DFB formulations cause morphological damage to adult zebrafish, with veterinary formulation exhibiting itself as the most toxic. This work was funded by the São Paulo Research Foundation (FAPESP) under grant numbers 22/03094-5 (Zebratox Project: Toxicological Screening of Larvicides of Relevance to Public Health and Veterinary Medicine), 23/15540-2, 23/09884-0, 2024/10993-1 and 24/01418-3, and the National Council for Scientific and Technological Development (CNPq), Brazil (grant number 153725/2024-9).

2.03.P-We070 Histopathological Effects Caused by Chronic Exposure to the Insecticide Diflubenzuron in Zebrafish

***Rafaella da Silva Brito*[1]**, *Amanda de Azevedo Valle*[1], *Flavio Tominaga*[1], *Nuha Dsouki*[2], *Fabio Kummrow*[3] *and Bruno Fiorelini Pereira*[4], *(1)Laboratory of Molecular and Translational Endocrinology, Division of Endocrinology, Department of Medicine, Escola Paulista de Medicina, Universidade Federal de S o Paulo, Brazil, (2)Department of Morphology and Physiology, Centro Universitario Faculdade de Medicina do ABC, Brazil, (3)Department of Pharmaceutical Sciences - Campus Diadema, Universidade Federal de S o Paulo, Brazil, (4)Department of Biological Sciences - Campus Diadema, Universidade Federal de S o Paulo, Brazil*

Vector-borne neglected tropical diseases (NTDs), such as dengue, chikungunya, yellow fever, and Zika, are major public health concerns. Diflubenzuron (DFB), a larvicide that inhibits chitin synthesis, is recommended by the World Health Organization for mosquito control in specific contexts, including drinking water reservoirs at concentrations up to 0.25 mg/L. Despite its reported safety for non-target organisms, data on the chronic environmental toxic effects of DFB remain limited. This study used zebrafish (Danio rerio) as a toxicity model to evaluate DFB chronic exposure effects. All procedures were approved by the Ethics Committee for the Use of Animals (CEUA) of the Federal University of São Paulo (approval number 5220291122). Wild-type zebrafish were exposed to six DFB concentrations (0.025 0.75 mg/L), a negative control, and a solvent control for 90 days. Histopathological analyses focused on the liver, intestine, and kidney. Chronic exposure to DFB caused significant liver tissue alterations, including peripheral nuclear displacement, fibrosis, hepatocyte dilation, and necrosis in the liver, with effects observed at concentrations as low as 0.025 mg/L. Chronic exposure to DFB resulted in a concentration-dependent reduction in hepatocyte nuclear area. At 0.025 mg/L, the average reduction was 2.9 μm^2 compared to the control, reaching 5 μm^2 after exposure to 0.75 mg/L for 90 days ($p < 0.05$). Renal alterations, such as reduced Bowman s capsule space and glomerular degeneration, were prominent at higher concentrations (? 0.25 mg/L). In the intestine, DFB exposure stimulated mucus production, goblet cell proliferation, and structural damage, including villus lysis and epithelial detachment. These findings demonstrate the potential of DFB to induce severe damage to multiple organs, even at low concentrations. The study underscores the need for further research on DFB s long-term ecotoxicological impacts and highlights the zebrafish as a valuable model for ecotoxicological studies. Integrating these insights into NTDs control strategies may help minimize environmental health risks. This work was supported by São Paulo Research Foundation (FAPESP) (grant numbers 2022/03094-5 Bruno Fiorelini, 2024/10993-1 and 2024/01418-3 Flavio Tominaga, 2023/09884-0 Rafaella Brito, 2023/15540-2 Amanda Valle)

2.04 Mechanistic Insights, Advances, and Challenges in Behavioral Ecotoxicology and Neurotoxicity Assessment

2.04.T-01 Pharmaceutical Pollution Alters River-to-Sea Migration Success in Atlantic Salmon (*Salmo salar*)

Jack Brand[1], Marcus Michelangeli[1], Samuel Shry[2], Eleanor Moore[3], Aneesh Bose[1], Daniel Cerveny[1], Jake Mitchell Martin[4], Gustav Hellstrom[1], Erin McCallum[1], Annika Holmgren[1], Eli S.J. Thore[1], Jerker Fick[5], Tomas Brodin[6] and ***Michael Grant Bertram***[6]*, (1)Swedish University of Agricultural Sciences, Sweden, (2)Karlstad University, Sweden, (3)Monash University, Australia, (4)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences, Sweden, (5)Umeaa University, Sweden, (6)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences, Sweden*

Despite the growing threat of pharmaceutical pollution, we lack an understanding of whether and how such pollutants influence animal behaviour in the wild. Using laboratory- and field-based experiments across multiple years in Atlantic salmon (Salmo salar; n = 730), we demonstrate that the globally detected anxiolytic pollutant clobazam accumulates in the brain of exposed fish and alters river-to-sea migration success. Clobazam exposure increased the speed with which fish passed through two hydropower dams along their migration route, resulting in greater migration success compared to controls. We found that such effects may arise from altered shoaling behaviour in fish exposed to clobazam. Drug-induced behavioural changes, even when seemingly beneficial, are expected to have wide-ranging consequences for the ecology and evolution of wild populations.

2.04.T-02 Mechanism of Ocular Toxicity of Antidepressants in Zebrafish

Marwin Jafari[1]*, Jason Tyler Magnuson[2], Katharina Brotzmann[3], Sebastian Eilebrecht[4], Fabian Essfeld[5] and Daniela Maria Pampanin[6], (1)University of Stavanger, Stavanger, Norway, (2)U.S. Geological Survey, Columbia, United States, (3)University of Heidelberg, Germany, (4)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology, Germany, (5)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (6)University of Stavanger, Norway*

Global use of antidepressants is steadily increasing, with incomplete removal during wastewater treatment raising concerns about risks to aquatic ecosystems. Antidepressants act on the neuronal system by affecting neurotransmitter levels and have shown to cause behavioural effects in aquatic organisms. While behavioural effects are often attributed directly to altered neurotransmitter levels, there is a knowledge gap regarding whether effects on the visual system also contribute to these effects. This work aims to assess adverse effects of antidepressants on the visual system of early life stage zebrafish and to determine the underlying mechanism. Embryos were exposed to sublethal concentrations of the tricyclic antidepressants amitriptyline (AMI) and nortriptyline (NOR) and the selective serotonin reuptake inhibitor sertraline (SER). Effects to visual function were assessed via the optokinetic response (OKR) assay, cellular structure of the eye via histology, and gene expression via mRNA sequencing and qPCR. The OKR assay, which measures eye movements in reaction to an optical stimulus, showed significant effects for 4.99 and 234 µg/L of AMI and 20.7 µg/L of NOR (measured concentrations), with zebrafish embryos exhibiting 24%, 83% and 60% less eye saccades compared to the solvent control (0.01% DMSO) respectively. Histology revealed a significant increase in retinal pigment epithelium (RPE) thickness for both the 234 µg/L AMI (13.34 µm) and 20.7 µg/L NOR (13.29 µm) groups, compared to the solvent control (11.52 µm). Transcriptomics revealed significant effects to processes including synaptic signalling, neuron morphogenesis, and visual perception. Among the differentially expressed genes associated with visual perception, several genes involved in photoreception (opn1mw1, rho) and vision (arr3a, pde6c) were dysregulated. OKR assay with SER showed a significant decrease in eye saccades compared to the control, 34% and 86% respectively, at 100 and 1000 µg/L (nominal). Histology revealed a significant decrease by 17% in RPE thickness for 1000 µg/L SER. The results provide evidence that antidepressants can induce ocular toxicity in early life stage zebrafish on multiple levels of biological organization. While serotonin is implied to be involved in the mechanism, current experiments with the transgenic zebrafish line tg(tg:mCherry) focus on testing the hypothesis that thyroid disruption is the mechanism connecting altered serotonin levels to ocular toxicity. The authors would like to thank the European Commission and the Ministry of University and Research (MUR, Italy), the Federal Ministry of Education and Research (BMBF, Germany), the Research Council of Norway (RCN, Norway) and State Research Agency (AEI, Spain) for funding in the frame of the collaborative international consortium PHARMASEA financed under the 2020 AquaticPollutants Joint call of the AquaticPollutants ERA-NET Cofund (GA Nº 869178). This ERA-NET is an integral part of the activities developed by the Water, Oceans and AMR JPIs. The PhD grant of Marwin Jafari is funded by the Univerisity of Stavanger (Norway).

2.04.T-03 Early Life Exposure to Endocrine Disruptors: Understanding the Neuroendocrine Impact Using Metabolome Mapping of Rat Models

Pim Leonards[1], *Sara Evangelista*[2], *Marja Lamoree*[1], *Margret Schlumpf*[3], *Jesus Tresguerres*[4], *Beatriz Linillos Pradillo*[5] *and Walter Lichtensteiger*[3], *(1)Vrije Universiteit Amsterdam, Netherlands, (2)Environment & Health, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (3)GREEN Tox and Institute of Veterinary Pharmacology and Toxicology, Switzerland, (4)Universidad Complutens, Spain, (5)Universidad Complutense, Spain*

Exposure to endocrine-disrupting chemicals (EDCs) in humans during pregnancy and early stages of life can impair normal brain development and reproductive function patterns, leading to severe pathologies later in life. Studies have shown developmental neurotoxicity effects of bisphenols (BPA mostly) and phthalates. However, for many chemicals, such as pyrethroids, per- and polyfluoroalkyl substances (PFAS), organophosphate flame retardants, and plasticizers, hardly any information is available on the relation between endocrine disruption (ED) and potential neurodevelopmental (DNT) effects. To better understand the link between ED and DNT outcomes, rats (F0 rat dams) were exposed to six EDCs (BPF, BBzP, DINCH, PFOS, permethrin (PMT), triphenyl phosphate (TPHP)) from pre-mating until lactation. One pup/sex/litter was raised to adulthood for testing of activity, learning and memory, anxiety and social behavior. Targeted (steroid hormones, thyroid hormones, neurotransmitters) metabolomics and untargeted lipidomics of hippocampus (PND6) samples were used to map the metabolic pathways affected by these six EDCs and link these to the memory function. Changes in specific neurosteroids, neurotransmitters and hundreds of lipids in developing rat hippocampus were sex- and chemical-specific and correlated to adverse outcomes on memory of adult rat littermates. Memory function (Morris water maze) was impaired in adult male offspring by BPF and BBzP, and in females by DINCH and TPHP. Steroids, neurotransmitters and lipids levels in hippocampus (PND 6) correlated with sex-dependent behavioral outcomes. For instance in females pregnenolone-sulphate (PREG-S), GABA, and in males PREG-S, acetylcholine, histamine and corticosterone, and in both sexes hundreds of lipids were significantly regulated in the adverse memory function group compared to the control. Previously studies demonstrated a significant correlation between PREG-S and cognitive function, and also a relation between PREG-S and the neurotransmitter acetylcholine. Altered lipid levels in hippocampus (PND 6) by EDCs correlated with sex-dependent behavioral outcomes; lipids were mainly upregulated in females and mainly downregulated in males. Our findings will primarily be useful to understand the molecular mechanism of EDC toxicity in the developing neuroendocrine system, to elucidate the relationships with behaviour and memory function, and provide potential biomarkers for ED-linked DNT. This project received funding from EU Horizon 2020 (No. 825759, ENDpoiNTs).

2.04.T-04 The Application of Mass Spectrometry Imaging to Study Neurodevelopment and its Disruption by PFOS in a Tadpole Model

Rikke Poulsen[1], *Emma M Field*[2], *Angela Jackson*[3], *Haley Kuecks-Winger*[2], *David Goodlett*[2], *Helena Petrosova*[2] *and Caren C. Helbing*[2], *(1)Environmental Science, University of Victoria, Victoria, Canada, (2)Department of Biochemistry and Microbiology, University of Victoria, Canada, (3)University of Victoria, Canada*

Mass spectrometry imaging (MSI) is an exciting emerging technology that adds spatial information to mass spectrometry analysis, allowing mapping of specific biomolecules in the tissue. This is particularly interesting in the brain, where different tissue regions have distinct functions, and in sensory organs such as the olfactory system. Here we utilized a representative of true frogs, the cosmopolitan tadpole model American bullfrog (Rana [Lithobates] catesbeiana), and MSI to first construct a brain developmental atlas throughout metamorphosis. Then we used this baseline to study neurodevelopmental disruption due to PFOS exposure. Premetamorphic tadpoles were exposed to PFOS in a dose-range (0-100 µg/L) for 48 h. Tadpole heads were sampled for MSI and blood and brain samples were also analyzed with a complementary 4D lipidomics technique (LC-TIMS-MS/MS) using the same mass analyser. Along with the effects of toxicant exposure, the MSI also showed the tissue localization of PFOS which localized to a specific neuroendocrine gland and to the olfactory epithelium. Hence, the present study gives unprecedented information about tissue distribution of a legacy contaminant, as well as tissue specific effects. The possibility to link the results to a developmental baseline allows us to also evaluate the biological significance of affected biomolecules and suggest new biomarkers for assessment of developmental neurotoxicity.

2.04.P-Tu173 Environmentally Relevant Concentrations Of Seleno-Methionine Impair Neurodevelopment and Behaviour in Larval Zebrafish (*Danio rerio*)

Md Helal Uddin[1], *Clarenz Salvador*[2], *Jinnath Rehana Ritu*[1], *Douglas P. Chivers*[1] *and Som Niyogi*[2], *(1)Department of Biology, University of Saskatchewan, Canada, (2)Department of Biology & Toxicology*

Centre, University of Saskatchewan, Canada
Selenium (Se) is an essential micronutrient to fishes; however, it becomes extremely toxic when its concentration rises slightly above the physiological optimum. In contaminated systems, fishes accumulate Se primarily as seleno-methionine (Se-Met). While the detrimental effects of Se-Met in adult fishes are well characterized, the embryotoxicity of Se-Met in fishes remains poorly understood beyond the teratogenic effects. With that in mind, zebrafish embryos (2-hour post fertilization, hpf) were exposed to environmentally relevant concentrations of Se-Met (0, 5, 10, and 25 ?g/L) until 120 hpf. We found that exposure to Se-Met (10 and 25 ?g/L) induced significantly higher larval mortality and deformity rates compared to the control. In addition, our study also indicated that exposure to Se-Met (5 and/or 10 ?g/L) impaired thigmotactic and reflexive behaviours in zebrafish larvae. Furthermore, Se-Met exposure induced a dose dependent increase in reactive oxygen species (ROS) generation and apoptosis, dysregulation of proteins and genes involved in the dopaminergic, serotonergic, and cholinergic signaling pathways, and disrupted neurogenesis in larval zebrafish. Overall, our findings provide important new insights into the neuro-behavioural effects of Se-Met exposure in embryonic zebrafish, further highlighting
the risks by selenium contamination in aquatic ecosystems. Md Helal Uddin was supported by the Dean's Graduate Scholarship of the University of Saskatchewan. 2.04.P-Tu175 High-Content Screening in *C. elegans* for Neuronanosafety: Impacts of Silver Nanoparticles on Neurodegeneration

Nivedita Chatterjee[1], *Marie Pierron*[2], *Laurent Mouchiroud*[2] *and Ernesto Alfaro-Moreno*[1], *(1)International Iberian Nanotechnology Laboratory, Portugal, (2)Nagi Bioscience, Switzerland*
With the increasing production and use of nanomaterials, concerns about their neurotoxic potential have risen, prompting investigations into their effects on neuronal health. Caenorhabditis elegans (C. elegans), with its fully mapped nervous system and conserved genes, serves as an excellent model for studying neurotoxicity due to its genetic tractability and rapid neurobehavioral assessments. As a New Approach Methodology (NAM) tool-kit, it provides a cost-effective, ethical alternative to traditional animal models, enabling high-content screening and nanosafety research. This study evaluates the neurobehavioral and neurodegenerative effects of silver nanoparticles (AgNPs) on C. elegans using the high-content screening platform SydLabTM One from Nagi Bioscience. Significant growth inhibition and developmental delays were observed at higher concentrations (0.5 and 5 ?g/mL) of AgNPs, with a mean growth (area) rate of 2.56±0.49 ?m²/hour for controls, compared to 1.45±0.28 for 0.5 ?g/mL. Reproductive assessments showed reduced progeny accumulation, with a mean rate of 2.4±1.75 progeny/hour at 0.5 ?g/mL compared to 4.15±1.77 for controls, and no progeny observed at 5 ?g/mL until 80 hours, indicating reproductive failure at highest concentrations. Additionally, we investigated the differential neurobehavioral and neurodegenerative effects of AgNPs (0.05 ?g/mL) across wild-type and neurodegenerative disease models (Alzheimer s disease model, GMC101 and Parkinson s disease model, NL5901) over 11 days. Survival (% viability) and behavioral endpoints, including mean body bending frequency (Hz) and locomotion speed (mm/sec), indicated increased sensitivity to AgNPs in the Alzheimer s disease model (GMC101). In contrast, the Parkinson s disease model (NL5901) showed no significant differential effect. This increased sensitivity in the Alzheimer s model was supported by glutamatergic neurodegeneration observed in the reporter strain (DA1240). These findings suggest that AgNPs exposure may be associated with amyloid-beta aggregation, potentially amplifying Alzheimer s disease risk. Overall, C. elegans proves to be a valuable model for high-content neurobehavioral screening, offering predictive insights into nanoparticle effects on vulnerable populations, making it an ideal tool for NAM in neurotoxicology and nanosafety research. This study was funded by the European Union s H2020 projects, Sinfonia (N.857253), LEARN (N.101057510) and iCare (N.101092971).

2.04.P-Tu178 Neurobehavioural Effects of Bisphenol S on the Early Life Stages in Zebrafish (*Danio rerio*)

A.K.M. Munzurul Hasan, *Mahesh Rachamalla, Sravan Kumar Putnala, Md Helal Uddin, Som Niyogi and Douglas P. Chivers, Department of Biology, University of Saskatchewan, Canada*
Bisphenol S (BPS) is a widely used synthetic compound known as an endocrine-disrupting chemical (EDC). It is commonly found in epoxy resins and polycarbonate plastics, materials frequently used for food storage containers and baby bottles. The ability of BPS to bind predominantly to estrogen receptors raises significant concern, as it can interfere with different neurological functions leading to neurobehavioural deficits. Despite extensive research documenting various adverse effects of BPS in adult fish, its neurobehavioural effects, especially in early life stages of fish, remain poorly understood. In the

present study, zebrafish embryos (4-hour post fertilization, hpf) were exposed to environmentally relevant concentration of BPS (vehicle control, 0 and 30 ?g/l) until 120 hpf. Subsequently, behavioural effects of BPS were evaluated by examining various behavioural responses including thigmotaxis (120 hpf), reflexive movement (120 hpf), social preference (21 dpf (day post fertilization), and object recognition (26 dpf). These results indicated that exposure to BPS impaired thigmotaxis, reflexive movement, social and object recognition behaviours in zebrafish larvae. In addition, reactive oxygen species (ROS) production and apoptosis were evaluated at 120 hpf zebrafish larvae, which were found to be elevated following exposure to BPS. Moreover, gene expression analysis at 120 hpf indicated that BPS exposure resulted in the dysregulation of genes involved in serotonergic (slc6a4a, slc6a4b, tph2, htr1aa, htr1ab, htr1b, htr1d, htr2aa, htr2b) and cholinergic (ache, chata, creb1a) neurotransmitter pathways, apoptosis pathway (caspase-3, p-53), oxidative stress response (gpx, mn-sod), and neuroinflammation (il-1?, il-6). These findings suggest that BPS induces oxidative stress and apoptosis, which likely leads to disruption of neural development and signaling pathways involved in regulating behavioural responses. Overall, our study highlights that developmental exposure to BPS can induce marked behavioural deficits in larval zebrafish, and provides new insights into the neurotoxic mechanisms underlying its behavioural effects.

2.04.P Mechanistic Insights, Advances, and Challenges in Behavioral Ecotoxicology and Neurotoxicity Assessment

2.04.P-Tu172 EthoCRED: A Framework to Guide Reporting and Evaluation of the Relevance and Reliability of Behavioural Ecotoxicity Studies

Michael Grant Bertram[1]*, Marlene Ågerstrand*[2] *and Tomas Brodin*[1]*, (1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences, Sweden, (2)Stockholm University, Sweden*

Behavioural analysis has been attracting significant attention as a broad indicator of sub-lethal toxicity and has secured a place as an important subdiscipline in ecotoxicology. Among the most notable characteristics of behavioural research, compared to other established approaches in sub-lethal ecotoxicology (e.g. reproductive and developmental bioassays), are the wide range of study designs being used and the diversity of endpoints considered. At the same time, environmental hazard and risk assessment, which underpins regulatory decisions to protect the environment from potentially harmful chemicals, often recommends that ecotoxicological data be produced following accepted and validated test guidelines. These guidelines typically do not address behavioural changes, meaning that these, often sensitive, effects are not represented in hazard and risk assessments. Here, we propose a new tool, the EthoCRED evaluation method, for assessing the relevance and reliability of behavioural ecotoxicity data, which considers the unique requirements and challenges encountered in this field. This method and accompanying reporting recommendations are designed to serve as an extension of the Criteria for Reporting and Evaluating Ecotoxicity Data (CRED) project. As such, EthoCRED can both accommodate the wide array of experimental design approaches seen in behavioural ecotoxicology, and could be readily implemented into regulatory frameworks as deemed appropriate by policy makers of different jurisdictions to allow better integration of knowledge gained from behavioural testing into environmental protection. Furthermore, through our reporting recommendations, we aim to improve the reporting of behavioural studies in the peer-reviewed literature, and thereby increase their usefulness to inform chemical regulation.

2.04.P-Tu174 Mechanism of Ocular Toxicity of Antidepressants in Zebrafish

Marwin Jafari[1]*, Jason Tyler Magnuson*[2]*, Katharina Brotzmann*[3]*, Sebastian Eilebrecht*[4]*, Fabian Essfeld*[5] *and Daniela Maria Pampanin*[1]*, (1)University of Stavanger, Department of Chemistry, Bioscience and Environmental Engineering, Norway, (2)U.S. Geological Survey, United States, (3)States3University of Heidelberg, Centre for Organismal Studies, Germany, (4)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology), Germany, (5)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

Global use of antidepressants is steadily increasing, with incomplete removal during wastewater treatment raising concerns about risks to aquatic ecosystems. Antidepressants act on the neuronal system by affecting neurotransmitter levels and have shown to cause behavioural effects in aquatic organisms. While behavioural effects are often attributed directly to altered neurotransmitter levels, there is a knowledge gap regarding whether effects on the visual system also contribute to these effects. This work aims to assess adverse effects of antidepressants on the visual system of early life stage zebrafish and to determine the underlying mechanism. Embryos were exposed to sublethal concentrations of the tricyclic antidepressants amitriptyline (AMI) and nortriptyline (NOR) and the selective serotonin reuptake inhibitor sertraline (SER). Effects to visual function were assessed via the optokinetic response (OKR) assay, cellular structure of the eye via histology, and gene expression via mRNA sequencing and qPCR. The OKR assay, which measures eye movements in reaction to an optical stimulus, showed significant effects for 4.99 and

234 µg/L of AMI and 20.7 µg/L of NOR (measured concentrations), with zebrafish embryos exhibiting 24%, 83% and 60% less eye saccades compared to the solvent control (0.01% DMSO) respectively. Histology revealed a significant increase in retinal pigment epithelium (RPE) thickness for both the 234 µg/L AMI (13.34 µm) and 20.7 µg/L NOR (13.29 µm) groups, compared to the solvent control (11.52 µm). Transcriptomics revealed significant effects to processes including synaptic signalling, neuron morphogenesis, and visual perception. Among the differentially expressed genes associated with visual perception, several genes involved in photoreception (opn1mw1, rho) and vision (arr3a, pde6c) were dysregulated. OKR assay with SER showed a significant decrease in eye saccades compared to the control, 34% and 86% respectively, at 100 and 1000 µg/L (nominal). Histology revealed a significant decrease by 17% in RPE thickness for 1000 µg/L SER.
The results provide evidence that antidepressants can induce ocular toxicity in early life stage zebrafish on multiple levels of biological organization. While serotonin is implied to be involved in the mechanism, current experiments with the transgenic zebrafish line tg(tg:mCherry) focus on testing the hypothesis that thyroid disruption is the mechanism connecting altered serotonin levels to ocular toxicity. The authors would like to thank the European Commission and the Ministry of University and Research (MUR, Italy), the Federal Ministry of Education and Research (BMBF, Germany), the Research Council of Norway (RCN, Norway) and State Research Agency (AEI, Spain) for funding in the frame of the collaborative international consortium PHARMASEA financed under the 2020 AquaticPollutants Joint call of the AquaticPollutants ERA-NET Cofund (GA Nº 869178). This ERA-NET is an integral part of the activities developed by the Water, Oceans and AMR JPIs. The PhD grant of Marwin Jafari is funded by the Univerisity of Stavanger (Norway).

2.04.P-Tu175 High-Content Screening in *C. elegans* for Neuronanosafety: Impacts of Silver Nanoparticles on Neurodegeneration

***Nivedita Chatterjee*[1]*, Marie Pierron*[2]*, Laurent Mouchiroud*[2] *and Ernesto Alfaro-Moreno*[1]*, (1)International Iberian Nanotechnology Laboratory, Portugal, (2)Nagi Bioscience, Switzerland*

With the increasing production and use of nanomaterials, concerns about their neurotoxic potential have risen, prompting investigations into their effects on neuronal health. Caenorhabditis elegans (C. elegans), with its fully mapped nervous system and conserved genes, serves as an excellent model for studying neurotoxicity due to its genetic tractability and rapid neurobehavioral assessments. As a New Approach Methodology (NAM) tool-kit, it provides a cost-effective, ethical alternative to traditional animal models, enabling high-content screening and nanosafety research. This study evaluates the neurobehavioral and neurodegenerative effects of silver nanoparticles (AgNPs) on C. elegans using the high-content screening platform SydLabTM One from Nagi Bioscience. 2.04.P-Tu176 Integrating Habitat Selection Response with Biochemical and Behavioral Effects in Zebrafish Caused by Glyphosate Under Both Forced and Non-Forced Exposures

Jaine Ames[1]*,* ***Beatriz Barbosa Moreno***[2]*, Safa Bejaoui*[3]*, Nejla Soudani*[3]*, David Salvatierra*[4]*, Giseli Swertes Rocha*[5]*, Maria Pilar Gonzalez*[4]*, Maria Ubeda-Manazanaro*[4]*, Vania L. Loro*[1] *and Cristiano V.M. Araujo*[4]*, (1)Universidade Federal de Santa Maria, Brazil, (2)Universidade Federal de S o Paulo, Brazil, (3)University of Tunis El Manar, Tunisia, (4)Institute of Marine Sciences of Andalusia, Spain, (5)Universitat Rovira I Virgili, Spain*

Glyphosate is a widely used pesticide in agriculture, with high occurrence in aquatic systems and huge potential to affect non-target species. Among the problems caused by glyphosate, the behavior modulation of organisms deserves special concern. Behavior results from a reaction to an environmental stimulus, processed through physiological mechanisms. Therefore, any behavioral response relies on a biochemical processing process. Although many studies have demonstrated the harmful effects of glyphosate on aquatic species, the integration of the traditional exposure approach (forced exposure) with scenarios with a chemically heterogeneous environment (non-forced exposure systems) has not been addressed. Therefore, the present study aimed to evaluate the effect of contamination by glyphosate on the habitat selection (avoidance and colonization) behavior of zebrafish (Danio rerio) under a non-forced exposure scenario (HeMHAS - Heterogeneous Multi-Habitat Assay System), in which fish were exposed to a glyphosate gradient. Secondly, it aimed to integrate the habitat selection response with biochemical alterations (oxidative damage and enzymatic antioxidant defense) and behavioral changes (swimming pattern, sociability, aggressiveness, and predatory response) measured under a forced exposure approach. The concentrations in all the experiments were: 0, 5, 50, and 100 µg/L. In habitat selection tests, zebrafish tended to prefer the least contaminated compartments, either in colonization or avoidance tests. On forced exposure, fish changed their swimming and foraging behaviors, which can represent a serious risk to the species' traits and survival. All the biochemical markers (levels of hydrogen and lipid peroxide, malondialdehyde, protein, ferric reducing antioxidant potential, reduced glutathione, glutathione-S-transferase and peroxidase, metallothionein, catalase, carboxylesterase, superoxide dismutase and acetylcholinesterase and Na+K+ATPase activity) were affected by glyphosate in a concentration-dependent relationship. A correspondence was observed between selection habitat and behavior and between markers of oxidative stress, including oxidative damage and activation of antioxidant defense mechanisms. In summary, habitat selection represents a particularly sensitive indicator, closely linked to behavioral and biochemical alterations. These interactions could enrich approaches for assessing environmental risks associated with contaminants.

2.04.P-Tu177 Impacts of the Antidepressant Fluoxetine on Behaviours and Immune Responses in Fish

Gabriel Melhado *and Bob Wong, School of Biological Sciences, Monash University, Australia*

Pharmaceutical pollution in freshwater ecosystems raises global environmental concerns, particularly regarding its potential impact on the fitness of aquatic wildlife. Among pharmaceuticals, antidepressants pose specific risks due to their effects on neurological mechanisms. One antidepressant of emerging concern is fluoxetine, a selective serotonin reuptake inhibitor (SSRI) commonly prescribed for treating depression and anxiety in humans. Fluoxetine can disrupt behavioural regulation by impacting serotonin reabsorption in the brain. Changes in serotonin levels can lead to disturbances to key behaviours (i.e., locomotion, feeding, and aggression) that are essential for survival. Furthermore, since serotonin plays a vital role in regulating both behavioural and physiological responses, alterations in serotonin levels due to fluoxetine exposure may also be expected to affect immune function. In turn, this can influence the ability of organisms to cope with potential infections and diseases in the wild. Accordingly, this study investigated the effects of 28-day fluoxetine exposure at three environmentally realistic concentrations control (0 ng/L), low fluoxetine (measured average concentration: 4 ng/L), and high fluoxetine (measured average concentration: 637 ng/L) on body condition, behaviours and immune function of rainbowfish (Melanotaenia fluviatilis). Body mass and behavioural responses, including distance travelled, average velocity, time freezing, and shelter use, were assessed alongside immune traits, such as total white blood cell (WBC) counts and the neutrophil/lymphocyte (N/L) ratio. While no significant changes were found in body condition or behaviours, fluoxetine exposure decreased WBC counts and increased the N/L ratio. Our findings highlight the potential immunosuppressive effects of fluoxetine on aquatic species, even in the absence of behavioural alterations, suggesting that freshwater pollution caused by pharmaceuticals may have multifaceted impacts on the fitness and survival of aquatic species in contaminated freshwater habitats. This work was supported by the Society of Environmental Toxicology and Chemistry (SETAC) Australasia and the Australian Council of Environmental Deans and Directors (ACEDD) "Peter Teasdale Memorial Award".

2.04.P-Tu178 Neurobehavioural Effects of Bisphenol S on the Early Life Stages in Zebrafish (*Danio rerio*)

A.K.M. Munzurul Hasan*, Mahesh Rachamalla, Sravan Kumar Putnala, Md Helal Uddin, Som Niyogi and Douglas P. Chivers, Department of Biology, University of Saskatchewan, Canada*

Bisphenol S (BPS) is a widely used synthetic compound known as an endocrine-disrupting chemical (EDC). It is commonly found in epoxy resins and polycarbonate plastics, materials frequently used for food storage containers and baby bottles. The ability of BPS to bind predominantly to estrogen receptors raises significant concern, as it can interfere with different neurological functions leading to neurobehavioural deficits. Despite extensive research documenting various adverse effects of BPS in adult fish, its neurobehavioural effects, especially in early life stages of fish, remain poorly understood. In the present study, zebrafish embryos (4-hour post fertilization, hpf) were exposed to environmentally relevant concentration of BPS (vehicle control, 0 and 30 ?g/l) until 120 hpf. Subsequently, behavioural effects of BPS were evaluated by examining various behavioural responses including thigmotaxis (120 hpf), reflexive movement (120 hpf), social preference (21 dpf (day post fertilization), and object recognition (26 dpf). These results indicated that exposure to BPS impaired thigmotaxis, reflexive movement, social and object recognition behaviours in zebrafish larvae. In addition, reactive oxygen species (ROS) production and apoptosis were evaluated at 120 hpf zebrafish larvae, which were found to be elevated following exposure to BPS. Moreover, gene expression analysis at 120 hpf indicated that BPS exposure resulted in the dysregulation of genes involved in serotonergic (slc6a4a, slc6a4b, tph2, htr1aa, htr1ab, htr1b, htr1d, htr2aa, htr2b) and cholinergic (ache, chata, creb1a) neurotransmitter pathways, apoptosis pathway (caspase-3, p-53), oxidative stress response (gpx, mn-sod), and neuroinflammation (il-1?, il-6). These findings suggest that BPS induces oxidative stress and apoptosis, which likely leads to disruption of neural development and signaling pathways involved in regulating behavioural responses. Overall, our study highlights that developmental exposure to BPS can induce marked behavioural deficits in larval zebrafish, and provides new insights into the neurotoxic mechanisms underlying its behavioural effects.

2.04.P-Tu179 From Brain to Sperm: how Psychoactive Drugs Can Affect Fish Reproduction
***Ganna Fedorova**[1], Gayani Rajakaruna Kapukotuwa[1], Anatolii R Sotnikov[1], Alina Sadchenko[1], Vitaliy R Kholodnyy[1], Filip Dycka[2], Jan sterba[2], Tomas Randak[1] and Serhii R Boryshpolets[1], (1)University of South Bohemia in ceske Bud?jovice Faculty of Fisheries and Protection of Waters, Czech Republic, (2)University of South Bohemia in ceske Bud?jovice Faculty of Science, Czech Republic*
There is a growing concern about the occurrence of psychoactive drugs in the aquatic environment. Recent studies indicate adverse effects of psychoactive drugs on aquatic life at environmentally relevant concentrations. Several studies confirm behavioural changes in fish and crayfish exposed to psychoactive drugs. Despite this, very little is known about the mechanisms of those changes. Psychoactive drugs have a specific action on one or more neurotransmitters or neuroreceptors, which are present in neuron cells in both humans and fish. Individual targets are well conserved, suggesting that psychoactive drugs in fish act through similar mechanisms as in humans. Neuronal signaling is important not only for brain function but also for sperm function. It is regulated by signals, several of which correspond to neurotransmitters that activate the transduction signaling implicated in the molecular control of sperm physiology. Mammalian spermatozoa express receptors for many neurotransmitters and neuromodulators. Information on the presence of neurotransmitters and their receptors in fish sperm and gonads is limited. If neurotransmitters may be involved in sperm physiology, then constant exposure of fish to psychoactive compounds, which are ubiquitous in the aquatic environment, may lead not only to behavioural changes but also affect sperm functioning and, consequently, reproduction. The specific scope of the study was to do a comprehensive analysis of the common neurotransmitters (monoamines, trace amines, amino acids, and others, as well as some of their precursors and metabolites) in the brain, gonads and sperm of the European perch (Perca fluviatilis), and then check if they will be altered by the exposure to psychoactive drugs. Among 31 analyzed neurotransmitters (including some of their precursors and metabolites), 22 were determined in the brain, 19 in the gonad, and 15 in the sperm. Psychoactive drugs were bioaccumulated in all three tissues. Brain and gonads had similar levels, while sperm had slightly lower concentrations. There was a significant decrease in glutamate concentration in sperm after 7 and 23 days of exposure to methamphetamine, while there was slight increase in the brain after 23 days. This may have potential effects on fish sperm function that, in turn, may influence fish reproduction. The authors thank the Czech Science Foundation [project No. 22-03754S], The South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses (CENAKVA, ID 90238, MEYS CR)

2.04.P-Tu180 Exploring the Molecular Basis of Transient versus Persistent Behavioral Alterations Using a Multi-Omics Approach in the Zebrafish Model
***Colette vom Berg**[1], Melissa von Wyl[1], Severin Ammann[1], Rene Schonenberger[2] and Ksenia J Groh[1], (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Eawag - Swiss federal Institute of Aquatic Science and Technology, Switzerland*
Chemical-induced alterations in fish behavior can occur through specific disruptions of the nervous system or nonspecific physiological disturbances. Zebrafish (Danio rerio) larvae serve as a model for assessing neurotoxicity, particularly in locomotion studies. Our research investigates the transient and reversible nature of behavioral changes induced by the neuroactive pharmaceuticals buspirone and fentanyl, analyzing their effects through an exposure/depuration experimental setup. Utilizing transcriptomics (RNAseq), global proteomics and targeted metabolomics, we aimed to elucidate molecular

responses associated with these drugs during a 9-day assessment period. Larvae were exposed to either buspirone or fentanyl continuously for 6 days and subsequently placed in chemical-free medium for 3 days. Behavioral assessments revealed reduced locomotor activity induced by both chemicals, with recovery profiles indicating distinct patterns: larvae depurated from buspirone exhibited restored locomotion in dark phases, while those exposed to fentanyl showed recovery only in light phases. Our neurochemical analysis demonstrated rapid recovery of serotonin levels in buspirone-exposed larvae, while adrenaline levels remained consistently low across both treatments. Notably, noradrenaline exhibited quicker recovery in buspirone-exposed larvae compared to gradual recovery in fentanyl-exposed counterparts. Proteomic analysis revealed common alterations in metabolic pathways, oxidative phosphorylation, motor proteins, and cardiac muscle contraction, alongside specific alterations such as impacts on the apelin signaling pathway with buspirone and necroptosis pathway modulation with fentanyl. Evaluation of the RNAseq data and its integration with proteomics and metabolomics results is currently ongoing and expected to further increase the depth of molecular insights gained from this work. Our findings enhance the understanding of neuroactive compounds effects on zebrafish locomotion and facilitate insights into the underlying molecular mechanisms. The identified molecular markers can inform assessments of lethal, sublethal, and behavioral effects during early developmental stages, contributing to a comprehensive understanding of neurotoxic impacts on fish and aiding future ecotoxicological interpretations of behavioral effects.

2.04.P-Tu181 Early Life Stress Disrupts Later Life Coping Behaviours in Zebrafish

***Carla Ferreira Melo**[1], Melissa Diogo Faria[2] and Miguel Oliveira[1], (1)University of Aveiro, Portugal, (2)IDAEA-CSIC, Spain*

Animals experience stressful unpredictable conditions throughout their life cycle, including critical developmental periods. Stress at early life stages may affect brain function, leading to persistent behavioural disruption and potentially the expression of personality traits. However, the currently available data is limited, making it unclear if and how early-life stress impacts personality development, animal fitness, and the ability to cope with other environmental stressors, such as contaminants. This study examined the consequences of abiotic stress during different early life stages of zebrafish development on later coping behaviours to identify the most sensitive developmental stage(s). Animals were chased with a net for 20 sec, subjected to high aeration, low temperature (8.0 ±?1?°C) for 30 sec and air exposure for 5 sec after recovering normal activity from low-temperature exposure. Stress was applied at three specific developmental stages according to organisms´ tolerance and temporal patterns of cortisol synthesis: at 96 hours post fertilisation (hpf), 7 days post fertilisation (dpf) and 15 dpf. They were then reared under standard zebrafish housing conditions until the juvenile stage (45 dpf). The control group was not exposed to any stressors and was kept under the same conditions as the other experimental groups. At 45 dpf a battery of behavioural phenotyping trials was carefully selected to characterise bold and shy behavioural profiles among experimental groups to assess the modulatory role of stress on personality expression. Five independent assays were conducted, each in triplicate, with three replicates per condition. Overall, the results show that stress during early development plays a key modulatory role in later behavioural phenotype expression. The differences between shy and bold phenotypes observed in the control group were lost at 45 dpf in fish exposed to early-life stress for all the tested behavioural endpoints (total distance swum, inactivity time, and aggressiveness) and independent of the developmental stage exposed to stress. Bold individuals appeared to be more susceptible to early stress, especially those exposed to stress at 4 and 7 dpf, suggesting reduced phenotypic plasticity and adaptive flexibility. These outcomes suggest that early-life stress may compromise animals´ fitness potentially affecting their sensibility and ability to cope and adapt to contaminants. Thanks are due to the financial support to CESAM by FCT - Foundation for Science and Technology (UIDB/50017/2020 + UIDP/50017/2020+LA/P/0094/2020) and to FCT/MCTES for the financial support to the project NanoPlanet (DOI10.54499/2022.02340.PTDC). 2.04.P-Tu182 Assessing Neurodevelopmental Impacts of a Novel Bio-Hybrid Fuel for Combustion Engines in Zebrafish

***Angelina Miller**[1], Katja Schroder[1], Caitlin Steindorf[1], Pedro Inostroza[1], Miaomiao Du[1], Sarah Johann[2], Henner Hollert[2], Martina Ross-Nickoll[1] and Thomas Backhaus[1], (1)Institute for Environmental Research, RWTH Aachen University, Germany, (2)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany*

A crucial step towards a carbon-neutral future is transitioning the transportation sector to renewable energy sources. One promising approach is the development of bio-hybrid fuels, which utilizes bio-based feedstocks, carbon dioxide, and green hydrogen produced from renewable energy. While bio-hybrid fuels offer significant advantages from an engineering and environmental perspective, including increased engine efficiency and reduced greenhouse gas emissions, it is imperative to assess their human and environmental impacts early during their development. Specifically, certain compounds within these fuels may pose neurotoxic risks during production, handling, or accidental release. Using a multi-level neurotoxicological approach, we systematically assessed whether and to what extent the bio-hybrid fuel blend candidate KEAA (ketone-ester-alcohol-alkane) induces neurodevelopmental changes in zebrafish embryos up to 120 hours post fertilization (hpf). We examined sublethal effects on coiling activity (24 hpf), touch-evoked response (72 hpf), and swimming behavior (120 hpf) in the Light/Dark-Transition Test. These behavioral analyses were complemented by morphological and enzymatic analyses, including measurements of body length, eye size, yolk sac size, swim bladder inflation, as well as acetylcholinesterase (AChE) inhibition. Results show that KEAA exposure exerts a clear, concentration-dependent effect on zebrafish larval morphology. At an incubation temperature of 26 °C, concentrations above 113 mg/L decrease body length and eye size, while yolk sac depletion is significantly slower at 120 hpf. AChE inhibition is 50 % at a concentration of 316 mg/L at 26 °C but show a biphasic concentration-response at an incubation temperature of 28 °C. This suggests that neurotoxic effects at exposure concentrations near the EC10 are temperature-sensitive. These findings provide essential early-stage data on the neurotoxic potential of bio-hybrid fuels like KEAA, informing safer fuel design to minimize human and environmental risks. This work was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany´s Excellence Strategy Cluster of Excellence 2186 The Fuel Science Center ID: 390919832.

2.04.P-Tu183 Psychoactive Pollutant Alters Movement Dynamics of Fish in a Natural Lake System

Jack Brand[1], *Michael Grant Bertram*[2], *Daniel Cerveny*[1], *Erin McCallum*[1], *Gustav Hellstrom*[1], *Marcus Michelangeli*[3], *Daniel Palm*[1] *and Tomas Brodin*[2], *(1)Swedish University of Agricultural Sciences, Sweden, (2)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences, Sweden, (3)Griffith University, Australia*

Pharmaceutical pollution poses an increasing threat to global wildlife. Psychoactive pharmaceutical pollutants (e.g. antidepressants, anxiolytics) are a distinctive concern due to their ability to act on neural pathways that alter fitness-related behavioural traits. However, despite increasing research efforts, very little is still known about how these drugs influence the behaviour and survival of species in the wild. Here, we capitalise on the development of novel slow-release pharmaceutical implants and acoustic telemetry tracking tools to investigate how the commonly detected psychoactive pollutant temazepam (an anxiolytic) influences the movement dynamics of brown trout (Salmo trutta) in a natural lake system. Briefly, 90 brown trout were administered with a slow-release implant containing either no pharmaceuticals (i.e. control [µg/g]) or temazepam [50 µg/g] that mimics tissue concentrations that fish commonly experience in the wild. Fish were then released into Lake Orsa in central Sweden, where their movement was tracked for ~10 months. We found that temazepam altered movement dynamics and decreased the migration success of brown trout in the wild most likely due to temazepam-exposed fish suffering increased predation compared to unexposed conspecifics. These findings underscore the potential for pharmaceutical pollution to alter key fitness-related behavioural traits under natural conditions. Funding was provided by the Swedish Research Council Formas (2020-02293 to M.G.B.; 2020-00981 to E.S.M.; 2020-01052 to D.C.; 2022-00503 to M.M.; 2018-00828 to T.B.), the Kempe Foundations (SMK-1954, SMK21-0069, and JCSMK23-0078 to M.G.B.), the Marie-Claire Cronstedt Foundation (to M.G.B.), the ÅForsk Foundation (20-51 to M.G.B.), the Orsa Fisheries Conservation Area Association (to D.P.), the Oscar and Lili Lamm Memorial Foundation (FO2021-0016 to M.M.), and the European Union s Horizon 2020 research and innovation programme under the Marie Sklodowska Curie grant agreement (101061889 to M.M.).

2.04.P-Tu184 Behavioral and Reproductive Effects of the Antidepressant Fluoxetine Associated With Traditional and Compostable Microplastics

Beatriz Barbosa Moreno[1], *Jaine Ames*[2], *David Salvatierra*[3], *Giseli Swertes Rocha*[4], *Ítalo Braga de Castro*[1] *and Cristiano V.M. Araujo*[3], *(1)Universidade Federal de S o Paulo, Brazil, (2)Universidade Federal de Santa Maria, Brazil, (3)Institute of Marine Sciences of Andalusia, Spain, (4)Universitat Rovira I Virgili, Spain*

The aquatic environment faces increasing challenges due to the introduction of diverse pollutants, such as microplastics and pharmaceutical residues like antidepressants, , which pose significant threats to aquatic life. Fluoxetine (FLU), a widely prescribed antidepressant, stands out among these pollutants due to its prevalence and hydrophobic nature, which may lead to its adsorption onto matrices such as sediments and plastic fragments. Microplastics (MPs), particularly those smaller than 5 mm, ubiquitously permeate aquatic environments, acting as vectors for pollutants and posing direct or indirect threats to aquatic organisms. Efforts to mitigate plastic pollution have led to the development of biodegradable and compostable polymers aimed at reducing environmental persistence. However, these alternative materials may also generate microplastics (CMPs) capable of transporting pollutants. The interaction of CMPs with organisms remains understudied compared to traditional MPs. Recent studies have demonstrated the adsorption of FLU onto various aged MPs, raising concerns about the potential ecological impacts of these interactions. Ecotoxicological assessments, using models organisms such as Daphnia magna, are crucial to comprehensively understanding the impacts of FLU-contaminated CMPs and traditional MPs on aquatic organisms. Sub-lethal effects, particularly on behavior and reproduction, require careful evaluation in those assessments. Therefore, the aim of the current study was to evaluate the effects of traditional and compostable microplastics associated with FLU on behavior and reproduction of D. magna. The behavioral evaluations include unforced exposure methods, such as the avoidance and colonization tests using the Heterogeneous Multi-Habitat Assay System (HeMHAS), designed to simulate real-world scenarios and assess ecological risks. The avoidance and colonization evaluation were carried out using a multi-habitat scenario, with the control at the center and contaminant variables arranged around it, aiming to detect repellence and attraction to the MP, CMPs or FLU. Reproduction after 21 days exposure, showed that the mixture of traditional MPs with the highest concentration of FLU had an influence on the number of offspring compared to other treatments, demonstrating that the interaction between these two pollutants is concerning and requires further study to understand its potential environmental impacts.

2.04.P-Tu185 Alterations in Behaviour After Exposure to Leachate from SARS CoV-2 Colloidal Gold Test Strips in *Danio rerio* (Zebrafish)

*De Wet Wolmarans[1], Tarryn Lee Botha[2] and **Christene Goldman**[2], (1)North-West University, South Africa, (2)University of Johannesburg, South Africa*

Nanomaterials are used to improve various industries due to their unique properties, and this increase in use results in the increased prevalence of these materials in the environment. Since nanogold is thought to be safe and biocompatible, it has gained interest for possible applications in the medical industry. Thus, conducting toxicological assessments is important to understand the health risks that may be caused by nanogold. There are conflicting reports on the cytotoxicity of nanogold, with some claiming it is safe and compatible while others claim it is capable of bioaccumulation in various tissues and capable of inducing mitochondrial damage. Zebrafish are a useful model due to their genetic similarities with humans and other mammals and are frequently used to assess behavioural changes induced by different substances. Zebrafish are highly social and can thus be used to assess memory by using social interactions as a reward. To confirm whether SARS CoV-2 colloidal gold tests kits are capable of leaching nanogold into the environment scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS) and UV-vis spectroscopy were used, and attenuated Total Reflectance-Fourier Transform Infrared spectroscopy (FTIR-ATR) was used to test for other chemicals present on the test strips. Using ViewPoint digital tracking software, a novel tank diving test was then conducted to assess the baseline behaviour of the experimental fish in novel environments, after which they were trained in two sessions to only be familiarised with two zones of a 3D-printed T-maze by using conspecifics as a visual reward. Lastly, the behaviour of the fish following exposure to leachate, alarm substance from donor fish, and a combination of both was quantified by removing the conspecifics and further quantifying behaviour. Prior to exposure, the control group displayed risk-taking behaviour which remained consistent after removing the conspecifics from the maze. The fish exposed to leachate, alarm substance, and a combination of both displayed increased anxiety-like behaviour compared to the control group and did not explore the unfamiliar zone of the maze. There were statistically significant differences between the overall time spent moving or distance travelled in specific zones within the maze compared between exposure groups. This study highlights that further research is required in the safe development of commercially available nano-based products.

2.04.P-Tu186 In Silico Pre-Screening to Identify Neurotoxic Substances Which Are Considered Out of Applicability Domain for The Fish Embryo Acute Toxicity (FET) Test

*Ulla Simanainen[1], Marco Evangelista[2], **Pia Talja**[1], Anna-Maija Nyman[1], Shoko Furuno[1], Kai Craenen[1], Marta Sobanska[1] and Tomasz Sobanski[1], (1)European Chemicals Agency, Finland, (2)European Chemicals Agency and Department of Theoretical and Applied Sciences, University of Insubria, Italy*

The classification hazardous to the aquatic environment under CLP regulation relies on data from fish, and generation of such data raises animal welfare concerns. The Fish Embryo Acute Toxicity (FET) test is a potential alternative to acute fish toxicity study, but neurotoxic substances are considered out of the applicability domain of the method. The aim of the project was to evaluate how well (Q)SAR models can predict neurotoxicity, and if these (Q)SAR models could be a feasible screening tool to identify neurotoxic substances and thus out of the applicability domain when considering FET test as an alternative to acute fish toxicity study. The ability of (Q)SARs to predict neurotoxicity and identify neurotoxic substances was evaluated using 113 neurotoxic substances (harmonised classification as STOT RE 1/2 or STOT SE 1/2/3 with the nervous system as target organ or because they induce narcotic effects). These substances fall within the scope of REACH or are active substances in biocidal or plant protection products. The following (Q)SAR models, predicting neurotoxicity and inhibition of acetylcholinesterase, were used: Derek Nexus 2.6, ASTER (Assessment Tools for the Evaluation of Risk), ProTox 3.0, and Linear discriminant analysis model. Models were applied only to mono-constituent organic substances (89/113). Publicly available SMILES were mainly derived from the US EPA CompTox Chemicals Dashboard. Only 36% of neurotoxic substances (32/89) were identified as potential neurotoxicants (positive prediction) by one or more (Q)SAR models. The positive predictivity of individual models ranged from 4.5% (4/89) to 22.5% (20/89) with only four substances predicted as positive by more than one model. These results indicate that the predictive capacity of each model alone is low, but could be slightly improved by combining results from all four models. The ability to identify the neurotoxicants by the models was influenced by the substance type (i.e. ASTER and LDA models provided positive predictions only for substances registered for biocidal or plant protection products). As a conclusion, the selected (Q)SAR models were not able to identify majority of the neurotoxicants included in this study, and therefore would not serve as a reliable screening tool for substances that are outside of the applicability domain for the FET. In general, the findings indicate a need for better (Q)SAR models for improved identification of potential neurotoxic substances.

2.04.P-Tu187 Neurobehavioral and Neurochemical Effects of Nano-Polypropylene Accumulation in Zebrafish (*Danio rerio*)

Minji Kim *and Sang Don Kim, School of Environment and Energy Engineering, Gwangju Institute of Science and Technology, Korea, Republic of*

Plastic pollution, particularly nanoplastics (NPs), is a significant environmental contaminant that poses potential toxicological risks to organisms and ecosystems. Although extensive research is currently underway to study the toxicity of NPs, our understanding remains limited, primarily because of the constraints of standardized toxicity studies using polymers of specific sizes and types. To address this gap, we conducted toxicity experiments using directly synthesized polypropylene nanoparticles (PP-NPs) in zebrafish (Danio rerio). The presence of PP-NPs in the zebrafish brain was confirmed using pyrolysis gas chromatography-mass spectrometry (Py-GC/MS) and bio-transmission electron microscopy (bio-TEM). The accumulation of PP-NPs in the brain of D.rerio leads to neurotoxicity, reducing motility and aggressiveness. Changes in neurotransmitter levels and neural activity associated with behavior further supported these findings. This study suggests that environmental plastic pollutants may accumulate in the brain and cause neurotoxicity in organisms, emphasizing the need for appropriate management of these substances.

2.04.P-Tu188 Flazasulfuron Based-Herbicide and Glyphosate Effects on Zebrafish (*Danio rerio*) Larvae Behavior

Dercia Santos[1]*, Luis Felix*[1]*, Ana Luzio*[1] *and Sandra Mariza Monteiro*[2]*, (1)Centre for the Research and Technology of Agro-Environmental and Biological Sciences, CITAB, University of Tras-os-Montes and Alto Douro, Portugal, (2)Centre for the Research and Technology of Agro-Environmental and Biological Sciences, CITAB and Inov4Agro, Institute for Innovation, Capacity Building and Sustainability of Agri-Food Production, University of Tras-os-Montes and Alto Douro, Portugal*

Flazasulfuron (FLA) and glyphosate (GLY) are two non-selective herbicides commonly applied in agriculture. Consequently, their overuse and cumulative practices lead to environmental contamination of aquatic ecosystems. However, few studies dealing with FLA s ecotoxicity to non-target biota are available, and for GLY there is a lot of divergent data regarding its toxic effects. The present study aimed to evaluate the effects of a flazasulfuron-based herbicide and glyphosate on zebrafish (Danio rerio) larvae behavior. For this, zebrafish larvae at 7 days old were exposed to 6 treatments: control (E3 medium), dimethyl sulfoxide (DMSO, 0.01%), commercial glyphosate-based herbicide (30 µg/L), commercial flazasulfuron-based herbicide (30 µg/L), and to the respective active ingredients flazasulfuron (30 µg/L) and iodosulfuron-methyl-sodium (10 µg/L). Based on the profile simulations using the Exposure Pattern Analysis Tool (EPAT), an exposure of 24h to the treatments, followed by a recovery period of 10 days, and a new exposure of 36h, was defined. Four replicates were established, with 20 larvae per group. Larvae were maintained at 28 ± 0.5°C and 14:10 h (light: dark) photoperiod. Mortality was assessed daily, and after each exposure period (24 and 36 h), 8-10 animals were sampled from each group/replicate for behavioral assessment. The behavior of larvae was monitored using a video-tracking system (TheRealFishTracker), and the following parameters were evaluated: locomotor performance (e.g. mean speed, total distance moved, mean absolute turn angle), social (average inter-individual distance IID; and the nearest neighbor distance - NND) and avoidance/anxiety behaviors. Considering the results, the survival and development of larvae were not significantly affected by the treatments, despite glyphosate presenting a higher mortality rate than the remaining groups. After 24h of exposure, neither the locomotor nor the social behavior were affected by the herbicides and active ingredients ($p>0.05$). However, after the second exposure period of 36h, it was observed a higher absolute turn angle in larvae of the flazasulfuron-based herbicide exposed group ($p<0.01$). The absolute turn angle is considered a sensitive parameter to evaluate motor coordination, therefore changes in this parameter could indicate a disorganized locomotor pattern. Our study evaluated the ecotoxicity of FLA and GLY on larvae behavior, helping to further advance herbicide risk assessment. This work is funded by the Project Vine&Wine Portugal Driving Sustainable Growth Through Smart Innovation, Ref. no. C644866286- 00000011, co-financed within the scope of Mobilization Agendas for Business Innovation, under Reg. (EU) 2021/241, in the Recovery and Resilience Plan (PRR) of Portugal, and by National Funds by FCT - Portuguese Foundation for Science and Technology, under the project UIDB/04033/2020.

2.04.P-Tu189 Innovative AI-Driven Bioluminescence Paper Biosensing: Advancing Rapid Toxicity Testing and Next-Generation Risk Assessment through Integrated Analytical and Computational Approaches

Faisal Nazir, *Denise Gregucci, Maria Maddalena Calabretta and Elisa Michelini, Department of Chemistry Giacomo Ciamician , University of Bologna, Italy*

Water monitoring is essential for ecosystems and human well-being and plays a crucial role in sustaining life and health. The ISO 11348 method, based on either freshly prepared or freeze-dried bioluminescence marine Gram-negative bacteria Aliivibrio fischeri, is widely used to monitor water quality. A. fischeri emit photons of visible light as a byproduct of their metabolism, but since their viability is affected by toxic agents, the decrease in bioluminescence can be used to assess the toxicity of water and environmental samples. However, this method requires benchtop instrumentation, facilities for bacterial cultures and skilled personnel, with high cost and is time-consuming. To turn this method into a portable, low-cost, and user-friendly toxicity biosensor, we developed a toxicity sensing paper composed of immobilized bacteria on a paper-based platform that exploits a smartphone camera as a light detector. The paper biosensor included 6 wells for the calibration curve and a central well for the sample. In addition, a customized android application, named Scentinel App, was developed to analyze the image of the toxicity sensing paper and to convert the decrease in light intensity into quantitative information about sample toxicity. The analytical performance of the biosensor was evaluated with different water contaminants such as NaClO, microcystin-LR, 3-5 dichlorophenol, and lead nitrate, and with real water samples, showing promising results. The app combined with the paper sensor was also evaluated with different smartphone models, showing promising results both in terms of analytical performance and ease-of-use with potential applicability for use by the general population. The authors thank for funding the European Union s Horizon Europe project FARMWISE under GA No. 101135533

2.04.P-Tu190 An Effect of Color? Impact Of Food Dyes and Micro(Nano)Plastics on Fish

*Luis Casaleiro, Valerie Pires, Carla Ferreira Melo, Catia Venancio, Carolina Frazao, Monica Almeida, Isabel Lopes and **Miguel Oliveira**, University of Aveiro, Portugal*

Humans are increasingly exposed to an array of potential materials that may compromise their health. Among the substances that are raising health concerns are artificial food dyes, that have seen an increased consumption over the last decades. Despite regulatory agencies efforts to assure their safety, the current available data concerning their effects is limited and often contradictory. Furthermore, these substances may interact with other materials involved in food production and packaging. Thus, this study focused on the acute effects of artificial food dyes on early life stages of Danio rerio. It effects were also studied in combined exposure with micro(nano)plastics, products that are also raising concern regarding their potential effects on human health. Larvae were exposed for 96 hours to a range of concentrations of food dyes and mortality, morphological abnormalities and behaviour endpoints (e.g., swimming performance) were assessed. The obtained results provide relevant information for a more robust risk assessment of food dyes and highlight the need of more studies on the subject. Thanks are due to Portuguese Fundação para a Ciência e a Tecnologia (FCT)/MCTES for the financial support to CESAM (UIDP/50017/2020+UIDB/50017/2020+LA/P/0094/2020) and the project Nano Planet (DOI: 10.54499/2022.02340.PTDC) through national funds.

2.04.P-Tu191 Fish on Zoloft: Physiological and Behavioural Effects of Sertraline on *Danio rerio* Early Life Stages

*Márcio Barreto, Carla Ferreira Melo, **Miguel Oliveira** and Isabel Lopes, Centre for Environmental and Marine Studies) & Department of Biology, University of Aveiro, Portugal*

Antidepressants, widely consumed pharmaceuticals, often enter the environment through patient excretion and improper disposal. Wastewater treatment plants are insufficient at fully removing these drugs and their active metabolites. Designed for biological effects at low concentrations, antidepressants may pose hazards to non-target organisms. Sertraline, a selective serotonin-reuptake inhibitor, is the most consumed drug in its class and has been detected in various aquatic systems, where it may exert biological effects. This study aimed to assess lethal and sublethal effects of sertraline on embryos and larvae of Danio rerio and assess the influence of stress coping styles (bold-shy continuum). Danio rerio embryos and larvae were exposed to five concentrations of sertraline (0.21 5 mg L-1) plus a negative control (E3 medium) for 144 and 96h, respectively. Lethal and sublethal effects, including mortality and malformations, heart rate (48h) and behaviour, were assessed at the end of each exposure period. For the personality assay, embryos exposed to 0, 0.01 and 0.1 µg L-1 sertraline until 8dpf, were classified in a bold-shy axis using a group risk-taking test, and fitness-related behaviours were analysed using the a tracking system. Mortality reached 100% at the highest tested concentrations (i.e., 5 and 2.27 mg L-1), while at 1.03 mg L-1 a 45% malformation rate was observed, excluding this group from behavioural analysis. Under dark periods, embryos exposed for 144h exhibited, compared to control, a less anxious behaviour at 0.21 mg L-1, with decreased swimming distance, time and distance spent in the outer area and increased inactivity time, while at 0.57 mg L-1 decreased swimming distance and increased inactivity time were observed. During light period, angles of class 1 and 8 percentages decreased at 0.57 mg L-1. In a stressful context (light-dark transition), exposed organisms showed reduced swimming distance, time spent in the outer area, angles of class 4 and 5, while angles of class 1 and 8 and inactive time increased at 0.51 mg L-1 compared to control. For the personality assay, bold larvae exposed to 0.1 µg L-1 exhibited thigmotaxis similar to shy larvae, while control and 0.01 µg L-1 kept significant differences between personality type. These findings suggest sertraline induces significant behavioural changes at non-lethal concentrations, with environmentally relevant levels potentially modulating behavioural traits in stressful contexts.

2.04.P-Tu192 BMAA-Induced Neurotoxicity: Unveiling the Behavioural and Developmental Impacts on Larval Zebrafish

Jinnath Rehana Ritu[1]*, Md Helal Uddin*[1]*, Maud C. O. Ferrari*[2] *and Douglas P. Chivers*[1]*, (1)Department of Biology, University of Saskatchewan, Canada, (2)Department of Biology, Department of Veterinary Biomedical Sciences, University of Saskatchewan, Canada*

Rising global temperatures and increasing eutrophication have amplified the prevalence of harmful algal blooms (HABs), posing significant ecological challenges worldwide. Among the toxins produced during HABs, ?-N-Methylamino-L-alanine (BMAA), a neurotoxic amino acid synthesized by cyanobacteria, diatoms, and dinoflagellates, has emerged as a critical environmental concern. Investigation of BMAA neurotoxicity to aquatic species is still in its early stages and the molecular mechanism by which BMAA induces its toxicity during the early development of zebrafish remains poorly understood. In this study, zebrafish embryos (2 hours post-fertilization, hpf) were exposed to environmentally relevant concentrations of BMAA (0, 10, 20, and 40 ?g/L) until 120 hpf to elucidate its developmental and neurotoxic effects. No significant differences were observed in mortality and deformity rates among treatment groups; however, concentrations of 20 and 40 ?g/L impaired thigmotactic and reflexive behaviours in the larval zebrafish. Exposure to BMAA at concentrations of 20 and 40 µg/L led to increased levels of apoptosis and reactive oxygen species (ROS), implicating oxidative stress-induced cell death as a key pathway in BMAA neurotoxicity. This study provides important insights into the neurotoxic effects of BMAA on zebrafish during early development. By examining how BMAA influences zebrafish development and cognition at early stages, our findings contribute to a broader understanding of the ecological impacts of neurotoxic microalgae on aquatic biodiversity, highlighting the need for further research on the long-term consequences of such exposures. Jinnath Rehana Ritu was supported by the Dean's Doctoral Scholarship of the University of Saskatchewan. This work is supported by a discovery grant from the Natural Sciences and Engineering Research Council of Canada (NSERC) to Douglas P. Chivers and Maud Ferrari.

2.04.P-Tu193 Early Stage Behavior and Sleeping Pattern Disorder in Zebrafish Larvae After DEP and BBzP Exposure

Soon Seok Kim[1]*, Sangwoo Lee*[1]*, Kojo Eghan*[2]*, Donggon Yoo*[1]*, Hang-Suk Chun*[1] *and* ***Woo-Keun Kim***[1]*, (1)korea institute of toxicology, Korea, Republic of, (2)korea institute of toxicology, Ghana*

The zebrafish, a diurnal vertebrate, is commonly used in circadian rhythm studies due to its genetic and neurological similarities to humans. Circadian rhythms, which regulate sleep, hormones, behavior, and physiological responses to environmental changes, can be disrupted by various environmental factors. Phthalic acid esters (PAEs) are pervasive endocrine disruptors that individuals are frequently exposed to in daily life. However, the impact of PAEs on circadian rhythms during early development remains poorly understood. This study aimed to investigate the effects of exposure to diethyl phthalate (DEP) and butyl benzyl phthalate (BBzP) on the behavior and circadian rhythms of developing zebrafish larvae using a series of layered assays. Zebrafish larvae were exposed to the two PAEs from less than 2 hour post-fertilization (hpf) until 96 hpf. The results demonstrated a concentration-dependent reduction in tail coiling (TC), touch-evoked response (TER), and locomotor activity, alongside an increase in sleep time and alterations in sleep bouts and sleep latency during both 24-hour and Light1/Dark/Light2 (7/10/7-hour) periods. Additionally, exposure to BBzP led to increased acetylcholinesterase (AChE) and dopamine (DA) levels, and a decrease in 5-hydroxytryptamine (5-HT) levels. Gene expression analysis revealed that DEP and BBzP exposure increased the expression of circadian rhythm and light-response-related genes. In conclusion, exposure to these PAEs disrupts the circadian rhythm of zebrafish larvae, providing novel insights into the developmental impact of these common environmental contaminants. Further research is needed to understand the broader implications of these findings for human health and environmental safety. This study was supported by the Korea Institute of Toxicology (KIT) Research Program (no. 2710008763, KK-2401-01) and Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products Program, funded by Korea Ministry of Environment (MOE) (2022002980005,1485019201)

2.04.P-Tu194 Neurotoxic Effects of Dibutyl Phthalate and its Metabolite in Zebrafish Larvae Model

*Suyeon Lee[1], **Sangwoo Lee**[1], Kojo Eghan[2] and Woo-Keun Kim[1], (1)korea institute of toxicology, Korea, Republic of, (2)korea institute of toxicology, Ghana*

Although dibutyl phthalate (DBP), commonly used as a plasticizer, raises significant neurotoxicity concerns, the effects of the metabolite mono-n-butyl phthalate (MBP) are not yet clear. This study investigates DBP and MBP's developmental and neurotoxic effects on zebrafish (Danio rerio) larvae. Wild-type and transgenic (tg(elavl3) and tg(mbp) zebrafish were exposed to DBP and MBP from 4 hpf to 120 hpf. Developmental toxicity was assessed using a variety of parameters, including survival, hatching rate, eye size, deformity, tail coiling, touch-evoked response, and locomotive activity. Neurotoxicity and oxidative stress markers and their associated gene transcription were evaluated by ELISA and qPCR. Fluorescence imaging revealed neurogenesis and demyelination. Studies have shown that both DBP and MBP caused significant changes in touch-evoked response at 72 hpf. Behavioral analysis revealed that DBP exposure affects various aspects, e.g., travel distance, velocity, and turning angle. Gene transcriptional analysis indicated significant effects on neurodevelopmental genes (sox2, manf, gfap) and oxidative stress genes (gsta1, gr), providing further insight into the molecular mechanisms of DBP and MBP. Specifically, MBP showed greater influence on molecular markers for neurodevelopment compared to DBP. These findings improve understanding of the neurotoxic potential of DBP and MBP in aquatic species, thus highlighting the importance of considering metabolites in toxicity and risk assessment. This work was supported by the Korea Environmental Industry & Technology Institute (KEITI) through the Core Technology Development Project for Environmental Diseases Prevention and Management [grant number 2480000072 (RS-2021-KE001705)].

2.04.P-Tu195 Ecotoxicological Effects of Imidacloprid: Study of Neurotoxic Impacts on Zebrafish Embryos and *Daphnia Magna*

***Ines Lacchetti**[1], Walter Cristiano[1], Melissa Barra[2], Lucia De Marchi[3], Luigi Intorre[3] and Laura Mancini[1], (1)Environment and Health, Italian National Institute of Health, Italy, (2)Italian National Institute of Health, Italy, (3)Universit di Pisa, Italy*

Imidacloprid, a widely used neonicotinoid insecticide, has been identified as a contaminant of emerging concern under the Water Framework Directive due to its persistence and potential ecological risks. However, there are still a limited number of studies investigating the ecotoxicological effects of imidacloprid on aquatic ecosystems, leaving critical gaps in understanding its impact on aquatic species, food webs, and overall ecosystem health. The study assesses the environmental impact by detecting acute and neurotoxic effects on fish Danio rerio and a crustacean Daphnia magna. Acute toxicity was evaluated with the Fish Embryo Toxicity (FET) test (OECD 236, 2013) on zebrafish and Immobilisation test (OECD 202, 2004) on daphnia. EC50 was calculated and sublethal effects such as morphological spine deformation, depigmentation and lack of balance were registered. Neurotoxic effects were evaluated with two internal laboratory protocols: the Coiling Activity Tail (CAT) test, which measures spontaneous tail movements in zebrafish embryos, and a Behaviour Locomotor Activity (BLA) test on daphnia, which describes the effect on velocity, distance and social interaction. The EC50 obtained is in line with the values used for deriving environmental quality standard (EQS) for inland surface water for imidacloprid in the context of the WFD common implementation strategy. The results indicate that imidacloprid exhibits both acute toxicity and neurobehavioral impacts, even at concentrations analogous to those found in aquatic environments. These findings highlight the importance of regulating imidacloprid to mitigate its risks to aquatic ecosystems. Moreover there are still few neuro-ecotoxicological studies on imidacloprid in literature, and this study can contribute to the implementation of knowledge of potential effects related to environmental risk.

2.05 Lab and Field Collected Invertebrates and in Situ Studies in Ecotoxicology: Challenges and Opportunities

2.05.T-01 Evaluating the Sensitivity of Diverse Freshwater Macroinvertebrates to Chemicals with Different Toxic Modes of Action

Amy Rose Ockenden[1], *Rana Al-jaibachi*[2], *Anthony Turner*[3], *Nichola White*[3] *and Lorraine Maltby*[3], *(1)University of Sheffield, New Zealand, (2)University of Sheffield, United Kingdom, (3)School of Biosciences, University of Sheffield, United Kingdom*

Freshwater macroinvertebrates are increasingly threatened by chemical pollution, with one-third of freshwater insect species at risk of extinction. Predicting chemical impacts on these communities is challenging due to wide variation in species sensitivity. Current ecotoxicological assessments often focus on model organisms like Daphnia magna, which do not adequately represent the diversity and sensitivity of broader freshwater ecosystems. Sensitivity to chemicals is influenced by their toxic mode of action (TMoA). Chemicals with broad TMoAs, such as metals, exhibit low variability in species sensitivity, whereas those with specific TMoAs, such as insecticides, produce highly variable responses across species, complicating risk assessments. This study investigates whether species sensitivity to chemicals within a given TMoA follows consistent patterns, enabling predictive modelling for untested chemicals. We tested the acute toxicity of 12 chemicals across four TMoA categories triazoles, polycyclic aromatic hydrocarbons (PAHs), synthetic pyrethroids, and strobilurins. Toxicity tests were performed on nine UK-relevant freshwater macroinvertebrate species (arthropod and non-arthropod), both field collected and laboratory cultured, representing diverse taxonomic and functional groups. EC?? values were calculated from immobilization data collected over 48 96 hours under controlled conditions. Then, rank order correlations were performed to assess the consistency of species sensitivity across chemicals within and between TMoA groups. Results showed substantial variation in species sensitivity depending on TMoA. Snails were highly sensitive to fungicides but less sensitive to synthetic pyrethroids, while water hoglice were most sensitive to PAHs. We found that the rank order of species sensitivity is more similar within chemicals sharing the same TMoA compared to those with different TMoAs. For example, comparisons between deltamethrin and permethrin showed a high positive correlation (Kendall Tau = 0.852), whereas, comparisons between permethrin and azoxystrobin (different TMoA) showed no/weak negative correlation (Kendall Tau = -0.384). These results confirm that species sensitivity follows predictable patterns within chemicals sharing the same TMoA. This consistent pattern of toxicity allows for more predictable ecotoxicological assessments, reducing the need for extensive testing of new chemicals that are structurally similar. NERC 'Assessing and Managing the Impacts of Mixtures of Chemicals on UK Freshwater Biodiversity in a Changing World' (NE/X015831/1)

2.05.T-02 How to Use Experimental Data and Modelling of the Wild-Caught Non-Standard EPT Taxon *Cloeon dipterum* for Environmental Risk Assessments of Pesticides

Hanna Samantha Schuster[1], *Charles Hazlerigg*[2], *Katie Smith*[1] *and Nadine S Taylor*[3], *(1)Cambridge Environmental Assessments, United Kingdom, (2)Enviresearch Ltd, United Kingdom, (3)Cambridge Environmental Assessments, Boxworth, United Kingdom*

In the European Union (EU), non-standard test species are often used to refine the aquatic risk assessments (RA) of pesticides. Representatives of EPT taxa (Ephemeroptera, Plecoptera and Trichoptera) are of particular interest as they are classed as sensitive and vulnerable to pesticides. The mayfly Cloeon dipterum is an abundant species across the UK and Europe, residing in ponds and river margins as larvae. Despite being considered a good representative of EPT taxa in RA (mainly acute studies), there is little published information on the reproducible laboratory conditions necessary, particularly for chronic tests. To improve the outcome for chronic studies with C. dipterum, two laboratory studies were conducted. In the first study temperature, food concentration and photoperiod were each varied (4/5 levels) in isolation, with the other parameters fixed for each of the changing treatment conditions. A control scenario was common across all three treatment conditions. In the second study, the organisms were exposed to three diffferent concentrations of Imidacloprid (1, 33, 100 ?g/L), and a control scenario, at two differing exposure patterns (24 hour exposures separated for either 2 or 9 days). Some adjustments were made in the design of Study 2, based on the findings of Study 1 and the outcome of a mayfly ringtest. In both studies, body length and instar stage were measured weekly, and mortality and emergence recorded daily. A major finding of the first study was the strong relationship between temperature and growth and development, against the associated effect on mortality (e.g., higher temperature led to faster growth and development, but also higher mortality). Furthermore, a change of the food source used in the second study showed how periphyton was a superior food source over the vegetarian fish food used in Study 1, with an improvement in the control emergence from 40 to 80%. The second study indicates the suitability of instar development for the assessment of sublethal endpoints. Whereas there was no distinct difference in mortality between the exposure patterns, the Instar Development Index highlighted that the effects were more pronounced in the exposure scenario with the pulsed exposures in quick succession, compared with the longer interval between exposures. These results provide new insight into the culturing of C. dipterum and show potential to be used to calibrate/validate DEB modelling implemented in line with EU pesticides RA.

2.05.T-03 Sequential Pesticide Exposure: Concentration Addition at High Concentrations _ Inhibition of Hormesis at Ultra-Low Concentrations

***Imrana Mushtaq*[1]*, Naeem Shahid*[1]*, Ayesha Siddique*[2] *and Matthias Liess*[1]*, (1)Department Ecotoxicology, Helmholtz Centre for Environmental Research & Institute for Environmental Research, RWTH Aachen University, Germany, (2)Department Ecotoxicology, Helmholtz Centre for Environmental Research, Germany*

Sequential pesticide exposure is a common scenario in both aquatic and terrestrial agricultural ecosystems. Predicting the effects of such exposures is thus highly relevant for risk assessment. However, there is currently no information available for predicting the effects of sequential exposure to the same toxicant at both high and low concentrations. Here we exposed one-week-old individuals of Daphnia magna to the pyrethroid Esfenvalerate for 24 hours and compared the effects with individuals treated twice with half the concentration after 7 and 14 days. We showed that at the concentrations close to the LC50, both the survival and population growth rates from the two half-pulses were consistent with the concentration addition approach. At low (1/10th to 1/100th of the LC50) and ultra-low concentrations (1/100th to 1/1000th of the LC50), survival was around 100%, while the population growth rate showed a hormetic increase following the one-pulse exposure but not for the two-pulse exposure. We hypothesize that this hormetic effect is due to lower systemic stress (SyS) after pesticide exposure in combination with only one rebound stress pulse. Our study suggests that while the lethal effects of sequential exposure are according to the concentration addition model, the sublethal effects at low and ultra-low concentrations need to consider hormetic effects.

2.05.T-04 Improving Interim Freshwater Guideline Values for Aluminium by Investigating the Effects of Laboratory-Spiked and Field-Collected Water on Aquatic Invertebrates

***Sara M Long*[1]*, Megan Carve*[2]*, David Buckles*[1]*, Alexandra Dupen*[1]*, Kathryn Hassell*[3]*, Hung Vu*[1]*, Dayanthi Nugegoda*[1] *and Vincent J. Pettigrove*[1]*, (1)Aquatic Environmental Stress Research Group, School of Science, Bundoora West Campus, RMIT-University, Australia, (2)Ecotoxicology Research Group, School of Science, Bundoora West Campus, RMIT-University, Australia, (3)Applied Chemistry and Environmental Science, School of Science, RMIT-University, Australia*

Aluminium is a non-essential metal frequently found in aquatic environments from both natural and anthropogenic sources, with no known biological function. In Australia, species protection guidelines for aluminium recognise that pH significantly affects its bioavailability and subsequent toxicity to organisms. Therefore, the 95% species protection value is set at 0.8 µg/L for pH < 6.5, and 55 µg/L for pH > 6.5. Surveys of freshwater bodies around Melbourne, Australia, found that aluminium concentrations often exceed these guideline values, sometimes by several orders of magnitude. The validity of current species protection guideline levels was investigated. This study aimed to assess the effects of acute and chronic exposure to environmentally relevant concentrations of aluminium on two freshwater invertebrates: Chironomus tepperi, a non-biting midge, and Austrochiltonia subtenuis, a freshwater amphipod, at pH < 6.5 and neutral pH. Additionally, the study evaluated the impact of field-collected water on acute endpoints in these two species. Laboratory exposure results indicated that amphipods were more sensitive than chironomids at pH levels below 6.5, with significant reductions in survival and growth during acute and chronic exposures at 2,500 µg/L. In contrast, a significant reduction in survival for C. tepperi was observed only at 5,000 µg/L. Amphipod growth significantly declined at aluminium concentrations of 100 µg/L or higher. Although chironomids appeared smaller at all aluminium concentrations, the reduction was not statistically significant. Interestingly, at neutral pH, chironomids were more sensitive, showing a significant decrease in acute survival at 5,000 µg/L, while amphipods showed no significant impact at any aluminium concentration. Water was collected from five sites based on aluminium concentrations from previous surveys. We predicted that we would observe effects on survival and growth at two sites with the highest concentrations of aluminium, based on the laboratory results. Acute exposure to the field-collected water revealed no significant impact on C. tepperi survival but unexpectedly, there was a significant increase in C. tepperi growth. This may be related to factors such as water hardness and nutrients. These findings can be used in the revision of the current interim Australian and New Zealand Aluminium freshwater guidelines, providing a more robust ecologically relevant level of protection for local species.

2.05.T-05 Organophosphate Esters Disrupt Copepods Health and their Associated Microbiome: From a Large Cross-Atlantic Ocean Field Study to Confirmatory Lab Experiments

Maria Paula Carrillo[1], *Naiara Berrojalbiz*[1], *Albert Calbet*[2], *Jordi Dachs*[1], *Jon Iriarte*[3], *Enric Saiz*[2], *Claudia Sanz Lanzas*[1], *Nuria Trilla*[1], *Carlos Barata Dr*[1] *and maria vila-costa*[1], *(1)IDAEA-CSIC, Spain, (2)ICM-CSIC, Spain, (3)Environmental Chemistry, IDAEA-CSIC, Spain*

Organophosphate esters (OPEs) are widely used as flame retardants, plasticizers, and additives, making them significant emerging contaminants in marine environments. They pose a threat to marine organisms due to their bioaccumulation and toxicity. Copepods play a vital role in aquatic ecosystems through feeding, nutrient cycling, and migration, but their role in the distribution and impact of OPEs remains unclear. Additionally, copepod-associated microbial communities, sensitive to environmental changes, may play a key role in understanding OPE effects. This study aimed to investigate the impact of six OPEs on copepod Paracartia grani, focusing on reproduction, bioaccumulation, and microbiome changes under controlled conditions. Furthermore, the findings were integrated with field observations of changes in copepod-associated microbiomes along an Atlantic transect, where OPE concentrations were measured in the water column. For the experiment, copepods were exposed to a mixture of six OPEs (TCEP, TCPP, TNBP, TPHP, EHDPP, and TCMP) at two concentrations: 200 ng/L and 2000 ng/L. Egg production, bioaccumulation, and 16S rRNA gene amplicon sequencing were assessed. Field copepod and water samples were collected from 24 stations along a latitudinal transect from Vigo (Spain) to Punta Arenas (Chile). DNA was extracted for 16S rRNA gene sequencing to characterize copepod-associated microbiome and OPE concentrations were measured in water samples. Exposure to OPEs resulted in a >30% reduction of egg production, regardless of concentration. OPE bioaccumulation in copepods was influenced by the compounds LogKow values, and copepods eliminated OPEs through fecal pellets. OPE exposure significantly altered the copepod-associated microbiome, increasing the relative abundance of Enterobacterales and Pseudomonadales, which were identified as key contributors of OPE exposure. In the field study, OPE concentrations in surface and DCM water layers correlated positively with stations in the northern and northern-central Atlantic Ocean. Similar to the experimental results, OPE concentrations positively correlated with Enterobacterales (Vibrio, Photobacterium and Pseudoalteromonas). In conclusion, OPEs significantly impact copepod reproduction and associated microbiome composition. The findings emphasize the importance of linking laboratory experiments with field studies, using omics approaches, to understand the real-world effects of pollutants on marine ecosystems.

2.05.P Lab and Field Collected Invertebrates and in Situ Studies in Ecotoxicology: Challenges and Opportunities

2.05.P-We071 In Situ Mussel Watch at Volcanic CO_2 Vents: Exploring Ocean Acidification Impacts on Contaminant Dynamics and One Health Risks

Marco Munari[1], *Roberto Ciampaglia*[2], *jacopo fabrello*[1], *Ilaria D'Aniello*[1], *Annalisa Capasso*[1], *Aurora Maraglino*[1], *Sonia Manzo*[5], *Simona Schiavo*[5], *Juri Rimauro*[5], *Laura Caiazzo*[5], *Martina Simonelli*[2], *Camilla Della Torre*[6], ***Silvia Giorgia Signorini***[6], *Silvia Franzellitti*[7], *Mirko Mutalipassi*[8], *Antonio Terlizzi*[8], *Fiorenza Michelki*[9], *Chris Knight*[9], *Theresa Burnham*[10], *Antonino Miccio*[11], *Fiorentina Roviezzo*[2] *and valerio matozzo*[1], *(1)University of Padova, Italy, (2)University of Naples, Italy, (5)Italian National Agency for New Technologies, Energy and Sustainable Economic Development, Italy, (6)University of Milan, Italy, (7)University of Bologna, Italy, (8)Stazione Zoologica Anton Dohrn, Italy, (9)Stanford, United States, (10)University of Maine, United States, (11)Area Marina Protetta Regno di Nettuno, Italy*

This study presents a "Mussel Watch" field experiment aiming to examine how ocean acidification (OA) gradients affect contaminant accumulation and physiological stress in marine organisms, specifically the Mediterranean mussel Mytilus galloprovincialis. Recent findings indicate that organisms inhabiting naturally acidified environments experience considerable energetic and oxidative stress, suggesting potential impacts on their capacity to manage environmental contaminants. This research leverages OA gradients around Ischia, where mussels were monitored over a two-month period to investigate how OA conditions may influence contaminant bioaccumulation and toxicological effects. A central component of this study involves analyzing contaminant concentrations within mussel tissues to explore potential risks in a One Health framework. These contaminant profiles will then expose human cell cultures to the detected concentrations, simulating realistic environmental exposure scenarios. This approach will help assess how OA-related changes in contaminant dynamics could pose broader ecological and human health risks. This study highlights the impact of ocean acidification on contaminant bioaccumulation, physiological stress, and mortality in Mytilus galloprovincialis. It shows that acidified conditions, like those near CO? vents, can reduce contaminant accumulation but increase stress and mortality. These findings emphasize the complex interactions between environmental stressors and contaminants, with implications for ecosystem resilience and public health. Further research is needed to understand the mechanisms and long-term effects of ocean acidification.

2.05.P-We072 Unveiling the Toxic Trail: How Methylmercury Accumulates and Impacts Zebra Mussels in Field and the Lab

Clarisse Seguin[1], *Damien Rioult*[1], *Mariia Petrova*[1], *Evan Bossard*[1], *Emmanuel Tessier*[2], *Aurelie Dufour*[3], *Nathalie Le Bris*[4], *David Renault*[4], *David Amouroux*[2], *Lars-Eric Heimburger-Boavida*[3] *and Claudia Cosio*[1], *(1)Universite de Reims Champagne-Ardenne, UMR-I 02 SEBIO, France, (2)Universite de Pau et des Pays de l'Adour, E2S UPPA, CNRS, Institut des Sciences Analytiques et des Physico-Chimie pour l'Environnement et les Materiaux (IPREM), France, (3)CNRS/INSU, Aix Marseille Universite, Universite de Toulon, Mediterranean Institute of Oceanography (MIO), France, (4)UMR CNRS 6553 EcoBio, Universite de Rennes, Rennes, France*

Methylmercury (MeHg) bioaccumulation in food webs poses a health risk linked to fish consumption. However, the role of freshwater primary consumers at the base of food web in the Hg cycle remains insufficiently explored. *Dreissena polymorpha*, is a food source for crustaceans, fish, birds, and mammals. This study aimed to assess the bioaccumulation and effects of environmentally relevant dietary MeHg concentrations in *D. polymorpha*. Mussels were exposed by caging in the Seine River where high Hg levels in fish were documented and in controlled laboratory experiments to better understand how *D. polymorpha* accumulates MeHg.

Mussels were caged in the Seine River (Paris) with 1 cage retrieved weekly for 3 weeks. In laboratory, mussels were fed 4 days with microalgae (*Chlorella vulgaris*) pre-exposed to Me²?¹Hg and I¹??Hg. Bioaccumulation of MeHg was analyzed in *D. polymorpha*, *C. vulgaris*, and water. Metabolomic, lipid peroxidation, enzymatic activity and transcript levels of antioxidant defense were performed.

In the field, MeHg concentrations and proportions (up to 95%) in *D. polymorpha* increased over time. 13 metabolites in 7 metabolic pathways, including amino acid and energy metabolism, showed significant reductions, suggesting a metabolic shift that could affect the mussel's fitness. While lipid peroxidation, enzymatic activity, and transcript levels of antioxidant and defense were modulated, these changes were not statistically significant.

In the laboratory, MeHg concentrations in *D. polymorpha* increased over time, while its proportion remained stable at 10.3 ± 0.9%. No evidence of Hg methylation or demethylation was detected in the mussels. In *C. vulgaris*, MeHg was predominantly localized in the intracellular compartment, indicating that the MeHg accumulated by *D. polymorpha* likely originated from this fraction of the microalgae. Metabolomic profiles, enzymatic activity, and transcript levels associated with the antioxidant and defense systems showed no significant changes.

This study demonstrated that *D. polymorpha* rapidly bioaccumulates MeHg in both field and laboratory conditions. Laboratory experiments further revealed that MeHg is absorbed from Hg-contaminated food rather than being methylated in the gut. At the low MeHg concentrations tested in the laboratory, no significant biological effects were observed. Future experiments will focus on dose-response analyses across a wider range of dietary MeHg concentrations to better understand its impacts.

Disclaimer/Disclosure: This research was funded by MeSeine, ANR MercurFood, ANR Hot-Hg, DIMER. The authors would like to thank URCATech Mobicyte Platform for equipment availability, Océane Asensio for technical help and Dr Iris Barjhoux for her guidance and support in navigating the statistical analyses.

2.05.P-We073 Investigating Primary Producers Buffer Effect Against Mercury Pollution in Two Marine Invertebrate Species

Marco Munari[1], *Jacopo Fabrello*[2], ***Ilaria D'Aniello***[1], *Annalisa Capasso*[2], *Sabrina Pavanello*[2], *Roberto Ciampaglia*[3], *Isabella Moro*[2], *Marta Formentin*[4], *Sonia Manzo*[5], *Fiorentina Roviezzo*[3], *Chiara Campaci*[2] *and Valerio Matozzo*[2], *(1)Integrated Marine Ecology, University of Padova, Padova, Italy, (2)University of Padova, Italy, (3)Department of Pharmacy, University of Naples Federico II, Italy, (4)University of Paodva, Italy, (5)Department for Sustainability, ENEA, Italy*

Human activities have substantially impacted marine ecosystems through the introduction of contaminants. Oxygen release from photosynthetic organisms may support marine animals' aerobic performance in challenging conditions, such as ocean warming. However, the role of oxygen in mitigating pollution effects remains poorly understood. This pilot study investigates whether oxygen supersaturation can alleviate the impact of mercury pollution, simulating conditions of high primary productivity. Experiments were conducted on two commercially important species, the sea urchin *Paracentrotus lividus* and the clam Ruditapes philippinarum. Adult specimens were collected from the Venice Lagoon and exposed to a combination of two oxygen saturation levels (90% as the control and 160%, simulating daily supersaturation) and two mercury concentrations (0 and 1 μg/L, as mercury chloride) for seven days. Biomarkers of oxidative stress, immunosurveillance, and mercury bioaccumulation were assessed in both species, while physiological and behavioral traits were analyzed exclusively for *P. lividus*. Results revealed species-specific responses to mercury under hyperoxic conditions. Notably, clams exhibited reduced mercury bioaccumulation under hyperoxic conditions compared to normoxic ones. In sea urchins, higher mercury accumulation was observed in female gonads compared to males, while no significant effects on physiological and behavioral traits were detected. This study forms part of the RETURN Extended Partnership, funded by the European Union s NextGenerationEU initiative (National Recovery and Resilience Plan NRRP, Mission 4, Component 2, Investment 1.3 D.D. 1243 2/8/2022, PE0000005).

2.05.P-We074 Di(2-ethylhexyl) Phthalate Induced Altered Expressions of Genes Involving in Immune Response, Cellular Defense and Apoptosis in the Mud Crab

Ihn-Sil Kwak *and Kiyun Park, Chonnam National University, Republic of Korea*

Di(2-ethylhexyl) phthalate (DEHP), an extensively used plasticizer, mainly serves as an additive to render polyvinyl chloride soft and flexible. It is ubiquitously distributed in the aquatic environment and considered an endocrine disruptor chemical (EDC). In the present study, we investigated the potential effects to DEHP exposure on immune responses (interleukin enhancer-binding factor: ILF), cellular defense (heat shock factor 1: HSF1, heat shock protein 70: HSP70, HSP90, HSP40, HSP83, HSP67B2, HSP60, and HSP21), and apoptotic responses (BAX, p53, Bcl-2) in the mud crab Macrophthalmus japonicus. To do this, we characterized the partial sequences of HSF1 and ILF. Phylogenetic relationships were analyzed in crustacean HSF1 and ILF genes. DEHP exposure induced increase of the HSF1 and ILF gene expressions. In addition, it changed the expression levels of seven HSPs (upregulation of HSP70, HSP40, HSP67B2, HSP83, and HSP90 and downregulation of HSP21 and HSP60) in the gills and hepatopancreas of M. japonicus exposed to DEHP. These expressions of HSPs were conjugated with responses of HSF1 and ILF. Apoptotic signals of BAX, p53, and Bcl-2 were altered in both tissues of M. japonicus at the protein levels by DEHP exposure. These results suggest that long-term exposures to DEHP could trigger the unbalance of immune system and cellular homeostasis, and finally increase of apoptotic cells leading to mortality of the mud crab.

2.05.P-We075 Effects of Neonicotinoids Exposure on the Blue Crab (*Callinectes sapidus*): Bioaccumulation, Neurotoxicity, and Behavioral Implications

Pilar Gomez-Ramirez[1]*, Beatriz Fernandez*[2]*, Francisco Acosta-Cifuentes*[2]*, Tatiana Oporto*[2]*, Ignacio Franco*[2]*, Livia Spadetto*[1]*, Antonio Zamora-Lopez*[3]*, Antonio Andres Herrero-Reyes*[3]*, Pedro Javier Jimenez-Montalban*[1] *and Concepcion Martinez-Gomez*[2]*, (1)Area of Toxicology, Faculty of Veterinary, Campus de Espinardo, University of Murcia, Spain, (2)Oceanographic Centre of Murcia, Instituto Espa ol de Oceanograf a (IEO, CSIC), Spain, (3)Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Spain*

Neonicotinoid insecticides may play an important yet underestimated role as stressors of coastal ecosystems, which may potentially contribute to the decline in marine crustacean populations. Phylogenetically, crabs are more closely related to the insects targeted by neonicotinoids than fish or mollusks. Thus, this study investigates the effects of two widely used agricultural neonicotinoids Acetamiprid and Imidacloprid on the blue crab (*Callinectes sapidus*), an ecologically and economically important estuarine predator, prey, and fishery species.

Microcosm experiments were conducted to assess the link between neonicotinoid exposure and bioaccumulation, and their role to produce neurotoxicity (measured through the acetylcholinesterase - AChE- activity), and behavioural effects (measured through endpoints such as aggressivity reflex, eyestalk responses, righting time, and foraging activity), which may have ecologically relevant implications for predator avoidance and survival. In the experiments, subadults and adult crabs were offered gelatin seafood pellets (approximately 8% of the individual s wet weight) every three days, contaminated either with Acetamiprid (nominal concentration of 3 μg/g wet weight) for 14 days, or and with Imidacloprid (nominal concentration of 1 μg/g wet weight) for 23 days. Each treatment and control group consisted on 12 individuals with a balanced sex ratio (1:1). Preliminary results showed a significant decrease in feeding frequency, along with notable behavioural symptoms such as chelae spasms and sustained spastic leg movements during stationary periods in the Acetamiprid-exposed group. Acetamiprid and Imidacloprid tissue distribution as well as AChE activity levels across various tissues will be presented. The results will be discussed with the aim of highlighting the potential implications for the survival and ecological role of blue crabs in estuarine ecosystems, as well its potential use as target species for pollution assessment in field studies.

Disclaimer/Disclosure: CRABMEDPOL project (PID2022-138720OA-100) is funded by the Spanish Ministry of Science, Innovation and Universities and the Spanish State Research Agency (MICIU/AEI/10.13039/501100011033).

2.05.P-We076 The Amphipod *Marinogammarus marinus* in Ecotoxicological Studies: Evaluating Responses to Environmental Stressors

Ariana Borges Moutinho[1], Hugo R. Monteiro[2], Helena David[3], Sara Novais[2], Marco F. L. Lemos[2], Carlos Barata[4], Ana Amorim[3] and ***Tiago Filipe da Silva Simoes****[2], (1)MARE Marine and Environmental Sciences Centre & ARNET Aquatic Research Network Associate Laboratory, Polytechnic of Leiria & Universidade de Lisboa, Portugal, (2)MARE Marine and Environmental Sciences Centre & ARNET Aquatic Research Network Associate Laboratory, Polytechnic of Leiria, Portugal, (3)MARE Marine and Environmental Sciences Centre & ARNET Aquatic Research Network Associate Laboratory, Faculdade de Ciencias, Universidade de Lisboa, Portugal, (4)Institute of Environmental Assessment and Water Research - Spanish Council for Scientific Research (IDAEA-CSIC), Spain*

Amphipods, a globally distributed order of crustaceans, are predominantly found in aquatic habitats, especially marine environments. They are considered good indicators of environmental health due to their sensitivity to a wide range of pollutants and their ecological importance in the food web. Despite this, few species have been used as test organisms in ecotoxicology, compared to other invertebrates. In this work, responses of the amphipod *Marinogammarus marinus* (Leach, 1816) to various stressors are evaluated and its potential as a model species is considered, as it revealed sensivity to all stressors tested. *M. marinus* is an epibenthic intertidal macroinvertebrate, inhabiting European Atlantic estuaries and coastal areas. As a non-model organism, it has been subject of limited research, although its potential has been suggested. The species is easy to maintain in laboratory, with periodic reproduction and high reproductive rates, and known life cycle. Specimens were field collected in Portugal, and laboratory cultures were established. In this study, *M. marinus* was exposed to metal contamination, toxic microalgae and temperature, with acute toxicity thresholds being determined. Amphipods exposed to cadmium presented, after 96 hours, an Lc50 (half maximal lethal concentration) of 0,725 mg/L (0,466 1,283) for juveniles and 0,871 mg/L (0,442 1,655) for neonates. For copper exposure, no mortality was observed for juveniles (Lc50>128 µg/L), and only limited mortality occurred in neonates after 96 hours. Regarding microalgae, juveniles were exposed to live strains of Ostreopsis. cf. siamensis and Prorocentrum lima, two toxin-producing dinoflagellates. After 48 hours, the amphipod mortality increased with exposure to O. cf. siamensis, comparing with the controls, with an Lc50 of 2143 cells/mL (1833 2500). The effect of P. lima in mortality could not be determined (Lc50>241 800 cells/mL), although there were effects in immobilization, with an Ec50 (effective concentration) of 111 851 cells/mL (80 913 154 291). Increased temperature was tested in juveniles exposed to P. lima for 96 hours. Elevated temperatures (24°C) increased mortality in controls after 72 hours, with the effects of toxic microalgae also intensified at 24ºC. These findings contribute to the knowledge on the sensitivity of *M. marinus* to environmental stressors such as pollution and climate-related changes and highlight the use this species in laboratory ecotoxicological experiments.

Grant awarded by FCT to Ariana Moutinho (2022.12946.BD). Contract granted by FCT to Tiago Simões (https://doi.org/10.54499/2021.02559.CEECIND/CP1671/CT0001).

2.05.P-We077 Effects of Gadolinium Exposure at Environmentally Relevant Levels in two Freshwater Invasive Species

Alessandra Maganza*[1], Camilla Mossotto[1], Alice Gabetti[2], Francesca Provenza[3], Serena Anselmi[3], Tecla Bentivoglio[3], Giuseppe Esposito[2], Antonia Concetta Elia[4], Monia Renzi[5], Marino Prearo[2] and Paolo Pastorino[2], (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua); Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (2)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy, (3)Bioscience Research Center srl, Italy, (4)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (5)Department of Life Sciences, University of Trieste, Italy*

Freshwater ecosystems are vital for biodiversity and human well-being, but they are threatened by pollution, overexploitation, habitat degradation and invasive species. In particular, human activities are closely linked to water pollution, with pollutants from agriculture and urban waste entering these ecosystems. Among emerging contaminants, gadolinium (Gd), used as a contrast agent in magnetic resonance imaging (MRI), has been of concern since the 1990s. After excretion, Gd passes through

wastewater treatment and enters aquatic systems, and its presence has been documented worldwide, particularly in densely populated urban areas of countries with advanced healthcare systems.
This study investigated the effects of Gd on two invasive freshwater species in Italy: the Louisiana red crayfish (*Procambarus clarkii*) and the zebra mussel (*Dreissena polymorpha*), both effective indicators of pollution. A total of 45 adult of *P. clarkii* and 450 of *D. polymorpha* specimens were exposed to four environmentally relevant concentrations of commercially sourced Gd (Gd_2O_3 - Inorganic Ventures, Christiansburg, VA, USA): 0 µg/L, 0.1 µg/L, 1 µg/L, 10 µg/L and 100 µg/L for 14 days.
After exposure, target organs were collected for oxidative stress analysis using biomarkers such as superoxide dismutase (SOD), glutathione peroxidase (GPx), glutathione S-transferase (GST), lipid peroxidation (LPO) and protein levels. For *P. clarkii*, oxidative stress was evaluated in three tissues: muscle, hepatopancreas, and gills. For *D. polymorpha*, three different tissues were analyzed to assess oxidative stress responses: foot and mantle, digestive gland, and gills.
The analyses revealed distinct oxidative stress responses in *P. clarkii* and *D. polymorpha*, with enzymatic defense activation dependent on Gd concentration. These findings are important for understanding how aquatic species respond to environmental stressors and for assessing ecotoxicological risks associated with Gd. Moreover, the use of invasive species in research could also support strategies aimed at containing these organisms, thereby contributing to biodiversity conservation initiatives.

2.05.P-We079 Dynamics of Zooplankton Biodiversity and Abundance in the Freshwater Lentic Mesocom System Located in Southern Poland
***Zuzanna Kacperek-Karetta**, Anna Maria Arendarczyk, Agnieszka Zmijowska, Katarzyna Gruszka, Malgorzata Czarnecka and Malgorzata Gorska, lukasiewicz-IPO Branch Pszczyna, Poland*
Outdoor mesocosm systems are used in risk assessment posed by introduction of plant protection products, wastewater and other chemicals into water and soil. Mesocosm studies are performed under field conditions and mimics ecosystems in natural environment. Therefore, it allows to predict, understand and confirm the effects of a chemical on selected, closely related aquatic ecosystem parameters. The analysis of zooplankton populations in mescosm studies could be crucial when assessing the effects of insecticides. Due to the field nature of the study, the aim of the presented project was to analyse the seasonal variability of selected species and genera of zooplankton during one summer season as well as selected groups of zooplankton in relation to selected parameters. The test was performed in stainless steel tanks, settled in the ground (about 2400 L each tank), situated in Southern Poland. The tanks were supplied with an appropriate amount of sediment and water and inoculated by adding sediment and water from natural reservoirs. Sampling was carried out from May 2024 to August 2024. Project included qualitative and quantitative zooplankton analysis, physico chemical analysis of water, e.g., temperature, pH, nitrites, nitrates, phosphate, ammonium, chlorophyll-a in water and Total Organic Carbon. During observations, the number of taxa verified to at least genus level ranged from 34 to 48 depending on the tank. The total abundance of taxa indicated changes in the number of individuals from subdivision Copepoda, superordo Cladocera and phylum Rotifera. Copepoda were represented throughout entire studied period mainly by Mesocyclops leuckarti while Cladocera were mainly presented by Daphnia longispina and Chydorus sphaericus. In phylum Rotifera the most abundant taxa were represented by genus Polyarthra sp., species Anuraeopsis fissa and Keratella quadrata, while Euchlanis dilatata and Hexarthra mira appeared only in July and August.
Shifted levels of Copepoda individuals numbers where observed during chlorophyll-a increases, which were recorded from the middle of July and emerged in relation to the phytoplankton blooming by e.g., Dolichospermum sp., Microcystis sp., Trachelomonas sp. or Ceratium hirundinella. The increase in chlorophyll-a level was associated also with a decrease in turbidity.
The obtained data may constitute a database for interpreting the risk experiments results, and may also implicate the processes of designing mesocosm field studies.

2.05.P-We080 Do Mesocosm Studies Still have a Future as Higher Tier Risk Assessment Tool?
*Seamus Taylor[1], Eric Bruns[2], Klaus Peter Ebke[3], Daniel Bruce Pickford[4], Tido Strauss[5], Nadine S Taylor[6] and **Udo Hommen**[7], (1)Adama, United Kingdom, (2)Bayer AG, Germany, (3)Mesocosm GmbH, Germany, (4)Syngenta,United Kingdom, (5)gaiac Reseach Institute, Germany, (6)CEA, United Kingdom, (7)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*
Mesocosm studies are recognised in the EU as the reference tier in aquatic risk assessments of plant protection products (PPPS) for algae, macrophytes and invertebrates. They have been used for over 30 years to analyse the effects of PPPs on aquatic populations and communities. However, the aquatic guidance document is now more than 10 years old, with the last multi-stakeholder workshop on the use of mesocosm studies (CLASSIC) held 25 years ago. Several critical issues have been raised in recent years, both from an industry and regulatory perspective. These include theacceptability and criteria for ecological

recovery, worst-case nature of tested exposure scenarios versus predicted exposure profiles, representativeness of lentic systems for stream communities, approaches to conducting studies focusing on macrophytes and/or phytoplankton, details on statistical methods, e.g.. the use of MDDs, and finally, the use of results from multiple mesocosm studies within a risk assessment. The aim of this poster is to outline the critical issues and to stimulate interest among tripartite stakeholders in setting up a SETAC working group and/or organising a SETAC workshop to prepare contributions as input for consideration in the future refinement of the aquatic guidance document.

2.05.P-We081 Maximising Species Abundance Counts in Mesocosm: What Traps Work Best?

Zoe Leanne Parker-Crosse[1]*, Nadine S. Taylor*[2]*, Marie Brown*[1]*, Ellie Welch*[1]*, Scarlett Sturt*[1]*, Katie Smith*[1] *and Cameron Swain*[1]*, (1)Cambridge Environmental Assessments, United Kingdom, (2)Cambridge Environmental Assessments, Boxworth, United Kingdom*

Aquatic, freshwater, mesocosms are designed to represent edge of field water bodies, creating a habitat that will support communities of aquatic macrophytes, algae, zooplankton and macroinvertebrates in a contained system. Macroinvertebrates and emergent insects play an ecologically important role in the ecosystem by performing essential biological and ecological functions and are often considered key sensitive taxa in higher tier studies. However, generating reliable data and endpoints for these groups can be difficult as they are naturally found in low and variable abundances.

Macroinvertebrates and emergent insects are diverse assemblages of organisms, existing all parts of the water column, in and on the sediment, and emerging from the surface of the water during adult stages. How to target collecting these organisms is, therefore, highly dependent on their life stage and the time of year. Macroinvertebrates also require safe places to shelter to avoid predation and thrive until reproduction or emergence. The ability to deploy multiple traps within a mesocosm study targeted to specific environmental niches, makes these test systems ideal for investigating the effects of stressors on this group of organisms. Whilst it may not be feasible to assess the abundance of these mesocosms as a whole, and there are limitations regarding the sample processing time and size, type and number per mesocosm, the use of specific traps allows the collection of these organisms in a targeted and efficient approach designed to maximise abundance counts. The decision of trap design and selection to achieve the best endpoints should give consideration to multiple influences, including the stressor being investigated (e.g., the GAP for a PPP), the species, and the most sensitive life stages, as well as seasonal influences during the in-life phase of the study.

The aim of this poster is to share our expertise on the selection, design and deployment of macroinvertebrate and emergent insect traps in mesocosm studies, to achieve robust and reliable endpoints. We hope that by sharing our considerations for trap selection and endpoint evaluation we open discussions on the representativity of mesocosm studies for these taxa, and help to optimise the experimental design of future mesocosm studies focussed on macroinvertebrate and emergent insects.

2.05.P-We082 Mesocosms Offer a Robust Higher Tier Test System with High Repeatability Despite Biological Variability: A Case Study With Diflufenican

Eric Bruns[1]*, Jutta Hager*[1]*, Udo Hommen*[2]*, Ivo Roessink*[3]*, Alan Samel*[4] *and Amanda Sharples*[5]*, (1)Bayer AG, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Wageningen Environmental Research, Netherlands, (4)Stone Environmental, United States, (5)FMC Corporation, United States*

Using the example of the herbicide diflufenican we would like to demonstrate the robustness of mesocosm studies despite their known higher biological variability compared to standardized single species tests. For diflufenican three different mesocosms exist. Based on lower tier studies, algae were the most sensitive group and thus the studies focused on direct effects on phytoplankton, periphyton and indirect effects on zooplankton and grazers. They were performed in the years 2007, 2010 and 2021 at three different test sites in Germany and the Netherlands. The test design of the three studies differs as well as the test periods and by this the weather conditions under which the three studies have been performed. Exemplarily, water temperatures differed between the first study (March - June 2007) with temperatures between 5 and 20°C and the latest study (June - August 2019) with water temperatures between 15.4 and 25.5°C.

The fact that three mesocosm studies exist for one single test item allows the evaluation of this study type with respect to the consistency and robustness of results. Similar effect thresholds (NOECs) were observed in the three mesocosm studies varying by a factor of about 3. The difference observed is within the factor chosen between two test concentrations used in these studies. Two of the three studies were performed before the AGD (EFSA, 2013) was published and did not fulfill the new requirement of a minimum of 8 potentially sensitive species with acceptable MDD values. Nevertheless, these two studies resulted in effect thresholds fully in line with the latest study (2021) which fulfilled the requirements of the AGD and resulted in an effect threshold between the ones of the two older studies. The example of these three studies investigating diflufenican demonstrates that mesocosms are a robust and suitable tool to be used in the environmental risk assessment. The comparison of the three studies demonstrates as well, that even older studies not completely fulfilling the current requirements have a scientific value and should be considered in a weight of evidence approach within the aquatic risk assessment for pesticides. In cases where more than one mesocosm exists it should be evaluated whether a combined evaluation is possible to fulfill the requirements of the AGD on 8 potentially sensitive species.

2.05.P-We083 Using Multiple Exposure Techniques to Identify the Sub-lethal Effects of Recycled Water Exposure on Shrimp

Gina Maxine Mondschein[1]*, Vincent J. Pettigrove*[2] *and Kathryn Hassell*[1]*, (1)RMIT University, Australia, (2)Aquest Research Group, RMIT University, Australia*

Globally, sewage wastewater is treated and repurposed for human consumption, agriculture, irrigation and the environment. Recycled water released into aquatic ecosystems still contains pollutants including pharmaceuticals, pesticides and metals. Laboratory studies have demonstrated that elevated concentrations of individual pollutants can be lethal to aquatic macroinvertebrates. In waterways, these organisms are exposed to lower concentrations of multiple pollutants over extended periods. Understanding how recycled water impacts aquatic ecosystems is crucial for preserving biodiversity and ecosystem health, yet it presents several challenges. Firstly, pollutants exhibit complex interactive and cumulative effects. Secondly, the composition and concentration of pollutants in waterways are highly dynamic. Finally, sensitivity to pollution varies significantly between taxonomically similar animals and may vary under different exposure conditions. My research will use field-collected water containing environmentally relevant concentrations of pollutants. Exposures will be sublethal to identify any stress response in shrimp. Experiments will be repeated with different species and populations of shrimp to test for family-level variation in sensitivity to aquatic pollution. Shrimp have been selected due to their ecological significance in aquatic ecosystems globally. A series of long-term exposures will be conducted under laboratory conditions and replicated in situ at a wastewater treatment facility. This will facilitate a comparison between stable laboratory conditions and variable field environments. Biomarkers and growth endpoints will be used to quantify the sublethal effects of pollution exposure. This study aims to bridge the gap between controlled laboratory and dynamic field conditions. By examining the sub-lethal responses to chronic exposure, we will gain a more nuanced understanding of how pollution affects aquatic ecosystems. Exposing an ecologically important species with a broad habitat range and global distribution ensures that the findings are widely applicable. Ultimately, we hope this research will have application in aquatic biomonitoring programs worldwide.

2.05.P-We085 Analysis of Phospholipids Modulation by Perfluorononanoic Acid on the Freshwater Gastropod *Physella acuta*

Ignacio Lopez-Alonso*, Jose-Luis Martinez-Guitarte and Maria-Angeles Garcia-Fernandez, Universidad Nacional de Educacion a Distancia, Spain*

Perfluoroalkyl substances (PFAS) emerge as persistent pollutants in different ecosystems, showing various effects. Freshwater ecosystems act as sinks for PFAS, affecting the flora and the fauna. There is a lack of data about these compounds' effects on living organisms, especially invertebrates. *Physella acuta* is a freshwater gastropod at the base of the food web. To explore PFAS's effects on this snail, perfluorononanoic acid (PFNA) was selected and used to expose the animals for one week. The results of the phospholipid profile analysis by nuclear magnetic resonance (NMR) are presented here. Phospholipids were extracted with a 2:1 water: chloroform mixture (v/v) followed by a second round with Folch methods. The phospholipid profile was analyzed by 1D 31Phosphorus NMR. The results showed a change in the profile depending on the PFNA concentration, with new signals indicating a change in the proportion of different phospholipids. Additional research is needed to elucidate the mechanisms involved in the alteration produced by PFNA, but combining 1D 31Phosphorus NMR with gene expression will help to understand the molecular pathways affected. Finally, 1D 31Phosphorus NMR offers a simple method to analyze the changes in phospholipid profile by toxicants on invertebrates, opening new possibilities for elucidating the mechanisms involved in the toxicity of PFAS.

2.05.P-We086 Acute Oral Exposure of the Non-target Foliar-dwelling Arthropod *Chrysoperla carnea* (Stephens) Using Artificial Diets

Sergio Lopez[1] *and Eugenia Soler Salcedo*[2]*, (1)Spain, (2)Eurofins, Spain*
Currently there are different test protocols to assess the risk of a plant protection product on non-target foliar-dwelling arthropods. However, these protocols usually propose residual exposure methods to test substances that may be ineffective for assessing the risk for microbiological products acting by ingestion. This work aims to propose new testing methodologies for microbiological substances, based on an oral exposure mode, which allow an accurate risk assessment on the aphidophagous predator, *Chrysoperla carnea* (Stephens), and are feasible for laboratories. For this purpose, several chemicals, with known effects by ingestion, were evaluated in order to validate the methodology.
Two to three day old larvae were acutely exposed during the first 48 hours to the test substance incorporated into an artificial diet. Different concentrations were tested to evaluate the pre-imaginal mortality and calculate the LC50 value. Our work provides an adequate acute oral exposition methodology as a first step for the development of future risk assessment trials for microbiological plant protection products with an ingestion mode of action on *C. carnea*.

2.06 Impact of Airborne Pollutants on Environmental Health and Biodiversity

2.06.T-01 Silent Threat: The Impact of Airborne Pesticides on Biodiversity
Saeed Albaseer[1]*, Luisa Orsini*[2]*, Veerle L. B. Jaspers*[3]*, Penny Vlahos*[4]*, Hussein Al-hazmi*[5] *and Henner Hollert*[1]*, (1)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)Environmental Genomics Group, School of Biosciences, University of Birmingham, United Kingdom, (3)Department of Biology, Norwegian University of Science and Technology (NTNU), Norway, (4)Department of Marine Sciences, University of Connecticut, United States, (5)Faculty of Civil and Environmental Engineering, Gdansk University of Technology, Poland*
Agricultural pesticide drift is a hidden threat, wherein the pesticides take to the air, extending well beyond the target application site and contaminating surrounding environments. While direct exposure to pesticides has been a common and well-informed subject of research, fallout from pesticide drift is not as well understood but nonetheless causes alarm. Recent studies have revealed an unsettling trend where, over time, populations of different species are clearly in decline due not in a small part to airborne pesticides. These chemicals act to promote the decline in biodiversity by their effects imposed on non-target organisms such as plants, insects, fungi, and many other forms of organisms living near habitats or even in ecosystems quite far away from where this might be used. Still, the full scale of their influence has not yet been determined. In the current study, the authors reviewed the most recent knowledge about the possible contribution of air-borne pesticides to the decline in biodiversity and discussed mitigation methods. The results indicated critical knowledge gaps and, therefore, a need for urgent measures to protect environmental health. Further studies should realistically be field-oriented, investigating multiple applications of pesticides and their interactive effects with flora and fauna in space and time.

2.06.T-02 Multiphase Transformation of Nitrogen Containing Organic Compounds in the Indoor Environment
Chen Wang*, Southern University of Science and Technology, China (Mainland)*
A wide variety of nitrogen containing organic compounds are present in indoor environments from the use of chemical products and emissions from occupant activities, including cooking, smoking, burning, etc. For example, organic amines including aromatic secondary amines and their derivatives, and azo dyes were detected in various dust substrates indoors. Most of these organic compounds are semivolatile, which can be easily sorbed to indoor surfaces such as glass, clothes, and furniture with the settlement of particles and gases indoors. In the indoor environment, there are many reactive oxidants, including ozone (O3), nitrous acid (HONO), and during cleaning, reactive chlorine species (hypochlorous acid - HOCl, chloramines - NHCl2, NH2Cl, chlorine gas - Cl2, etc.). Exposure of the surface sorbed organic compounds to these oxidants can lead to degradation of the organic contaminants and formation of potentially harmful transformation products both in air and on surfaces. In this talk, case studies involving multiphase transforamtion of nitrogen containing organic compounds in the indoor environment and its impact on indoor surface and air composition will be discussed. We identified the specific molecular identity of the products based on high-resolution mass spectrometry analysis. We confirmed that nitrosamines and other transformation products of organic amines are produced through heterogeneous reactions on surfaces in a real indoor environment. Transformation of organic compounds upon exposure to ozone and reactive chlorine species will also be presented.

2.06.T-03 Toxicity Assessment of Airborne Ultrafine Particles: Role of Transport Emissions
Benjamin Pina*, IDAEA-CSIC, Spain*

Airborne quasi-ultrafine particle samples were collected from different outdoor sites in Barcelona (NE Spain, 35 samples) and the Valencia subway (about 400 km south of Barcelona, 3 samples). Locations and schedules were designed to cover cold and warm seasons and to represent the impact of different types of transport (cars, trains, ships, and planes). PTFE filters were extracted with a mild organic solution (methanol:dichloromethane 1:2) and the extracts were used to test toxic effects in human cell lines (Induction of reactive oxygen species, inflammatory response) and in zebrafish embryos (expression of xenobiotic response-related genes, cyp1a1, gsa1 and hao1). The highest toxicity values were detected in sites receiving car and/or ship emissions, with maximums during the cold season. Chemical analyses followed by correlation and source apportionment analyses identified PAHs, combustion engines, and biomass burning emissions as the main drivers of the observed toxic effects. Although traffic restrictions and car emission limits significantly reduce organic pollutants in urban air, a potential ban on all combustion processes will be the only effective way to eliminate airborne toxicity in our cities.

2.06.T-04 Considerations for Using Moss as a Biomonitor for Airborne Microplastics
***Richard Cross**[1], Sarah Roberts[2] and Felicity Hayes[2], (1)CEH, United Kingdom, (2)UKCEH, United Kingdom*
Mosses have been proposed as a passive bio-monitor for the deposition of airborne microplastics. European moss surveys have long been reported on by the Working Group on Effects (WGE) of the Convention on Long-range Transboundary Air Pollution (LRTAP). The first moss survey at the European scale was conducted in 1990, with subsequent surveys at 5-year intervals. As part of the 2020 survey, a new sampling and analysis protocol was established to include an assessment of microplastics in the UK. To establish whether moss may be used as an effective bio-monitor for MPs, it is essential to consider the resolution and power achievable in the data, any confounding influences in monitoring design and the reproducibility of a suitable quantification method. Applying these criteria to the 2020 ICP Vegetation moss survey of 52 sites across the United Kingdom, a novel method using turbulent flow displacement to extract microplastics from large moss samples (~10 g material) was optimised. This balanced achieving low background contamination whilst also ensuring high recovery of microplastics from the moss superstructure. Extracted samples were analysed using micro-Fourier Transform Infra-Red spectroscopy (μ-FTIR).
Almost all moss samples were found to contain microplastics >25 μm in size, above limits of detection. Maximal differences between sites on a particle number per gram moss was ~35-fold. Six major genus of moss common to the United Kingdom were collected, representing a variety of mat and cushion phenotypes. Both moss characteristics but also variables associated with land use and geographies were used to explore possible influences over differences in polymer composition and abundance across the UK. Practical recommendations around sampling design for the use of moss as a biomonitor of microplastics will be critically discussed and recommendations made for future sampling design.

Disclaimer/Disclosure: ICP Vegetation (Work Package 7) - AQ0846.

2.06.T-05 Health Quality of Urban Particles According to their Load in Endocrine-Disrupting Compounds and Associated Toxic Potential
***Lucie Oziol**[1], Maya Bimbot[2], Diane Le Bayon[3], Fabrice Alliot[3] and Elodie Guigon[4], (1)Universite Paris Saclay, France, (2)Universite Paris Sacaly, France, (3)EPHE, France, (4)EPhe, France*
The harmful effects of air pollution are partly linked to atmospheric particles (PM), due to their size, but their composition can also play a role. Indeed, they can adsorb semi-volatile organic compounds (SVOCs) with suspected or proven endocrine-disrupting (ED) properties. In order to better understand the link between contamination of PM in ED compounds and associated biological effects, 3 urban sites were selected in Paris region (France). On each site, 3 classes of PM were collected (PM2.5, PM10 and TSP), at 2 contrasting seasons and 62 SVOCs were investigated in the PM extracts. The estrogenic and dioxin-like potential were analysed by in vitro bioassays. The results of this work highlighted the highest contamination of PM2.5 in accordance with the toxic potential of their bounded-organic contamination. A non-monotonic dose-response effect was observed for estrogenicity of some PM organic extracts. These data allowed us to understand the complexity of the characterization of the health hazard linked to PM according to their size, their origin and in relation to the molecules they adsorb.

2.06.P Impact of Airborne Pollutants on Environmental Health and Biodiversity

2.06.P-Th035 Analytical and Toxicological Evaluation of Residential Closed Combustion Waste Burning

Balazs Kakasi[1]*, Flora Judit Varga*[2]*, Adam Toth*[2]*, Beatrix Jancsek-Turoczi*[1]*, Andras Hoffer*[1]*, Szabolcs Tamas Nagy*[3]*, Nora Kovats*[4]*, Katalin Hubai*[4] *and Andras Gelencser*[1]*, (1)University of Pannonia, Research Institute of Biomolecular and Chemical Engineering, Air Chemistry Research Group; HUN-REN-PE Air Chemistry Research Group, Hungary, (2)University of Pannonia, Research Institute of Biomolecular and Chemical Engineering, Air Chemistry Research Group, Hungary, (3)Hungarian University of Agriculture and Life Sciences, Georgikon Campus, Institute of Animal Sciences, Hungary, (4)University of Pannonia, Centre for Natural Sciences, Ecotoxicology Research Group, Hungary*
In this work, we carried out controlled combustion experiments in a residential iron test stove, where specific types of household plastic waste were co-fired along with conventional solid fuels in order to mimic residential waste burning and to analyze the analytical and toxicological characteristics of the emissions. The eco-, cyto- and genotoxic effects of emission samples from closed combustion of legal solid fuels (black locust, oak, black coal, brown coal, briquettes) and various household plastic waste types (polyethylene terephthalate (PET), polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyurethane (PU)) were investigated. The flue gas emissions were collected in MilliQ water filled impingers and the samples underwent subsequent chemical and toxicological examination.
The total carbon (TC) content was determined, and PAH analysis was carried out by GC-MS. Ecotoxicity of the undiluted samples were measured by *Vibrio fischeri* bioluminescence inhibition assay and the boar sperm motility inhibition test were used for quick screening of toxic effects. Flow cytometric live/dead ratio and genotoxicity with alkaline comet assay were tested on A549 lung epithelial cells using 50, 25 and 5 mg Cdm-3 dilutions.
The findings of the ecotoxicity and boar sperm inhibition tests were categorized as toxic to highly toxic in every sample and showed a strong correlation with the total carbon concentration and PAH content. Cytotoxicity experiments show that emissions from co-incinerating garbage have more harmful impacts than emissions from burning just approved solid fuels. Following a 24-hour exposure period, samples from PP, PE, PET and PS incineration diluted to 50 mg Cdm-3 showed a considerably higher proportion of dead cells than the control. PP, PE, and PET samples showed significant levels of DNA fragmentation, but PS, black-, and brown carbon samples also showed minor genotoxic effects. The toxicity results were well correlated with the PAH content of the samples.

2.06.P-Th036 Prolonged Exposure of Emerging Contaminant-Phthalate Ester on Human Lung Cells: Cell Respiration Inhibition and Joint Toxicity Prediction
Cristian Ryan Arbolado Argamino[1]*, Dimple Pathania*[2]*, Ivan Kourtchev*[1]*, Anna Bogush*[1]*, Svetlana Stevanovic*[3]*, Matthew McKenzie*[4] *and Aaron Schultz*[4]*, (1)Centre for Agroecology, Water and Resilience, Coventry University, United Kingdom, (2)School of Engineering, Deakin University; Centre for Agroecology, Water and Resilience, Coventry University, Australia, (3)School of Engineering, Deakin University, Australia, (4)School of Life and Environmental Sciences, Deakin University, Australia*
Phthalate esters (PAEs) such as dimethyl phthalate (DMP), diethyl phthalate (DEP), and di-n-octyl phthalate (DOP) are synthetic chemicals used as solvent stabilisers, and plasticisers in commercial and industrial products, and are classified as priority contaminants of emerging concern (CECs) or new and emerging pollutants (NEPs). Humans are at constant risk of exposure to these toxic PAEs, but their regulations in the air remain limited. PAEs have been detected in inhalable particles such as PM2.5; however, their individual and combined effects on human lung cells beyond 48 h exposure remain unclear. This work evaluated the individual and combined toxicity of prolonged exposure (up to 168 h) to environmentally relevant concentrations of DMP, DEP, and DOP (i.e., 10 ?M - 1000 ?M) and the persistent organic polllutant (POP) bis-2(ethyhexyl) phthalate on Calu-3 human sub-bronchial gland cells. Individual exposure to the tested PAEs yielded the following maximal inhibitory concentration (IC50) at 24 h (4462 ?M DMP, 2049 ?M DEP), 72 h (3068 ?M DMP, 927 ?M DEP), and 168 h (418 ?M DMP, 106 ?M DEP, 343 ?M DEHP, 400 ?M DOP). The experimental results were predicted by the concentration addition (10 ?M - 1000 ?M) and independent action (100 ?M - 1000 ?M) joint toxicity models after 72 h exposure to the DMP-DEP mixture. Toxicity unit calculations predicted a difference in mixture interactions (e.g., synergistic and antagonistic) at different exposure time points for the DMP-DEP mixture. Exposure of live cells to individual or binary mixtures of PAEs showed that cellular oxygen consumption decreased as concentrations increased, indicating toxicity and inhibition of mitochondrial respiratory flux. Results of this work suggest that the currently set workplace air limit of 5 mg/m3 for DMP, DEP, and DEHP (24 h average) by UK regulations could be toxic to human lung cells and may need to be reviewed and updated. More work is needed to understand the toxicity mechanisms of PAEs on

human lungs to facilitate more accurate risk assessments and to set regulations on their atmospheric and workplace air concentrations.

2.06.P-Th037 Investigating the Allergenic Potential of Different Pollen Species in Terms of Their Cell Viability, ROS Measurement and Chemical Modifications on Exposure to Air Pollutants

Dimple Pathania[1]*, Ivan Kourtchev*[2]*, Svetlana Stevanovic*[3]*, Matthew McKenzie*[4] *and Anna Bogush*[2]*, (1)School of Engineering, Deakin University, Australia, & Centre for Agroecology, Water and Resilience (CAWR), Australia, (2)Centre for Agroecology, Water and Resilience (CAWR), Coventry University, United Kingdom, (3)School of Engineering, Deakin University, Australia, (4)School of Life and Environmental Sciences, Deakin University, Australia*

Airborne pollen may lead to severe allergies such as asthma, pollinosis, rhinitis, and lung inflammation. Australia and the UK have one of the highest prevalence of registered allergic disorders (Idrose et al. 2020). Climate change induced extreme weather occurrences, fluctuations in temperature and relative humidity, can influence the transport, dispersion and interaction of pollen allergens and air pollutants (Tran et al. 2023). In an urban setting, presence of pollutants can influence the allergenic potential of pollens via chemical modifications of allergenic proteins and thereby altering their immune response. The cellular mechanisms involved in physical barrier disruption and the influencing protein modifications underlying respiratory exacerbations are not fully understood (Bradbury et al. 2022). Hence, in current research, cellular response of Calu-3 lung epithelial cells has been assessed. The overall aims of this work are to (1) to assess the allergenic potential of different pollen species by assessing their cell viability and oxidative stress (2) to investigate the protein modifications in different pollen species upon exposure to air pollutants.

In this work, Grass, Pine, She Oak and Acacia were evaluated. Cell viability was determined by MTT assay Reactive oxygen species (ROS) measurements were conducted using 2',7'-dichlorodihydrofluorescein diacetate (H2DCFDA) probe. Cells were treated with pollen protein extracts for 24 h for cell viability assay. For the protein modifications, study will be conducted using Liquid chromatography mass spectrometry (LCMS) and to assess structural changes before and after the exposure to pollutants.

Cell viability results for Calu-3 cells showed a varied concentration dependent response among all species with lowest viability for pine pollen followed by grass pollen. Rate of ROS production was highest for grass pollen. The increase in rate of ROS generation was in concentration dependant manner. ELISA analysis of Ph1 p 5 allergen concentration in grass pollen suggested increase in concentration with increasing extract concentration. Additionally, the impact of anthropogenic pollutants on the protein modifications will be discussed. It is hypothesised that with rising levels of atmospheric oxidants, pollen proteins can undergo modifications (oxidation, nitration, cross linking,) and the formation of resulting complex could be the biomarker for oxidative stress in the lung cells.

2.06.P-Th038 Investigating Airborne Pesticide Deposition Using Trace Analysis in Precipitation, Soil, and Agricultural Plants

Benedikt Ringbeck[1]*, Bernd Gockener*[2]*, Katja Hombrecher*[3]*, Roland Kubiak*[4] *and Anna Peters*[5]*, (1)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)North Rhine-Westphalia Office of Nature, Environment and Consumer Protection (LANUV), Essen, Germany, Germany, (4)Scientific consultant/independent researcher, Germany, (5)Federal Office of Consumer Protection and Food Safety (BVL), Germany*

Airborne pesticide transport and deposition, e.g., from agricultural applications, is an underinvestigated source of environmental contamination with potential ecotoxicological relevance for off-target organisms. Furthermore, this leads to pesticide transport from conventional to organic farming, resulting in increasing concerns over pesticide exposure by consumers.

Therefore, the German Federal Office of Consumer Protection and Food Safety (BVL) funded a study to investigate the airborne deposition of relevant pesticides or pesticide metabolites on plants and soil, as well as in rain precipitation, with the aim of comparing the amounts of these substances deposited in the respective compartments. This study is intended to solve possible practical problems for a planned nationwide monitoring of airborne pesticide transport in Germany.

The study was performed on a field belonging to LANUV NRW in Essen, Germany. The experimental setup consisted of a bulk collector to capture rainfall. For the soil, a test soil was used that had no intentional pesticide use during the last 5 years. A soil layer was filled into plastic boxes, divided by a

fleece to collect percolation water. In other plastic boxes of the same surface area, each five pre-grown kale plants were planted. The test was set up over a 28 days long exposure period from June to July 2024 to capture airborne deposited pesticides on soil and kale as well as in rainfall precipitation.
This study further included method development, validation and trace analysis of ten pesticides/metabolites in water, soil and kale samples. The target analytes were selected based on findings in a pre-study in water samples from bulk collectors or based on typical application during the time of study performance. Analyses were performed by U(H)PLC-MS/MS including isotope-dilution analysis with limits of quantification in the low ng/L and ng/kg range, respectively.
The analytical results from the three compartments water (bulk collector), soil (including percolation water) and kale were related to their collection surface, resulting in ng/m² deposition values. This comparison allows to find the most suitable collector for airborne pesticide deposition that can be used in future monitoring studies. Furthermore, the results shed light on the extent of pesticide deposition onto non-target areas during the main application time of PPPs in early summer in Germany.

2.06.P-Th039 Development of Evaluation Methods and Monitoring Data Analysis for External Pollutant Ingress into Vehicles During Driving
***Ho-Hyeong Yang*[1]*, Bo-Gyeong Lim*[1]*, Yoon-Kyung Gwak*[1]*, Sun-Min An*[1]*, In-Ji Park*[2]*, Cha-Ryung Kim*[2]*, Hyun-Woo Lee*[2] *and Ho-Hyun Kim*[3]*, (1)Research Institute for Living and Industrial Environment in Seokyeong University, Republic of Korea, (2)Korea Automobile Testing & Research Institute, Republic of Korea, (3)Department of Nano-chemical, Biological and Environmental Engineering, Seokyeong University, Republic of Korea*
Globally, people spend about 5% of their day inside vehicles. Despite this relatively short duration, exposure to pollutants in vehicles can constitute a significant portion of daily exposure due to the high concentrations of surrounding pollutants.
The UN WP.29 is actively developing technologies to harmonize VIAQ (Vehicle Indoor Air Quality) evaluation methodologies. While guidelines exist for evaluating emissions from vehicle interior materials, no international standard addresses the inflow of outdoor pollutants into vehicles. This study aims to draft and refine a VIAQ evaluation method through real-road tests.
Pollutants entering vehicles during driving include atmospheric pollutants, exhaust emissions, and non-exhaust traffic-related emissions. Based on a review of regulations and research, PM2.5, PN, NO, and NO2 were selected as target pollutants. Given that indoor air quality is influenced by outdoor air levels, pollutants were measured simultaneously inside and outside vehicles using two identical devices equipped with isokinetic sampling probes and pumps to ensure reliability.
Real-road driving tests required developing route selection methods, including urban driving followed by highway driving, with each segment spanning at least 16 km. HVAC modes, another influencing factor, were classified as recirculation mode (RC), outdoor air intake mode (OA), and automatic mode (Auto).
The average indoor concentrations of PM2.5 and NO2 were lowest in RC mode and highest in OA mode, while NO concentrations were lowest in RC mode and highest in Auto mode. Cleaning efficiency was highest in RC mode for all pollutants, followed by Auto and OA modes.
Analyzing pollutant concentration data alongside external factors revealed significant correlations between indoor pollutant levels and factors such as season, outdoor concentrations, and HVAC conditions, with weaker correlations observed for powertrain types.
This study has limitations, including its focus on weekday daytime hours, which excluded rush hour conditions, and the omission of driver habits or experimental personnel effects in the analysis. Further studies with diverse regions and larger datasets are necessary to reduce biases and generalize findings. Despite these limitations, this research identified external air quality and other influencing factors affecting vehicle indoor air quality during driving, providing foundational data for developing VIAQ evaluation methodologies.

Disclaimer/Disclosure: This work is supported by the Korea Agency for Infrastructure Technology Advance-ment(KAIA) grant funded by the Ministry of Land, Infrastructure and Transport (Project No. RS-2023-00243220).

2.06.P-Th040 Multiple Biomarkers Assessment in the Gill and Blood of Nile Tilapia Induced by Settleable Atmospheric Particulate Matter from Metallurgical Industries
***Marisa Narciso Fernandes*[1]*, Iara Souza*[1]*, Fabricio Souza*[1]*, Mariana Morozesk*[1]*, Priscila Siqueira*[1]*, Magdalena Monferran*[2] *and Daniel Wunderlin*[3]*, (1)Federal University of São Carlos (UFSCar), Brazil, (2)National Uiversity of Cordoba, Argentina, (3)National University of Cordoba, Argentina*
Settleable atmospheric particulate matter (SPM) released by the metallurgical industries consisted of carbon and a mixture of metals that in contact with aquatic environment disaggregated in metal/metalloids

and metallic nanoparticles. They may be absorbed by fish affecting homeostasis. Nile tilapia, Oreochromis niloticus were exposed to 0, 10, 100 and 1000 µg SPM L-1, for 96 h and the bioaccumulation of metal/metalloids and metallic nanoparticles in the gills were evaluated using inductively coupled plasma mass spectrometer (ICP-MS) and transmission electron microscopy and energy-dispersive spectroscopy (EDS). Blood variables, genotoxicity and plasma ions were analyzed in blood; the enzymes related to ion transport and enzymes and molecules from antioxidant defense system and oxidative stress as well as histopathological alterations in gills were evaluated. Metal/metalloids bioaccumulated in the gills of at different concentrations being Fe>Zn> Sr>Al at highest concentrations. Nanoparticles containing Fe, Cr, Al, Cr and Si were identified in gill and blood cells. The activity of Na+/K+-ATPase, H+-ATPase were unchanged and carbonic anhydrase decreased after exposure to 1000 µg SPM L-1. Plasma Na+ and K+ were unchanged but Cl- content decreased after exposure to 1000 µg SPM L-1. The biotransformation enzyme of phase II, and the antioxidant enzyme catalase increased in the gills of fish exposed to 100 µg SPM L-1. Reduced glutathione increased in all exposure concentrations of SPM and metallothionein increased at the highest SPM concentration. Lipid peroxidation was unchanged. However, filament epithelium hyperplasia, lamellar epithelium hypertrophy, ionocytes hypertrophy and mucous cells proliferation were the most frequent changes in the gills resulting in the the increasing the histopathological alteration indexes in fish exposed to 100 and 1000 µg SPM L-1. SPM water contamination increased the metal/metalloids dissolved in water as well as metallic nanoparticles which are absorbed inducing changes in the blood cellular defense system, ionic regulation, and has genotoxic potential. The changes in the gills evidenced a response to reduce metal absorption present in the SPM and overcome ionic disturbance.

Morozesk received postdoctoral scholarships from FAPESP (Grant 2021/02906-3) and, P.R. Siqueira and F.A. Souza received PhD and Master scholarship, respectively, from Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES, Finance code 1).

2.06.P-Th041 Analysis of Emissions From Brake Abrasions in Rail Traffic
***Gina Bode**[1], Christian Dietrich[2], Georg Dierkes[2], Arne Wick[2], Thomas A. Ternes[3], Andreas Schaffer[4] and Sabrina Michael[1], (1)German Centre for Rail Traffic Reasearch at the Federal Railway Authority, Germany, (2)German Federal Institute of Hydrology (BfG), Germany, (3)G Qualitative Hydrology, German Federal Institute of Hydrology (BfG), Germany, (4)RWTH Aachen University, Institute for Environmental Research, Germany*
In transportation, non-combustion-related emissions are becoming more relevant due to the decline of combustion-related emissions. Although rail transport is considered one of the most environmentally friendly means of transportation, still abrasion-related emissions enter the environment. One of the main sources of abrasion-related emissions are brakes. Nowadays, block brakes made of composite materials are mainly used in freight transport due to their improved noise characteristics. Older freight wagons have been converted from cast iron blocks to LL-blocks (low noise, low friction), whereas new freight wagons are equipped with K-blocks (composite). In passenger transportation brake pads consisting of composite materials are also used. Such composite brakes consist of a variety of organic and inorganic components. However, the composition of the individual brake pads is not regulated and therefore largely unknown. Due to the different kinds of brake pads and the variance in their chemical composition, there is currently very little information available on the composition of brake emissions from rail traffic.
In order to be able to assess the potential risk to humans and the environment, information on the chemical characteristics of the brake pads and the resulting emissions is required.
Therefore, the goal of the present study is to elucidate the chemical composition of different composite brake pads and their abrasions in test bench investigations. Thus, several analytical methods are used to characterize the compositions and identify tracer substances characteristic for brake emissions.
Identification of the inorganic components of the brake pads was conducted using X-ray fluorescence spectroscopy (XRF). For the different brake linings different compositions were obtained. Besides Fe as the main element, Al, Ba, Ca, K, S, Si, Ti, Zn and Zr, were detected in larger fractions depending on the brake pad. The polymeric compound could be identified as phenolic resin by pyrolysis gas

chromatography mass spectrometry (py-GC-MS). Moreover, eluates of the brake material and environmental samples taken along a railway track will be analyzed via inductively coupled plasma - mass spectrometry (ICP-MS) and liquid chromatography-high resolution mass spectrometry (LC-HRMS) to assess a possible entry into soil and water.
Overall, the collected data will be included into a future risk assessment and a cross-modal analysis of abrasion related emissions.

2.06.P-Th042 Challenges of Climate Change: Risk Mitigation of Plant Protection Products Containing Semi-Volatile Active Substances Using the Example of Clomazone
Marlene Kolter *and Gertje Czub, Federal Office of Consumer Protection and Food Safety (BVL), Germany*
Semi-volatile active substances represent a special challenge in authorisation of plant protection products. Their use leads to exposition of non-target areas not only through spray-drift, but also through volatilisation with subsequent deposition. The process of volatilisation is highly dependent on multiple factors, for example the formulation of the plant protection product, the application technique, and especially the weather conditions. Considering the ongoing global warming, the problems caused by the transport of active substances with a potential for volatilisation to non-target areas can therefore be expected to increase.
Standard risk mitigation measures like the use of drift-reducing equipment and no-spray buffer zones are frequently used to reduce the entry of plant protection products into adjacent areas via spray drift. The exposition of adjacent areas via volatilisation and deposition, however, can only in part be addressed by those measures. Clomazone is a prominent example of a semi-volatile active substance. Small amounts of clomazone can already lead to visible bleaching in non-target plants. In the past, cases of bleaching have mainly been limited to applications of plant protection products containing clomazone in late summer. More recently, even after applications in spring cases of bleaching have been observed. This may in part be explained by increased applications during that time of the year, but it might also reflect a tendency towards weather conditions that favor volatilisation due to climate change.
In the presentation, we describe the different factors that influence the volatilisation of clomazone, and the set of special risk mitigation measures that have been established in Germany for the use of clomazone-based plant protection products. These measures have effectively minimised the cases of bleaching of non-target plants. Also, we outline the possible consequences of climate change to the risk represented by semi-volatile active substances. Finally, we discuss to which extent mitigation measures might require an adjustment in case exposure of adjacent areas to semi-volatile substances increases.

2.06.P-Th043 In Vitro Human Alveolar Macrophage (ImmuPHAGE™) Responses to Particulate Matter Exposure
Elinda Zeqiri[1]*, Ewelina Hoffman*[1]*, Rhamiya Mahendran*[1]*, Driton Vllasaliu*[2]*, Victoria Hutter*[3] *and Armond Daci*[4]*, (1)ImmuONE Ltd and Centre for Topical Drug Delivery and Toxicology, University of Hertfordshire, United Kingdom, (2)Institute of Pharmaceutical Sciences, King's College London, United Kingdom, (3)ImmuONE LTD and Centre for Topical Drug Delivery and Toxicology, University of Hertfordshire, United Kingdom, (4)Department of Pharmacy, Faculty of Prishtina, Kosovo, Kosovo*
Air pollution contributes to approximately 4.2 million deaths globally each year, with a significant portion attributed to respiratory diseases caused by particulate matter (PM). PM consists of microscopic particles that can penetrate the small airways, leading to oxidative stress and inflammation. Alveolar macrophages play a key role in both short- and long-term lung responses in the respiratory airways. Understanding their interaction with PM is essential for evaluating potential toxicological and immunological effects. This study investigates the in vitro respiratory toxicity of PM2.5 collected from Prishtina and Obiliq, two cities in Kosovo.
Human alveolar macrophages (ImmuPHAGETM) were exposed to PM2.5 (25, 50, 75, and 100µg/mL) for 24 and 48h. PrestoBlue reagent (Invitrogen, UK), CytoTox-ONE assay (Promega, UK) and fluorescent microspheres (ThermoFisher, UK) assessed average population responses for cell health and function. Individual cell responses using high-content image analysis (In Cell Analyzer 600, GE Healthcare, UK), were used to assess morphological features and cell health. Cells were fixed and treated with a cocktail of fluorescent dyes and individual cell phenotypes were profiled using four different morphology and cell stress descriptors as previously described.
Mitochondrial activity was significantly reduced ($p < 0.05$) for all exposure conditions assessed. Phagocytic activity was significantly reduced ($p < 0.05$) after 24h exposure but significantly increased after 48h exposure ($p < 0.05$). Individual cell profiling using high-content imaging revealed distinct phenotypic changes in alveolar macrophages exposed to PM identifying the evolution of macrophage response to PM whereby the initial response (24h) was associated with elevated cellular stress alone and

longer-term response (48h) was associated with enlarged cells and increased vacuolation. The combination of cell stress and morphological perturbations observed indicates a pathophysiological alveolar-macrophage response associated with adverse airway inflammation. This study demonstrates the value of in vitro tools in characterising individual cell responses to understanding the mechanism of lung response for environmental particulates. This approach can be used to assess potential acute and chronic impacts of PM in the airways to deepen our understanding of how particulate matter affects lung function and support the global effort to mitigate air pollution and protect public health.

2.06.P-Th045 The Impacts of Gaseous Air Pollution on Insect Fitness

***Rachael Haw*[1]*, Karl L. Evans*[1]*, Laurence Jones*[2] *and Stuart A. Campbell*[1]*, (1)University of Sheffield, United Kingdom, (2)UK Centre for Ecology and Hydrology, United Kingdom*

Air pollution is a major public health concern, contributing to approximately seven million deaths annually. While extensive research has focused on the human health impacts of air pollution, fewer studies have addressed its ecological consequences. Research on insects is particularly sparse, and they may be especially sensitive to air pollutants such as particulate matter (PM) and oxidising pollutants such as nitrogen dioxide (NO2) and ground-level ozone (O3). For example, flying insects can accumulate PM on their exoskeletons while foraging, and habitats exposed to diesel exhaust emissions tend to host significantly fewer insect pollinators. Most studies addressing this have pursued a field-based approach, and there is a notable lack of empirical evidence on how such pollutants directly affect insect fitness. This study fills this gap by assessing the impacts of NO2 on the growth and fitness of Spodoptera littoralis (Lepidoptera: Noctuidae) using a specialised fumigation chamber system. By examining the effects of an environmentally relevant range of NO2 concentrations, we quantify the risks to insect populations from direct exposure to air pollution. The results from this study provide crucial evidence about the effectiveness of current legislation to protect ecosystems from harmful pollutants.

2.06.P-Th046 The Kinetic, Modelling Study of Fenton-like with Organic Acids and Their Fate in the Aqueous Phase Fate

Elena Poschart, Hartmut Herrmann, Daniele Firak and ***Thomas Schaefer****, TROPOS, Germany*

The chemical element iron is ubiquitous in the aqueous phase of the Earth's atmosphere and plays a role in numerous chemical and photochemical processes. Moreover, it performs the function of a micronutrient for microorganisms, which in turn synthesise robust organic ligands. These ligands exert an influence on the solubility, reactivity and iron complex species, which could have an impact on the oxidation capacity in cloud water. Recent experimental observations indicate that in excess of 95% of the dissolved iron in clouds is complexed by organic ligands. The complexation of iron affects the reactivity of iron during the decomposition of hydrogen peroxide (H_2O_2), which is typically referred to as the 'Fenton-like' reaction. Furthermore, the Fenton-like reaction is utilised in water treatment, as it has the potential to effectively remove a range of organic pollutants.

Here we study the kinetic of the reaction of iron complexes of gluconic (GLU) and succinic acids (SUC) with H2O2 in respect to the conversion of Fe (II) at different peroxides and ligands concentrations in the aqueous phase. The investigation of Fe(II) to Fe(III) conversion was performed using the ortho-phenanthroline (oPhe) method also called the APHA 3500 colorimetric test and UV-VIS spectrometry. A kinetic model was developed using the COPASI software [6]. The Fenton-like reactions involving organic acids such as succinic and gluconic acids in the aqueous phase of clouds should be investigated in order to evaluate their influence to the iron catalytic cycles and hydroxyl radicals production in cloud water. Given the strong influence clouds have on the troposphere composition and subsequent impact on the climate. The second-order rate constant for the classical Fenton reaction in the absence of organic ligands at pH 5 was determined to be k2nd = 75 ± 3 L mol 1 s-1. The apparent second-order rate constants for Fenton-like reactions were observed to increase in the presence of succinic and gluconic acids. The rate constant of reaction between H2O2 and Fe(II)-GLU complex in the presence of the organic ligand was determined to be k2nd = (2.2 ± 0.8) × 103 L mol 1 s-1 at pH = 5. A developed theoretical kinetic model was employed to provide an explanation of the observed results and to predict the fate of iron complexation under atmospheric conditions. The results obtained will contribute to a better understanding of the oxidation capacity by the Fenton-like reaction in clouds.

2.06.P-Th047 Determination of PAHs in Indoor House Dust in Barranquilla Colombia and Their Relationship with Health, Using the Biological Model *Caenorhabditis Elegans*

Jhon Gutierrez Rondon[1]*,* ***Belkis Palacio***[2]*, Leonor Cervantes*[3]*, Barbara Julia Arroyo*[3] *and Katia Charris Ca Izares*[4]*, (1)Estudiante, Colombia, (2)Bolivar, Universidad De Cartagena, Colombia, (3)Universidad de Cartagena, Colombia, (4)Universidad Rafael Nuñez, Colombia*

Introduction: The presence of atmospheric pollutants including polycyclic aromatic hydrocarbons (PAHs),

inside homes, can affect the health and well-being of their occupants, becoming a risk factor for respiratory, cardiovascular, allergic disease, cancer and premature mortality among others. In Latin America, including Colombia, the impact on health of these substances present in indoor environments has been little studied.
Objective: The objective of this study was to determine the presence of PAHs in indoor dust from homes in the city of Barranquilla, Colombia, accumulated in the filters of air conditioners, and their possible effects on health using the biological model *Caenorhabditis elegans*.
Methodology: Dust inside the filters of air conditioners was collected from 29 residential dwellings in the 5 localities of the city of Barranquilla, from May to July 2024. The presence of PAHs in the dust was determined by gas chromatography-mass spectrometry (GC-MS). To assess the health risk of chronic exposure to PAHs from indoor dust, the biological model *C. elegans* was exposed for 48 h to different concentrations of aqueous extracts obtained from the dust. The criteria evaluated were lethality, fertility and locomotion in the wild-type strain N2 and oxidative stress expression in the sod1 and sod4 mutant transgenic strains. Data are expressed as mean ± SEM. ANOVA was used for statistical analysis. GraphPad Prism was used, and $p < 0.05$ was considered statistically significant.
Results: The data obtained provided evidence for the presence of PAHs in varying concentrations in indoor dust from homes in the city of Barranquilla. Exposure to dust extracts affected physiological parameters in *C. elegans*. Oxidative stress-related gene expression in GFP transgenic nematodes was related to the presence of PAHs..
Conclusions: The data obtained in this research can be used as a basis for future research to accompany governmental decisions aimed at regulating the generation of pollutants that negatively affect the quality of air breathed in homes.

2.06.P-Th049 Incorporation of Environmental Airborne Nanoparticles in Human Lung Cells

*Iara da Costa Souza[1] and **Marisa Narciso Fernandes**[2], (1)UFSCar, Brazil, (2)Univeridade Federal de Sao Carlos, Brazil*

The present study demonstrates the cellular internalisation of environmental settleable atmospheric particulate matter (SePM) and PM10 in bronchial epithelial and fibroblast human lung cells taken in urban areas subject to the major influences of the steel industry, iron pelletizing and civil construction. High resolution transmission electron microscopy (HRTEM), nanocrystallography, electron energy loss spectroscopy (EELS), nanoscale secondary ion mass spectrometry (NanoSIMS) and inductively coupled plasma mass Spectrometry (ICP-MS) were applied to characterise the SePM, including nanoparticles, at the subcellular level. PM10 shows higher element uptake in comparison to SePM, in which the metallurgical sources were more incorporated than those from civil construction/vehicular sources. Fibroblasts showed a higher metal incorporation than epithelial cells after SePM exposure. The internalisation of Al, Si, Ti, Fe and Zr was observed, with nanoparticles free in the nucleus (membrane not identified) and membrane-bound particles/clusters in the cell cytoplasm. Chemical and ultrastructural analyses demonstrate an association of titanium, iron and zirconium nanoparticles with metallurgical sources and secondly with vehicular emissions. This study raises concerns about releases of PM from metalliferous areas, requiring stricter environmental regulations of atmospheric quality to protect human health.

Disclaimer/Disclosure: This study was supported by Federal Brazilian Government parliamentary amendment MAX 600 Project (Grant 23068.016325/2016-09) administered by Espírito Santense Foundation of Technology (FEST), São Paulo Research Foundation (FAPESP, Grant 2019/08491-0), Espírito Santo Research and Innovation Foundation (FAPES/CNPq/ Decit-SCTIE-MS/SESA Nº 03/2018 PPSUS, Grant 214/ 2018-83170278) from Brazil and National Scientific and Technical Research Council (ANPCYT, FONCyT/PICT-1597), Argentina. I.C. Souza and M. Morozesk received scholarship support from São Paulo Research Foundation (FAPESP, Grant 2016/025257-2, 2018/25691-0 and 2021/02906-3).

2.07 Marine Ecotoxicology: Anthropogenic Pressures on Marine Organisms and Habitats, Current Challenges and Solutions

2.07.T-01 Intraspecific Differentiation and Importance of Cold Gametogenesis for Heat Tolerance in the Golden Kelp *Laminaria ochroleuca*

***Claudia Gattolin**[1], Isabella Moro[1], Neusa Martins[2], Gareth A. Pearson[2], Davide de Battisti[1], Luis Barreto[2], Ester A. Serrao[2] and Guillermo Monescillo[2], (1)University of Padova, Italy, (2)CCMAR, University of Algarve, Portugal*

Climate change is driving shifts in species distributions and adaptations to new environmental conditions.

Since sessile species cannot escape stressors, thermal plasticity becomes critical for survival in changing enviornments, as it allows organisms to adapt. Kelps (Laminariales, Phaeophyceae) are sessile and important "ecosystem engineers", providing essential ecosystem services and supporting biodiversity. This research investigates whether the optimal thermal reproductive range of *Laminaria ochroleuca*, a warm-temperate kelp species distributed from southern England to Morocco, including the Strait of Messina and the Azores, varies among populations and whether gametogenesis and sporophyte development temperatures affect the thermal tolerance and growth of F1 sporophytes.
Gametophytes from four populations representative of the species distribution (France, Morocco, Italy, Portugal) were exposed to temperatures allowing gametophyte reproduction (11°C, 13°C, 16°C, 18°C) under controlled conditions to assess reproductive success. Additionally, thermal tolerance of F1 sporophytes from one population was tested following gametogenesis at 11°C and 16°C and sporophyte growth rates and survival were assessed after exposure to sub-lethal and lethal temperatures.
Results showed intraspecific ecotype differentiation. The Mediterranean population had higher reproductive success at the highest temperature tested (18°C), reflecting adaptation to the region s rising sea temperatures. In contrast, Atlantic populations performed better at lower temperatures (11°C 16°C), consistent with local oceanographic conditions, that include cooler seawater temperatures and upwelling events. Additionally, F1 sporophytes developed at a cooler temperature (11°C) exhibited enhanced survival under heat stress (23°C), suggesting the presence of trans-generational plasticity and carry-over effects.
These findings highlight the importance of phenotypic plasticity in enabling local adaptation and suggest vulnerabilities to climate change. Rising ocean temperatures could lead to the loss of southern populations in North Atlantic, though deep refugia like the Messina Strait may persist. The results also show the possibility of developing heat-tolerant strains to support kelp restoration and aquaculture. By advancing understanding of *L. ochroleuca* thermal responses, this research provides valuable insights into managing and conserving kelp forests in a warming world.

2.07.T-02 Monitoring Plastic Additives and Micro- and Nanoplastics Contamination in Ireland's Coastal Regions

David Alcaide Benavides[1]*, Xavier Borrell*[1]*, Anne Morrissey*[2]*, Marta Llorca-Casamayor*[1] *and Marinella Farre*[3]*, (1)IDAEA-CSIC, Spain, (2)Dublin City University, Ireland, (3)IDAEA-CSIC, Barcelona, Spain*
Marine pollution caused by micro- and nanoplastics (MNPLs) and their associated additives presents increasingly complex ecological and toxicological challenges. These pollutants impact individual organisms and disrupt marine ecosystems by introducing bioaccumulative chemical loads through food chains. Plastic additives released during the degradation of plastics can affect endocrine functions, reproduction, and organism resilience to environmental stressors. Research on the Irish Sea is particularly scarce, especially in coastal areas. This region s biodiversity, economic reliance on marine resources, and exposure to Atlantic currents make it critical to assess the presence and impact of MNPLs and plastic additives in these waters. Water and sediment samples were collected from 10 sites across the Irish Sea. For water, two liters per sampling point were processed via solid-phase extraction (SPE) for additives and filtration for MNPLs, followed by ultrasonic-assisted extraction (USAE) using toluene. Sediments were analyzed by weighing five grams per sample and subjecting them to USAE with methanol for additives and toluene for MNPLs. Plastic additives were analyzed using liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS), employing a reverse-phase column. MNPLs were identified through size exclusion liquid chromatography coupled to mass spectrometry (LC-SEC-HRMS).
The analysis revealed a wide range of plastic additives, including plasticizers such as phthalates and adipates, flame retardants, and protective agents like antioxidants and corrosion inhibitors. Flame retardants had the highest concentrations in sediment samples (0.05 100 ng·g?¹), while corrosion inhibitors were found in lower ranges (1 15 ng·g?¹). Sites near ports and river mouths exhibited the highest pollution levels compared to seemingly isolated beaches.
Regarding MNPLs, common polymers such as polyethylene, polyamide, and polyvinylidene fluoride (PVF) were identified. Polymer concentrations in water ranged from 0.086 to 0.94 µg·L?¹, while polyamide was detected at lower concentrations (0.27 134 ng·L?¹). These polymers originate from diverse sources, including food packaging, synthetic rubber products, cosmetics, and electronic components. These findings highlight the environmental persistence and bioaccumulative nature of MNPLs and their additives, posing risks to marine life and human health through food web contamination.

Disclaimer/Disclosure: This work was supported by ONE-BLUE project (HORIZON-CL6-2023-ZEROPOLLUTION-01 Ref No. 101134929) and Innovation and the Generalitat de Catalunya through Consolidated Research Group ON-HEALTH 2021 SGR 01150

2.07.T-03 Mapping the Fate, Ecological Interactions and Impacts of Microplastic Pollution Across the Galapagos Marine Reserve

Ceri Lewis[1]*, Georgie Savage*[1]*, Gustavo A. Dominguez*[2] *and Jen Jones*[3]*, (1)Biosciences, University of Exeter, United Kingdom, (2)ESPOL, Ecuador, (3)Galapagos Conservation Trust, United Kingdom*

Plastic leakage from the Eastern Pacific rim countries of Ecuador and Peru is captured by the South Pacific Subtropical Gyre, transporting it towards the open ocean, where it pollutes oceanic islands such as Galápagos, famous for its unique biodiversity and a global conservation priority. Here we report the findings of our 5-year collaborative programme to characterise the widespread plastic contamination of the Galapagos marine ecosystem and determine how particle interactions with the environmental conditions and ecological processes of this unique archipelago impact microplastic fate and behaviour and uptake into wildlife. Field sampling campaigns focussing on the island of San Cristobal, the Eastern-most Island of Galapagos most exposed to the Humbolt current, were undertaken from 2018-2023. Samples were collected around the island for the sea surface, benthic sediments, beaches, mangroves and representative invertebrate biota for microplastics in combination with beach and mangrove macroplastic surveys. Our data reveals widespread and highly variable microplastic contamination of San Cristobal of both benthic sediments (6.7 86.7 particles·kg?1) and surface seawater (0.61 10.81 particles·m?3). Grab sampling (whole water 1 litre samples filtered to 1.2 µm) revealed elevated concentrations of up to 23.3 particles per litre (equivalent to 23,333 particles per m-3) at the town s outflow pipe, mostly comprising anthropogenic cellulose fibres. Mangroves were found to accumulate both macroplastic and microplastics, with concentrations of microplastics found in seawater within the mangroves found to be 4 orders of magnitude higher than that in their surrounding coastal waters. We have found evidence of ingestion of microplastics within every species investigated to date, from sea urchins to the iconic Galapagos marine iguanas. Our results highlight different sources of plastic contamination for different areas of the Galapagos archipelago, and their interactions with complex ecosystems. These factors act to influence hot spots of plastic accumulation and determine uptake rates into Galapagos wildlife. Working closely with the Galapagos National Park, our data is now supporting local management decisions, mitigation actions and clean up efforts to reduce plastic pollution in Galapagos.

Disclaimer/Disclosure: The authors thank the UK Global Challenges Resource Fund (GCRF) (Ref. NE/V005448/1), The Galapagos National Park Directive, The Galapagos Science Centre, The Galapagos Conservation Trust, The Royal Geographical Society and NERC (NE/S003975/1) for their support.

2.07.T-04 Maternal Transfer of PFAS in Marine Mammals via Lactation: Quantitative and Non-Targeted Analyses

Kara Michelle Joseph[1]*, Jack Ryan*[1]*, James Dodds*[1]*, Mike Power*[2] *and Erin Baker*[1]*, (1)Department of Chemistry, University of North Carolina at Chapel Hill, United States, (2)National Zoo and Conservational Biology Institute, Smithsonian National Zoo, United States*

Per- and polyfluoroalkyl substances (PFAS) are a class of anthropogenic chemicals widely used in a variety of consumer and industrial applications dating back to the 1950s. Due to their carbon-fluorine bonds, PFAS are resistant to thermal and chemical degradation and readily enter the environment, thus being ubiquitous in all ecosystems. Moreover, PFAS bioaccumulate, biomagnify, and have significant impacts on mammalian health. These impacts are exemplified in neonates during crucial stages of development, leading to changes in adiposity, decreased immune response, and disrupted thyroid function. High neonatal body burden of PFAS is greatly attributed to lactational transfer. Marine mammals are regarded as critical sentinel species for persistent organic pollutants (POPs) in aquatic ecosystems. However, there is little data on how PFAS perturb marine mammalian health, and it is currently unclear which PFAS analytes are transferred via lactation and how such transfer affects the biological functions of young mammals. For species that rely on milk as their main food source during key growth and developmental milestones, high milk PFAS concentrations could pose a serious threat to future ecological fitness with greater ramifications to trophic networks. Therefore, milk is a vital yet underutilized matrix for evaluating neonatal exposure despite its potential value in providing critical toxicologic data. This work presents an optimized extraction method for non-targeted analyses (NTA) of PFAS in mammalian milk, developed using Quick Easy Cheap Effective Rugged and Safe (QuEChERS) salts and dispersive solid-phase extraction (dSPE) followed by NTA with a platform coupling liquid chromatography, ion mobility spectrometry, and mass spectrometry (LC-IMS-MS). This optimized extraction showcased high recovery across four PFAS classes compared to alternative clean-up methods. The extraction method was also further optimized for smaller sample volumes while maintaining the ability to detect low PFAS concentrations (<1 ng/mL). These optimized methods will be applied to a host of longitudinal marine mammal milk samples for quantitative analysis and NTA, including apex marine predators, like bottlenose dolphins and sea lions. In addition to quantification of PFAS to track trends in concentration, NTA will be

applied to identify unique PFAS species that can inform future toxicologic studies with the potential to identify novel routes of exposure.

2.07.T-05 Temporal Variations of Marine Toxins in Catalan (NE Spain) Seawater: A Suspect Screening Comparison

Albert Pina Benages, Xavier Borrell, Marta Llorca-Casamayor and ***Marinella Farre****, Institute of Environmental Assessment and Water Research - Spanish Council for Scientific Research (IDAEA-CSIC), Spain*

Marine biotoxins, produced by microalgae, pose a growing threat to marine ecosystems, fisheries, and human health. These secondary metabolites can accumulate in marine organisms and enter the food chain, potentially causing severe intoxication in humans. This issue is particularly relevant in the Mediterranean Sea, where environmental changes and anthropogenic activities influence the occurrence and distribution of biotoxins. This study evaluates the temporal variation of marine biotoxins in surface seawater from the Catalan coast (NE Spain), comparing results from samples taken along 2024 and with a retrospective evaluation of samples previously studied by our group a decade ago to assess potential shifts in toxin diversity and concentrations.

A total of 36 seawater samples from the Catalan coast (NE Spain) were collected and analyzed using ultra-high-performance liquid chromatography coupled with high-resolution mass spectrometry. The results showed that okadaic acid (OA), a lipophilic toxin, was identified as the most prevalent compound, detected in 88% of the samples with an average concentration of 730 ng/L. The highest OA levels were observed in areas heavily influenced by urbanization, agriculture, or industrial activities, highlighting the role of anthropogenic inputs in enhancing eutrophication and microalgae growth. Beyond OA, the retrospective analysis revealed additional marine biotoxins, including 20-methyl spirolide G, azaspiracids (AZA-1, AZA-2, and AZA-3), pectenotoxin-1, and verrucarol. This marks the first identification of several of these compounds in seawater samples from the Catalan coast (NE Spain). Comparing the results of the lipophilic toxins with the samples taken along 2024, no lipophilic marine toxins were detected in the sampling sites.

This study provides valuable insights into the presence and distribution of marine biotoxins along the Catalan coast (NE Spain), highlighting the importance of continuous monitoring in understanding their dynamics. The absence of detectable lipophilic marine toxins in the first suspect screening of 2024 emphasizes the seasonal variability of these compounds and the necessity to further evaluate the lipophilic fraction as well as to monitor marine toxines along seasonal variations.

2.07.P Marine Ecotoxicology: Anthropogenic Pressures on Marine Organisms and Habitats, Current Challenges and Solutions

2.07.P-Th050 Effects of Short- and Long-Term Exposure to Natural Acidified Conditions in the Limpet *Patella Caerulea*

Silvia Giorgia Signorini[1]*, Marco Munari*[2]*, Fabio Crocetta*[3]*, Ilaria D'Aniello*[2]*, Lara Nigro*[4]*, Vittoria Correale*[2]*, Gaia Lucia Magarielli*[4]*, Riccardo Bernardi Malagugini*[2] *and Camilla Della Torre*[1]*, (1)Department of Biosciences, University of Milan; Department of Integrative Marine Ecology, Stazione Zoologica Anton Dohrn, Italy, (2)Department of Biology, Stazione Idrobiologica Umberto d Ancona, University of Padova, Italy, (3)Department of Integrative Marine Ecology, Stazione Zoologica Anton Dohrn, Italy, (4)Department of Biosciences, University of Milan, Italy*

Ocean acidification (OA) entails a detrimental impact on calcifying organisms by reducing carbonate availability, which makes their calcareous structures more fragile. Nevertheless, the gastropod *Patella caerulea* is able to inhabit the Castello Aragonese vent systems, a site naturally acidified by the volcanic CO2 emitted from the seafloor. This could happen through plasticity and/or adaptive mechanisms which still mostly remain unknown. The aim of this study is to compare the long-term strategies adopted by limpets that spent their entire life cycle in naturally acidified conditions with the short-term ones induced by an exposure of limpets to OA through an in situ transplant experiment.

In order to evaluate the effects of long-term exposure to OA, specimens of *P. caerulea* were collected from the pH gradient (N1: pH = 8.1; N2: pH = 7.7; N3: pH = < 7.4) of the vent and from the ambient pH site San Pietro (SP: pH = 8.1). For the transplant experiment, specimens of *P. caerulea* were collected from an ambient pH site (pH = 8.1) and transplanted to the three different stations of the vent for 30 days during the summer season. In both cases, molecular, biochemical, physiological, and metabolic mechanisms were investigated.

The most relevant result concerning physiology is a significant increase in respiration rate and a decrease in ammonia excretion rate in limpets collected in N3 only during summer season. Conversely, no effects were observed in organisms from the transplant experiment. Regarding energy-related metabolism, a

common trend was observed in both short- and long-term exposure, with a significant increase in glycogen content in limpets collected from the acidified sites of the vent. Moreover, OA induced oxidative stress only in transplanted limpets.
Overall, our results suggest that multiple mechanisms may contribute to boost tolerance to OA in the limpet *P. caerulea*, including ecological interactions, physiological functions, and energetic performance. The short-term exposure to OA didn't affect the survival of limpets transplanted to acidified conditions, which may be due to compensatory mechanisms or to the short duration of the experiment. Therefore, to gain a comprehensive understanding of the effects of OA, it is essential to examine adaptive strategies that may be developed over multiple generations, besides physiological adjustments induced by short-term exposure to low pH conditions.

2.07.P-Th051 Can Oxygen Supersaturation Boost Thermal Tolerance in Marine Fauna?
Ilaria D'Aniello[1]*, Annalisa Capasso*[1]*, Giovanni Vecchiatti*[1]*, Fabio Crocetta*[2]*, Mirko Mutalipassi*[2]*, Valerio Matozzo*[1]*, Isabella Moro*[1] *and Marco Munari*[1]*, (1)Department of Biology, University of Padova, Italy, (2)Department of Integrative Marine Ecology, Stazione Zoologica Anton Dohrn, Italy*
Marine coastal environments are significantly impacted by the phenomenon of global warming. Abrupt temperature increases, like marine heatwaves, can affect animal physiology, abundance, distribution, trophic interactions, survival, and mortality. These negative effects are often associated with an increased aerobic metabolic demand resulting from the thermal stress. However, coastal environments are typically characterized by the presence of photosynthetic organisms that serve as primary producers and may help to mitigate this trend by increasing the oxygen availability. In this experiment, oxygen supersaturation was used to simulate conditions of high primary production and was tested in combination with thermal stress to assess its impact on animal physiology and survival of some taxa. Species from 2 different phyla (Echinoderms and Cnidarians) were chosen among the most common species found in the Venice lagoon. Organisms were collected during summer 2024, from three different sites characterized by large coverage of macrophytes and different exposure to anthropogenic impacts. Lethal and sublethal site effects were tested on the species under different conditions i.e., by exposing the individuals to a thermal slope (1°C every 30 minutes) under both normal (~90% of dissolved oxygen) and supersaturated (~160% of dissolved oxygen, mean daytime value of oxygen due to primary production) oxygen levels. The results indicate that oxygen supersaturation can increase the thermal tolerance of the tested animals, both extending survival and reducing the metabolic rate under heatwaves. No significant differences were detected among sites, demonstrating the ubiquity of the dynamic tested herein. These results shed light on an understudied intrinsic interaction in marine ecosystems, providing fundamental knowledge about the resilience of organisms to global warming within the context of their natural environment.

2.07.P-Th053 Physiological Responses and Adaptive Mechanisms of Ulva sp. to Marine Heatwaves
Marta Paganin[1]*, Leyla-Lou Brauer*[2]*, Alizé Deguette*[3]*, Isabella Moro*[1]*, Marco Munari*[4]*, Ilaria D'Aniello*[1]*, Isabel Maria Alves Barrote*[5] *and Joao Miguel Sousa da Silva*[5]*, (1)University of Padova, Italy, (2)University of Oldenburg, Germany, (3)Centre of Marine Sciences, University of Algarve, Portugal, (4)University of Pavova, Italy, (5)CCMAR - Centro de Ciencias do Mar do Algarve, Portugal*
Marine heatwaves (MHWs) are becoming more frequent and intense due to climate change, significantly impacting marine ecosystems, including macroalgae such as Ulva spp.
This study aims to investigate the physiological responses of Ulva sp. to simulated heatwave conditions and to evaluate potential adaptive mechanisms when exposed to multiple heatwaves.
Algal samples were subjected to three thermal regimes: a single heatwave (SH), two consecutive heatwaves (DH), and a control condition without thermal stress.
The heatwave simulation involved raising the water temperature from 18°C to 24°C for 7 days, followed by a 7-day recovery period at 18°C. Physiological changes were assessed by measuring biomolecule levels (pigments, proteins, sugars, and starch) and photosynthetic performance using photosynthesis-irradiance (PI) curves at the end of each heatwave peak and during each subsequent recovery phase.
The analysis of photosynthetic parameters and biomolecule levels revealed distinct physiological responses to thermal stress. Both the SH and DH treatments showed a significant increase in photosynthetic activity (Pmax) during heatwave peaks and recovery periods, although the response varied between treatments. The DH treatment exhibited a higher Pmax during the initial recovery phase and at the second heatwave peak, suggesting potential adaptive responses such as increased synthesis of photosynthetic pigments and enhanced energy allocation for cellular repair. Additionally, the rise in chlorophyll-a and carotenoid levels in the DH treatment indicated that Ulva sp. might use pigments to improve light capture and provide antioxidant protection under stress. Protein levels also increased in the DH treatment, suggesting the synthesis of structural and stress-response proteins that help maintain cellular integrity during repeated heat exposure.

Overall, Ulva sp. demonstrated physiological plasticity in response to thermal stress, indicating a potential resilience to future warming events.
The results provide valuable insights into the adaptive capacity of macroalgae, with significant implications for both the conservation of marine ecosystems facing climate-induced thermal stress and the rapidly growing industry of macroalgae cultivation for food and pharmaceutical purposes.

2.07.P-Th054 Health and Reproduction of the Red Seaweed *Palmaria palmata* in a Climate Change Scenario

Pierre Liboureau[1]*, Renan de Oliveira*[2]*, Lisia Gestinari*[2] *and Daniela Maria Pampanin*[1]*, (1)Faculty of Science and Technology, University of Stavanger, Norway, (2)Institute of Biodiversity and Sustainability, Federal University of Rio de Janeiro, Brazil*

In cold and temperate climates, macroalgae constitute the main habitat-forming species for coastal ecosystems and provide various benefits to local human communities. *Palmaria palmata* is an ecologically relevant seaweed distributed throughout the North Atlantic. It is also a species of interest for the development of at-sea aquaculture for human consumption due to attractive nutritional and bioactive properties. It is, however, characterised by a complex life cycle requiring different life stages (sporophytes, male and female gametophytes) to reproduce in a short, specific sequence.
Climate change is increasing the frequency and intensity of extreme weather events, including marine heatwaves (MHW) and heavy rainfalls, both leading to short-term but intense changes in environmental conditions. Additionally, industrial activities emit increasing quantities and variety of pollutants, many of which eventually end up in aquatic systems. The effects of these emerging climatic and anthropogenic pressures on seaweed populations are poorly documented, leading to inadequate or inexistant conservation and protection policies.
In this research, we investigated the individual and synergetic effects of MHW, intense rainfalls and pollutants on the health and reproductive ability of *P. palmata*. Unique (3ºC, 7 days) and repeated (3ºC, 3 x 7-days cycles) temperature increases, and salinity decreases (4-10 PSU, 14 days) were used to simulate MHW and intense rainfalls, respectively. Effluent from a local wastewater treatment plant was diluted to three environmentally relevant concentrations to represent pollutants routinely present in marine systems. Seaweed health was monitored before, during and for 10 weeks after exposures by measuring growth, photosynthetic activity (maximum quantum yield and electron transport rate), oxidative stress (lipid peroxidation) and chemical composition (pigments, proteins, polysaccharides and phenolic compounds). All plants were placed in conditions favouring sporogenesis to monitor effects of treatments on reproductive ability, and spore output was quantified to measure reproductive success.
The identification and quantification of changes in wild seaweed populations, which influence their life cycle dynamics and overall health status, provided an effective method for assessing the impacts of climate change on ecosystems.

Disclaimer/Disclosure: The authors thank the Nordic Atlantic Cooperation (NORA, project j.nr.510-213, RØDTANG/SØLSTAIN) and the Norwegian Directorate for Higher Education and Skills (HKDir, project NorBra 2025: One Health perspective, a key for a sustainable future, UTF-2020/10137) for experimental funding, and the University of Stavanger for a PhD grant.

2.07.P-Th055 Evaluating the Potential of Chemical and Thermal Priming to Enhance Thermal Tolerance in Juvenile Sporophytes of the Golden Kelp *Laminaria ochroleuca*

Claudia Gattolin[1]*, Isabella Moro*[1]*, Neusa Martins*[2]*, Gareth A. Pearson*[2]*, Davide de Battisti*[1]*, Ester A. Serrao*[2]*, Luis Barreto*[2] *and Guillermo Monescillo*[2]*, (1)University of Padova, Italy, (2)CCMAR, University of Algarve, Portugal*

Laminaria ochroleuca is increasingly threatened by rising seawater temperatures due to climate change, with critical ecological and economic implications. This study investigated whether chemical and thermal priming could enhance the thermal tolerance of juvenile sporophytes. While priming techniques in terrestrial plants have been extensively studied, their application in seaweeds remains unexplored. This research aimed to assess their potential for improving kelp resilience, supporting restoration and aquaculture.
Juvenile sporophytes of *L. ochroleuca* were exposed to four priming treatments over 2 days: control (13°C), thermal priming (23°C), chemical priming with 0.05 mM hydrogen peroxide (H_2O_2) at 13°C, and thermo-chemical priming (0.05 mM H_2O_2 at 23°C). Sporophytes were then subjected to temperatures including sub-lethal and lethal for 14 days. At the start and end of the experiment, growth rates were evaluated by sporophyte area, and photosynthetic performance was assessed using chlorophyll fluorescence parameters (Fv/Fm and rapid light curves).
Results revealed that priming treatments had limited effects on thermal tolerance. Growth rates gradually

declined as temperature increased, and 25°C proved lethal, resulting in severe stress or mortality. Photosynthetic performance similarly decreased at higher temperatures, likely due to heat-induced photoinhibition. At 13°C, priming treatments improved some photosynthetic parameters, suggesting enhanced photosynthetic activity under optimal conditions. However, these benefits did not seem to persist under heat stress.
The lack of significant effects may reflect the short duration of the priming treatments or the absence of lasting stress memory in juvenile sporophytes. While priming did not enhance heat tolerance in this study, it may be more effective when applied to earlier life stages, such as gametophytes, where transgenerational plasticity and carry-over effects could improve resilience in offspring. Future research should investigate whether longer priming exposure enhances heat tolerance in sporophytes and explore the role of epigenetic modifications in stress tolerance. This study highlights the challenges of applying priming techniques to kelps, the need to understand phenotypic plasticity in macroalgae and to develop innovative approaches to address climate change. Developing stress-tolerant strains through priming could benefit both mariculture industry and kelp forest restoration.

2.07.P-Th056 Mauritius Oil Spill: Hydrocarbon Residues Remain in the Mangrove Systems Three Years Later

*Alan Scarlett[1], Robert K. Nelson[2], **Marthe Monique Gagnon**[3], Christopher Reddy[2] and Kliti Grice[1], (1)Western Australian Isotope and Geochemistry Centre, School of Earth and Planetary Sciences, Curtin University, Australia, (2)Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, United States, (3)School of Molecular and Life Sciences, Curtin University, Australia*

The grounding of the MV Wakashio off the coast of Mauritius in July 2020 was the world s first major spillage of Very Low Sulfur Fuel Oil (VLSFO). Nearly 3 years following the spill, sediments were collected from two mangroves ecosystems: a reference site and an impacted site, with sediments analysed by comprehensive two-dimensional gas chromatography and by gas chromatography-mass spectrometry. No petroleum hydrocarbons were identified at the reference site. At the impacted site, molecular biomarkers matched the profile of the MV Wakashio VLSFO. A linear regression of terpenoid ratios between the original Wakashio fuel oil and that of the sediments collected at the impacted site produced a R2 of 0.9995, indicating a positive match between them. It was observed that under the Mauritius tropical conditions, the VLSFO has undergone significant weathering with several mono- and polycyclic aromatic hydrocarbons being absent from the hydrocarbon mixture. However, some environmentally resilient 4- and 5-rings PAHs were still present in the sediments at the impacted site. Overall, most of the compounds known to be toxic to marine organisms have dissipated but the continued presence of oil in the mangrove systems is known to negatively impact the mangrove forests in the long term.

2.07.P-Th058 Influence of Sun Creams on Corals

***Guido Gonsior**, Maren Dill, Sara Cuellar and Gundula Gonsior, GG BioTech Design, Germany*

Corals play a crucial role in the marine ecosystem. They form one of the most species-rich ecosystems on earth. And coral reefs are one of the most endangered ecosystems. The harmfulness to coral ecosystems of various UV filters in sun creams, which are supposed to protect our skin from UV light, was investigated and appears to have been proven. However, the current state of the data is not yet clear. Above all, the question remains as to whether the environmentally relevant concentrations are sufficient to cause toxic effects. In addition, there are still no standardized lab tests. Further, the focus here has often been on individual components of sun creams only. But there are many different formulations on the market. These are not only worn in the water when swimming. Exposure via wastewater after showers should be viewed critically, too. Especially as many hotels located on trophic seas have inadequate wastewater treatment systems. We present data from various sun creams that were applied directly into the water or discharged via wastewater.

2.07.P-Th059 Toxicity of Arsenate and Arsenite to Coral Species *Acropora cervicornis* and *Orbicella faveolata*

*Cailey Elise Dorman[1], **Dorothy-Ellen Abigail Renegar**[2], Ellen Regina Englert Skelton[1], Amy C Hirons[1] and Dimitrios G Giarikos[1], (1)Nova Southeastern University, United States, (2)Dept. of Marine and Environmental Science, Nova Southeastern University, United States*

Port Everglades is a large seaport in Fort Lauderdale, Florida, located adjacent to the coral communities at the northernmost end of the Florida Reef Tract. There are questions regarding how resuspended sediments from the planned dredging and expansion of the port could impact nearby coral reefs. Numerical sediment quality assessment guidelines as well as threshold effect levels (TELs) and probable effects levels (PELs) have been derived for nine metals in Florida coastal waters. A recent study found concentrations of arsenic above TEL (7.24 µg/g) and PEL (41.6 µg/g) values in the port s sediments. Arsenic enters coastal waterways through anthropogenic activities and natural sedimentary processes. In corals, exposure to arsenic-contaminated sediments or solubilized arsenic may disrupt vital biological functions and symbiotic relationships, leading to coral bleaching and mortality. To assess the possible effects of soluble arsenic exposure on adjacent reef systems, the acute toxicity of arsenic species arsenate (As(V)) and arsenite (As(III)) were tested with coral species *Acropora cervicornis* and *Orbicella faveolata* using 96-hour static renewal assays. Each exposure assay included six treatments, consisting of five concentrations (ranging from 0.06-5 mg/L for As(V) and 0.03-2.5 mg/L for As(III)) and a negative control, with six replicate beakers per treatment. Effects were evaluated based on coral mortality (LC50), coral condition (EC50), and the photosynthetic efficiency of the dinoflagellate symbiont (IC50). Arsenic concentrations were analytically verified. During the exposure assays, arsenate and arsenite were found to induce polyp discoloration and polyp retraction. The three highest concentrations of As(V) solutions resulted in 100% mortality after a 24-hour period, while the highest concentration of As(III) led to 100% mortality after 48 hours. Arsenite, despite being tested at lower concentrations and within a narrower range, exhibited greater toxicity than arsenate. This observation is consistent with prior research conducted on other marine organisms. The results of these experiments provide new data to support management decisions relating to the testing and disposal of arsenic-contaminated sediments in tropical coastal environments.

Disclaimer/Disclosure: Experimental corals were collected and retained under Florida Fish and Wildlife Conservation Commission Special Activity License SAL-24-2609-SRP.

2.07.P-Th060 Coral Reef Research: Identification of Chemical Stressors with Negative Influence on Tropic Costal Ecosystems

***Guido Gonsior**, Gundula Gonsior, Sara Cuellar and Maren Dill, GG BioTech Design, Germany*

Coral reefs act as natural barriers that protect coasts from erosion and storm damage and reefs provide an important source of food through fisheries and other marine resources. Beside these corals also contribute to carbon sequestration by absorbing CO2 from the atmosphere and storing it in the form of limestone. Also, tourism based on coral reefs is an important source of income for many countries.

Overall, coral reefs are essential to the health of the oceans and the well-being of the people who depend on them. The protection and conservation of these ecosystems is therefore of paramount importance. The deterioration of water quality in coastal waters is jeopardising marine fauna. The highly sensitive corals in particular are under increasing pressure from industrial wastewater, fertilisers and pesticides from agriculture, as well as from cosmetics.

However, up to now, less focus was given on the pharmaceutical which were identified to have a huge effect on ecosystems. Therefore, first studies were initiated to clarify potential issues. We present data of effects from selected pharmaceuticals (e.g., Valsartan, Diclofenac) on coral eco systems.

2.07.P-Th061 Dietary Markers and Contaminant Trends in Eastern Beaufort Sea Belugas: Exploring the Impact of Prey Shifts on PCBs and PBDEs

***Laura Zeppetelli-Bedard**[1], Emily Choy[2], Magali Houde[3], Lisa Losetto[4] and Jonathan Verreault[1], (1)Environmental Toxicology Research Center, Department of Biological Sciences, University of Quebec at Montreal, Canada, (2)Department of Biology, McMaster University, Canada, (3)Environment and Climate Change Canada (ECCC), Gatineau, Canada, (4)Institute of Ocean Sciences, Fisheries and Oceans Canada, Canada*

The Eastern Beaufort Sea (EBS) beluga is one of Canada s largest populations and is ethically harvested by the Inuvialuit communities in the Northwest Territories. Climate change in the Arctic has been linked to a potential shift in diet from mainly Arctic Cod to Capelin, which may also result in a decline in body condition of belugas, especially for juvenile males and females. However, how this climate-induced prey shift may impact the animal s exposure to environmental contaminants remains unclear. Given recent observations of changes in the diet of EBS belugas, this study aimed to explore the relationships between the diet (as estimated by dietary fatty acid (FA) markers) and concentrations of polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) in their blubber over 22 years. Specific objectives were to evaluate temporal trends of these contaminants as well as their relationships with specific FA dietary markers (20:1n-7, 20:1n-9, 20:4n-6, 20:5n-3, 22:1n-11 and 22:6n-3) and principal components derived from FA signatures. Our results highlighted no significant change in blubber PCB and PBDE concentrations between 1995 and 2017. However, concentrations of both PCBs and PBDEs peaked in blubber samples in 2014, coinciding with a low Arctic Cod biomass and the lowest recorded body condition of belugas during the same year. Moreover, several monounsaturated FAs (20:1n-7, 20:1n-9, 22:1n-11) were positively correlated with PCB concentrations, whereas specific polyunsaturated FAs (20:4n-6 and 22:6n-3) were negatively correlated. We also observed that principal components derived from FA signatures were correlated with blubber PCB concentrations. PBDE data are currently undergoing analysis, but we predict similar relationships with FA markers as this class of contaminants exhibits comparable physico-chemical properties. These results suggest that dietary markers may be valuable predictors of PCB and potentially PBDE exposure in EBS belugas. Our observations also hint towards a complex connection between diet shifts, decreasing body condition and contaminant exposure in EBS belugas and underscores the necessity for further research and monitoring of contaminants in Arctic marine mammals.

2.07.P-Th063 Comparison of Metallic Concentrations in Two Breeding Colonies of the Endangered African Penguin (*Spheniscus demersus*)

Nicole Van Gessellen[1] *and Hindrik Bouwman*[2]*, (1)North-West University, South Africa, (2)Zoology, North-West University, South Africa*

The African penguin, *Spheniscus demersus*, is endemic to the southern African coastline. The IUCN (International Union for Conservation of Nature) has recently listed them from Endangered to Critically Endangered due to their significant decrease in numbers and their continual shifting of main breeding concentrations. Their decline is attributed to factors such as low fishing stock through overfishing, oil pollution, climate change, and displacement from previous breeding areas through human and predator disturbance. In this study, we examine metal pollution as a potential contributor to the decline of *S. demersus*. This was achieved by determining whether their egg content and eggshells could be used as indicators of metal pollution. We collected eggs from Bird Island and Robben Island and measured 20 metallic elements in egg content and eggshells separately.

2.07.P-Th064 Tracing History of Microplastic Pollution and Associated Environmental Changes by Using Fjord Sediment Archives

Karin Mattsson[1]*, Irina Polovodova Asteman*[2]*, Joachim Sturve*[3]*, Pere Masque Barri*[4] *and Marc Metian*[5]*, (1)Environment Laboratories, International Atomic Energy Agency, Principality of Monaco & Department of Marine Sciences, University of Gothenburg, Sweden, (2)Department of Marine Sciences, University of Gothenburg, Sweden, (3)Department of Biological & Environmental Sciences, University of Gothenburg, Sweden, (4)School of Sciences & Centre for Marine Ecosystems Research, Edith Cowan University, Australia, (5)Environment Laboratories, International Atomic Energy Agency, Principality of Monaco, Monaco*

Plastic particles pose a significant threat to the marine environment. Plastics will eventually degrade, breaking down and creating smaller-sized particles, so-called microplastics. In the ocean, sooner or later microplastics will sink and end up on the sea floor. Therefore, marine sediments are an important reservoir for microplastic (MP) accumulation. By combining radiometric dating of sediment cores with the extraction of MPs from different core intervals representing different time periods, the rate of plastic accumulation over time can be determined.

In this study, we collected sediment cores in the Hakefjord, in proximity to Stenungsund, a small town on the Swedish west coast and home to Sweden's largest producer of plastic pellets. There are two manufactures: one is producing polyethylene (PE) and the other one is producing polyvinyl chloride (PVC) pellets. The production of PE started in 1963 and had a constant production increase since then. Today approximately 0.75 million tonnes of PE pellets are produced yearly, which corresponds to 5% of the European market. The PVC industry has been in the area since 1968, and now they produce around 0.23 million tonnes of PVC pellets yearly.

Based on the radiometric dating by 210Pb, 137Cs and 226Ra, the sediment intervals taken in 2cm resolution are pooled according to their age. Particles are separated and sorted into size classes; >300 um, 100-300 um, and 30-100 um. Particles are identified with Fourier-transform infrared spectroscopy (FTIR) and Raman microscopy. By linking amount of MPs in the sediment to temporal industrial development, it is possible to track the emission of plastic pellets since the production started. Production volume and allowed emission rates have changed over the years and we aim to define the link between the two by using sediment archives.

Linked to the development of plastic industries in the fjord, we are also studying potential changes in benthic biodiversity by looking at meiofauna (metazoans and foraminifera) in the sediment cores by using conventional morphological methods and environmental DNA (eDNA). eDNA refers to whatever genetic material that can be recovered from an environmental sample. The species composition is estimated by metabarcoding based on molecular markers. In foraminiferal analysis, we study potential incorporation of small micro- and nanoplastics in the shell matrix by using SEM-Raman and how it changed over time.

2.07.P-Th065 The Impacts of Microplastic Ingestion on Zooplankton Lipid Physiology and Ecosystem Functioning: A Case Study on Arctic Copepods

Alena Sakovich*[1], *Clara Manno*[2] *and Erin McClymont*[3], *(1)British Antarctic Survey/Durham University, United Kingdom, (2)British Antarctic Survey (BAS), United Kingdom, (3)Durham University, United Kingdom

The accumulation of plastic waste in marine environments, particularly microplastics (MPs), presents a critical environmental challenge. MPs are pervasive across marine ecosystems, from surface waters to deep-sea sediments. Extensive research has highlighted their hazardous nature due to their bioavailability, capacity to vector pathogens, and potential to adsorb and transfer toxic substances. Zooplankton, as a pivotal component of aquatic ecosystems, is particularly vulnerable to MPs, which readily integrate into marine trophic chains, posing ecological risks through ingestion, bioaccumulation, and trophic transfer. These risks are particularly acute in Arctic marine ecosystems, where heightened vulnerability to climate change and other stressors amplifies their impact on biota.

Among arctic zooplankton, copepods are of particular interest due to their crucial role in marine biogeochemical processes, such as carbon sequestration. One of the mechanisms in this process is the lipid pump, where copepods accumulate energy-rich lipids during their active feeding seasons and subsequently transport these lipids to deeper ocean layers during overwintering and diapause. Despite their importance, the potential effects of MPs ingestion on the lipid metabolism of Arctic copepods remain underexplored. Meanwhile, feeding experiments with MPs can provide critical insights into how their ingestion may disrupt lipid metabolism, which is essential for energy storage in these ecologically significant copepod species.

This study investigated the effects of MPs ingestion on Arctic copepods Calanus hyperboreus during feeding experiments, where specimens were exposed to varying concentrations of MPs under conditions of food availability and deprivation The study examined changes in lipid metabolism and elemental composition (carbon and nitrogen content, along with isotopic signatures) as indicators of nutritional stress and physiological disruption. By analyzing shifts in lipid profiles of copepods along with their carbon and nitrogen content across different treatment groups, this research provides insights into how MPs ingestion affects the nutritional quality and energy storage of this key Arctic species.

The results of this study are expected to elucidate the physiological impacts of MPs ingestion on Arctic copepods and their broader ecological consequences of the Arctic marine ecosystems carbon sequestration processes.

2.07.P-Th066 Effects of Ammonia and Methanol Spills on Zooplankton in East Baltic and Bothnian Bay

Sinja Rist, Marja Koski and ***Themistoklis Konstantinopoulos****, DTU, Denmark*

The shipping industry is shifting to greener fuels, like ammonia (NH_3) and methanol (MeOH), following the goals of the International Maritime Organization (IMO) to substantially reduce greenhouse gas (GHG) emissions. This shift imposes the risk of spilling these substances into the marine environment with potential adverse effects on marine food webs. However, the lethal and sub-lethal effects, threshold concentrations or cumulative effects with other stressors on plankton communities are not known, not even in highly trafficked areas like the Baltic and North Seas. Given the significance of zooplankton in energy transfer within marine food webs, it is crucial to understand their response to NH_3 and MeOH spills under different environmental conditions.

In-situ experiments were performed in East Baltic and Bothnian Sea, during the COMBINE 3 scientific cruise on R/V Aranda. NH_3 effects were tested on seven zooplankton species under 24h. Temora longicornis, Eurytemora affinis, Limnocalanus macrurus, Thermocyclops spp., Acartia bifilosa, Bosmina longispina, and daphnia cucculata. Mortality was the endpoint of the experiments, and 5 concentrations of the chemicals were tested in each experiment. Measurements of carapace and total length was taken from all subjects. Moreover, the fecal pellet production was measured for all copepod species, and females carrying eggs of E. affinis were isolated in well plates for hatching success. Data was analyzed with the R statistical software and dose-response curves were fitted to the data.

Our preliminary results on the environmental conditions show a distinction between the northern Bothnian bay and the east Baltic water. LC50 for ammonia was between 0.5 and 1.5 for all species but Bosmina spp. which had low mortality in all tested concentrations. All copepods were negatively affected Fecal pellet production was affected in all copepods but cyclopoids. The hatching success of E. affinis was significantly affected by the tested concentrations.

Our results indicate that potential spills of ammonia and methanol will affect the examined ecosystems in areas were concentrations reach the tested concentrations. The risk of spills will increase as more ships shifting to Ammonia and Methanol fuels. Moreover, our study suggests that risk assessments should be performed in situ, as different environmental parameters might affect the outcome of Ammonia or Methanol loading in marine ecosystems.

Disclaimer/Disclosure: The project is partially funded by Orients Fund.

2.07.P-Th068 Toxicological Assessment and Environmental Distribution of Tetracene Along the Yellow Sea Coast

Junghyun Lee[1], *Seongjin Hong*[2], *Shin Yeong Park*[3], *Jiyun Gwak*[2], *Taewoo Kim*[3], *Seo Joon Yoon*[3] *and Jong Seong Kim*[3], *(1)Kongju National University, Republic of Korea, (2)Chungnam National University, Republic of Korea, (3)Seoul National University, Republic of Korea*

The aryl hydrocarbon receptor (AhR) agonist, tetracene is a highly toxic compound with notable environmental risks. This study employed various bioassays to evaluate its biological effects and tracked its environmental presence along the Yellow Sea coastline. Toxicity evaluations encompassed general (e.g., Microtox, algal assays) and specific effects, such as phytotoxic responses in algal species, glucocorticoid receptor activity (via GR-CAFLUX), and estrogenic activity, alongside endpoints for reactive toxicity, including immobilization in copepods and fish embryo mortality. Tetracene was found to significantly activate the glucocorticoid receptor without eliciting estrogenic responses. Exposure induced algal growth suppression (EC50: 1.31 2.39 mg L?¹) and copepod mortality (EC50: 0.52 mg L?¹), with Cyprinodon variegatus exhibiting acute lethality (LC50: 1.2 mg L?¹). Monitoring results revealed concentrations surpassing 4,000 ng g?¹ (dry mass) in Nantong, with levels above 200 ng g?¹ (dry weight) in Qinhuangdao and Huludao. These findings emphasize tetracene s ecological risks and highlight the need for targeted environmental management and remediation efforts.

Disclaimer/Disclosure: This study was supported by grants from the Ministry of Oceans and Fisheries of Korea (RS-2024-00417889).

2.07.P-Th069 Alkylation and Halogenation have Position-dependent Effects on PAH Potency for Aryl Hydrocarbon Receptor Activation and Early Life-stage Toxicity in Zebrafish (*Danio rerio*)

Justin Dubiel[1], *Emily Mertens*[1], *Vann Lynne Boyte*[2], *Lauren Eagon*[2], *Hannah Hartmann*[2], *Zhe Xia*[3], *Gregg Tomy*[3], *Steve Wiseman*[1] *and Jonathon Doering*[2], *(1)University of Lethbridge, Canada, (2)Louisiana State University, United States, (3)University of Manitoba, Canada*

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental chemicals originating from natural and anthropogenic sources. Certain PAHs induce toxicity by dysregulating the aryl hydrocarbon receptor (AhR) which has been linked to dose-dependant mortality and developmental malformations such as pericardial and yolk sac edemas, and spinal curvatures. The US Environmental Protection Agency (EPA) has designated 16 unsubstituted parent PAHs as priority pollutants. These EPA 16 PAHs have become widely accepted as standard test compounds and have been the focus of most PAH toxicity studies to date. As a result, the effect of substitutions such as alkylation and halogenation on PAH toxicity are not well characterized despite substituted PAHs being ubiquitous in some environmental matrices. This research aims to (1) characterize the effects of halogenation or alkylation on potency for dysregulating the AhR in vitro, and (2) determine whether differences in potency for in vitro AhR activation result in differential embryotoxicity. Potency for activation of the zebrafish (*Danio rerio*) AhR2 was quantified using a standardized in vitro AhR transactivation assay. Toxicity was assessed by exposing freshly fertilized zebrafish to each parent, alkylated, or halogenated PAH via microinjection. First, benz[a]anthracene (BAA) and three alkyl homologues: 4-MBAA, 8-MBAA, and 7,12-DMBAA were tested. Alkylation had a position-dependent effect on potency for AhR activation. The most potent alkyl PAH was 8-MBAA with a 6.9-fold increase in potency, while 4-MBAA increased potency by 1.4-fold and 7,12-DMBAA decreased in potency. Similar relative potencies were observed in vivo. Halogenation also had position-dependent effects on potency for AhR activation. Anthracene, the parent compound did not activate the AhR of zebrafish, but 9/11 halogenated PAHs did with EC50s as high as 1100 nM, and as low as 7 nM which is as potent as the prototypical AhR agonist TCDD (6 nM). The rank order of potency for early life-stage mortality matched the rank order of potency for AhR activation. These results show that substitution of PAHs can increase the potency of PAHs, and in vitro transactivation assays can be used to accurately investigate the effects of substitution on potency. Due to the abundance of PAHs in the environment and the potential for increased toxicity inclusion of substituted PAHs in future research could be essential to accurately assess risks posed by PAHs.

2.07.P-Th070 ONE-BLUE Project: Integrated Assessment of Contaminants of Emerging Concern (CECs) and Their Impacts in Marine Ecosystems: Mediterranean Case Study

The Mediterranean Sea is home to thousands of marine species, many of which are unique to the region and found nowhere else on Earth. Despite covering less than 1 percent of the world's ocean surface, the Mediterranean harbours 10 percent of all known marine biodiversity, making it an ecosystem of exceptional ecological significance. However, it is also among the most populated, as well as polluted and threatened marine areas in Europe, facing pressures from coastal urbanization, intense maritime traffic, plastic pollution, emerging contaminants, and climate change. Together, these factors are compromising the health and resilience of this fragile and vital ecosystem.
To address these concerns, the Mediterranean has been chosen as a key case study for the European ONE-BLUE project. This collaborative initiative seeks to close critical knowledge gaps on the presence, behaviour, and impacts of CECs in the marine environment through a multidisciplinary approach that integrates targeted and non-targeted chemical analyses, bioassays, and microbial assessments. The findings will contribute to a comprehensive understanding of how these contaminants move through and affect marine ecosystems.
The Mediterranean case study includes various study areas across the Spanish coast, the Tyrrhenian Sea, the northern and central Adriatic Sea, the Ionian Sea, and the Aegean Sea. Sampling areas cover diverse environments such as sites near fish and shellfish farms, industrial zones, shipyards, domestic and industrial wastewater treatment facilities, and river estuaries. Water and sediment samples are collected along the coastline and at offshore stations across various depths. Chemical analyses and toxicological tests will be conducted to assess the profile and concentration of CECs in both the water column and sediments.
Additionally, biota samples from different levels of the marine food web will be examined, including plankton (collected using 53, 125, and 200-micron nets), molluscs, fish, stranded sea turtles, and stranded marine mammals. Temporal trends in synthetic chemicals will also be studied in stranded cetacean samples from 2022 and stranded turtle samples from 2012, helping to assess the impact of mitigation measures and the phase-out of specific pollutants. Finally, to complete the analysis of the marine food chain, blood samples from Scopoli's shearwater nestlings will be collected just before their fledging period at six colonies across the Mediterranean Sea.

Disclaimer/Disclosure: This research is part of the ONE-BLUE project, which has received funding from the European Union s Horizon Europe research and innovation program under grant agreement No 101134929. The views expressed in this abstract are those of the authors and do not necessarily reflect the official opinion of the European Commission.

2.07.P-Th071 Spatial and Temporal Distribution of Metals in the Salt River Catchment, Cape Town
***Zikhona Menze**, SETAC member, South Africa*
The Liesbeek and Black Rivers are two major urban tributaries of the Salt River. The latter enters the ocean at Paarden Island, Table Bay. A multitude of pollution sources are found along the banks of these rivers, including industries, houses, sewage treatment plants, golf courses and informal settlements. The catchment has been severely modified and canalized, increasing flooding events and sediment loads downstream. This catchment is seen as potentially in the worst ecological condition of all Cape Town catchments and its condition is seemingly deteriorating consistently. However, the current degree of pollution is unknown for this catchment. This study investigates the spatial distribution of metals as well as temporal distribution, through comparison of new data with previous data from 2006, and comparison of wet and dry seasons. Sediment samples were acid digested and a range of metals were analysed with an ICP-MS. Preliminary results show that sections of both the Liesbeek and Black Rivers are heavily polluted with metals (e.g., Al and Fe) and that metal levels have significantly increased since 2006 due to increases in land use. Metal concentrations were also generally higher during the dry season, most likely due to the slower current. The Salt Rive itself has proven difficult to study as it is entirely canalized, which indicates that potentially high loads of polluted sediment are carried straight to the lagoon. This study will form an

important basis for further studies on the impacts of aquatic pollution on freshwater, coastal and marine biota.

2.07.P-Th072 Ecological Risk Assessment Post Tourist Season at the Croatian UNESCO Heritage Island of Hvar: Student STEM Research Immersion Program Promotes Environmental Stewardship and Community Outreach

Nikol Petric[1]*, Kristie Evenson*[1]*, Nela Tadic*[1]*, Noah Bozinovic*[2]*, Chris Stransky*[3]*, Damian Shea*[4]*, Chris Witte*[2] *and Goran Bozinovic*[2]*, (1)Pharos International Institute for Science, Arts and Culture, Croatia, (2)Boz Life Science Research and Teaching Institute, United States, (3)GEI Consultants, United States, (4)Statera Environmental, Inc., United States*

To assess the potential adverse anthropogenic effects on sea water quality at the end of the tourist season, a comprehensive ecological risk assessment was initiated at the Island of Hvar, Croatia in September 2024. Composite Integrative Passive Samplers (CIPS) were deployed for ten days at 16 sites that included two main town center bays, several public beaches, two ferry ports, boat-maintenance bay, a popular dive center, and secluded beaches along the 65-km island, which is one of the most popular summer tourist destinations in the world and a UNESCO World Heritage site. CIPS captures both water- and lipid-soluble contaminants, allowing measurement of time-weighted concentrations of industrial and persistent organic pollutants; the quantitative targeted chemical analysis using Liquid chromatography mass spectrometry is used to characterize over 400 known chemicals, including many carcinogens, mutagens, and persistent organic industrial pollutants: polychlorinated biphenyls, polyaromatic hydrocarbons, plasticizers, pesticides, herbicides, and plasticizers. Besides sea water chemical profiling and standard sea water measurements (pH, salinity, temperature, dissolved oxygen, conductivity / salinity), we collected native species of Mediterranean mussels (Mutilus galloprovincialis) and sea urchin (Arbacia lixula) within 25 meters of each sampling site. Animal tissues will be used to characterize body burdens of targeted chemicals and correlate the data with the site-specific CIPS chemistry profiles; moreover, animal tissues will be utilized for metagenomic analysis, quantifying the presence of bacteria, viruses, parasites, and other microbes. Pending our chemistry and metagenomics results, several animal tissues collected at specific sites will be used for selected gene expression profiling to identify biomarkers of exposure to complex industrial chemical mixtures. Our goal is to characterize and quantify the human activity impact on ecology and sea water quality at this popular and unique island.

Disclaimer/Disclosure: This pilot project has been generously supported by the Matko and Vera Milicic Foundation, Mayor s offices from Hvar and Stari Grad, and the Island of Hvar Nautical Center. Funding for research is provided by Statera, Inc (North Carolina, U.S.), and Boz Life Science Institute (San Diego, U.S.).

2.07.P-Th073 Effects of Surfactants on *Pelagia noctiluca* Ephyrae, a Promising Model Organism in Marine Ecotoxicology

Valentina Ferrari[1]*, Lucas Leclere*[2]*, Daniela Prevedelli*[3] *and Elisa Bergami*[3]*, (1)Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Italy, (2)Sorbonne University, CNRS, Oceanological Observatory of Banyuls-sur-Mer, France, (3)Department of Life Sciences, University of Modena and Reggio Emilia, Italy*

The effects of marine pollutants are usually assessed with standard ecotoxicity tests relying on a limited number of marine model invertebrates. Expanding the range of sensitive and ecologically relevant species is important to represent the full impacts of pollutants in marine ecosystems. Cnidarians are widely distributed in oceans and integral components of marine food webs and, among them, jellyfish are exposed to pollutants via multiple pathways, representing promising models for ecotoxicity studies. So far, few jellyfish species have been investigated for this purpose, focusing on the ephyra stage as suitable due to its susceptibility to toxic compounds.

Here we explore the use of the mauve stinger *Pelagia noctiluca* (ephyra stage) as a new model organism in ecotoxicology, by evaluating its responses to two common surfactants: Sodium Dodecyl Sulfate (SDS) and Tween 20.

After setting the optimal test conditions through preliminary tests, *P. noctiluca* ephyrae (10 ind/well) were exposed for 48h to reference toxicants (SDS: 0.1-50 mg/L, Tween 20: 0.0001-10%). At 24h and 48h, both lethal (mortality) and sub-lethal endpoints (behavior) were evaluated. Swimming behavior was determined both quantitatively, as the number of pulsations made by each ephyra within one minute, and qualitatively by tracking the ephyrae swimming path within the well and classifying the type of lappet movements (complete and wide contraction, altered contraction or immobility).

After 24h of exposure to SDS, 100% of mortality was observed at the concentration of 50 mg/L, whereas after 48h the same effect occurred at 10 mg/L. For Tween 20, all the ephyrae were dead at 0.1% after both

24h and 48h of exposition. LC50 values for SDS were 7.5 ± 0.6 mg/L and 6.1 ± 0.8 mg/L after 24h and 48h, respectively, while for Tween 20 LC50 values corresponded to 0.045 ± 0.00% at 24h and 48h. A significant reduction in the pulsation rates was found in the ephyrae exposed to low concentrations of both surfactants. Alterations in the swimming quality were further recorded with altered lappet contractions or ephyrae pulsations without movement.
Our findings show acute toxicity of SDS and Tween 20 to P. noctiluca. The high sensitivity of the ephyrae of this species compared with other established model organisms (e.g., Artemia franciscana, *Daphnia magna* and *Amphibalanus amphitrite*) underscore their potential use in ecotoxicological research, improving the impact assessment of pollutants on marine life.

2.07.P-Th074 Ecotoxicological Effects of Metal Mixtures from Offshore Wind Turbine Galvanic Anodes on Blue Mussels *Mytilus edulis*

***Moses Ndugwa**[1], Bavo De Witte[2], Lieven Bervoets[3] and Gudrun DeBoeck[3], (1)University of Antwerp, Antwerpen, Belgium, (2)ILVO, Belgium, (3)University of Antwerp, Belgium*
Moses Ndugwa1, Bavo DeWitte2, Lieven Bervoets1 and Gudrun De Boeck1
1University of Antwerp, Department of Biology, ECOSPHERE, 2020 Antwerp, Belgium.
2Flanders Research Institute for Agriculture, Fisheries and Food, Jacobsenstraat 1, 8400 Oostende, Belgium.

Offshore wind energy is a pivotal strategy for achieving carbon neutrality in electricity generation. Offshore locations offer the advantages of higher wind speeds and reduced spatial competition with human activities compared to onshore sites. However, the expansion of offshore wind farms to meet the 2050 carbon-neutral targets introduces potential pressures on marine ecosystems, particularly through trace metal emissions from galvanic anodes cathodic protection anti- corrosion systems. While zinc and aluminum are the primary metal ions emitted, other trace metals such as cadmium, lead, indium and gallium have also been reported as key components in these alloys. Despite well-documented toxic effects of zinc, aluminum, cadmium, and lead on marine organisms, such as oxidative stress, reduced growth potential, and DNA damage, little is known about the toxicity of gallium and indium, either alone or in combination with other metals. In a laboratory experiment, we are investigating ecotoxicological effects of a mixture of trace metal elements (Al, Zn, Cd, Pb, Ga, and In), emitted from galvanic anodes on the blue mussels *M. edulis*. Thereby the mussels will be exposed to increasing dissolved metal concentrations, achieved by dissolving pure chloride metal salts in relative proportions to the composition of aluminum based galvanic anodes. The lowest exposure concentrations will be comparable to those currently obtained around wind farms in the North Sea. Metal bioaccumulation, energy stores, oxidative stress enzyme activity, metallothionein induction, and expression of defense-related genes in gill and digestive tissues will be assessed after 1, 3, 7, and 14 days. Preliminary results after 7 days exposure show indication of some physiological effects of the exposed metals. This study will contribute to understanding the biological impacts of cumulative metal emissions from offshore wind farm anodes, enhancing environmental models and guiding sustainable planning to mitigate ecological effects while balancing offshore wind energy s socio-economic and environmental benefits.

2.07.P-Th075 Effects of Underwater Noise on Behavior and Physiological Stress Responses in Baltic Sea Blue Mussels (*Mytilus spp.*)

***Raisa Turja**[1], Rami El Dairi[1], Viivi Poyhonen[2], Okko Outinen[2] and Kari K. Lehtonen[2], (1)Finnish Environment Institute (SYKE), Finland, (2)Finnish Environment Institute (Syke), Finland*

Underwater noise pollution is a growing concern in marine ecosystems, with potential effects on the physiology and behavior of marine organisms. In the Baltic Sea, blue mussels (*Mytilus spp.*) are essential habitat-forming species that may be vulnerable to such disturbances. This study aimed to investigate the effects of vessel noise on blue mussel behavior and physiological stress responses, focusing on simulated traffic scenarios.
Baltic Sea blue mussels were exposed to two different noise treatments in controlled aquaria for a three-day period: (1) moderate boat traffic, and (2) intense boat traffic.
These treatments involved playback of field-recorded boat passage noise, presented at randomized intervals interspersed with periods of ambient noise. Traffic rates were derived from real-world data, combining AIS-based vessel tracking and hydrophone recordings from the Archipelago Sea. Behavioral responses were evaluated by continuously monitoring valve gape activity. Biochemical stress responses were evaluated by analyzing antioxidant enzyme activities as indicators of oxidative stress, lipid peroxidation as a marker of cellular oxidative damage, and acetylcholinesterase (AChE) activity as an indicator of neurotoxic effects in both exposed and control mussels.
Mussels exposed to noise treatments exhibited significant changes in valve gape behavior. Prolonged valve gape closure was observed during exposure periods with frequent boat passages, while periods

containing more randomly occurring boat passages induced more variable gape patterns, suggesting differential responses to noise type and intensity. Observed biochemical responses suggest that noise exposures trigger significant cellular stress. Additionally, change in AChE activity may indicate a neurophysiological response possibly linked to both oxidative stress and valve gape behavior.
The observed behavioral and biochemical responses suggest that underwater noise, even at varying intensities and patterns, induces stress in blue mussels, likely affecting their health and ecological role. These findings underscore the importance of recognizing noise pollution as a significant stressor in the Baltic Sea marine environment. They enhance understanding of how noise can contribute to cumulative impacts that may threaten the stability of the ecosystem.

2.07.P-Th076 Comparative Environmental Health Status Assessment Through Cell and Tissue Level Biomarkers in Wild Mussel and Oyster Populations from Locations with Different Anthropogenic Impact in the Basque Coast
***Itziar Arranz-Veiga**, Benat Zaldibar, Irune Valenciano, Xabier Lekube, Urtzi Izagirre, Manu Soto and Denis Benito, CBET Research Group, Department of Zoology and Animal Cell Biology, Faculty of Science and Technology, Research Centre for Experimental Marine Biology and Biotechnology PIE, University of the Basque Country UPV/EHU, Spain*
In the last decades, the distribution of Mytilus spp. in the Atlantic Ocean has considerably changed, and different mortality events have been reported in the area leading to a decrease in mussel population possibly due to multifactorial reasons (i.e., parasites prevalence, global warming, alien species pressure, anthropogenic impact among others). This raises the need for a change in the employed sentinel organisms, and oysters (Magallana gigas) have been considered a suitable alternative to mussels. Within this context, the aim of the present study is to determine if general stress cell and tissue level biomarkers are comparable in Magallana gigas and Mytilus galloprovincialis for environmental health assessment. For this purpose, histological, histochemical and chemical measurements were carried out in mussels and oysters gathered in three different sampling points of the coast of the Basque Country. Two of these sites are located at the mouth of the Bilbao estuary (Arriluze and Arrigunaga), which has been historically subjected to industrial wastes and presents a poor environmental quality, while the other site, Plentzia, is located in Butroe estuary, considered for this study as a reference site with low to moderate levels of pollutants. Preliminary results show that some of the biomarkers previously measured in mussels can be similarly applied in oysters, like atrophy of the digestive epithelium, connective to digestive tissue ratio or lipofuscin volume density, whereas others like adipogranular cell density, neutral lipid volume density and lysosomal biomarkers cannot be directly compared and need to be studied and adapted or modified. Additionally, mussels show higher number and more relevant histopathological alterations, such as greater prevalences of granulocytomas and haemocytic infiltrations. Overall, a worse health status is noted at the estuary of Bilbao compared to Plentzia, with higher levels of atrophy and lipofuscins; which is consistent with a higher presence of pollutants. Currently, knowledge on the responsiveness of oyster biomarkers is more limited than in mussels and further research is needed to establish baseline values to be considered as suitable candidates for their substitution as sentinel organisms in the Basque Coast.

Disclaimer/Disclosure: Funded by Basque Government Consolidated groups (IT1446-22, IT1743-22).

2.07.P-Th077 Acute Toxicity of Lithium to Marine Organisms of Different Biological Complexity
***Laura Noguera**[1], Sara Castano[2], Tamer Amr Hafez[1], Nerea Garcia-Velasco[1], Pamela Ruiz[1] and Urtzi Izagirre[1], (1)CBET Research Group, Department of Zoology and Animal Cell Biology, Faculty of Science and Technology, Research Centre for Experimental Marine Biology and Biotechnology PIE, University of the Basque Country UPV/EHU, Spain, (2)University of the Basque Country UPV/EHU, Spain*
Lithium (Li) is an alkali metal of emerging concern, mainly due to its increasing use to produce Li-ion batteries. However, little knowledge is available regarding its effects on marine life. In this work, the acute toxicity of Li was determined in different key marine species (bacteria *Vibrio fischeri*, copepod *Acartia tonsa*, shrimp *Palaemon Elegans* and sea urchin *Paracentrotus lividus*). Experimental concentrations were selected according to Fibbonacci scale: 0, 1, 5, 13, 34, 89, 233, 610 and 1597 mg/L. Li toxicity by Microtox® assay was based on the reduction of the bioluminescence in *V. fischeri* after 15 minutes of exposure. Copepods and shrimps were used for the exposure experiments in three replicates of 5-8 individuals each and mortality was checked daily for 2 days (copepods) and 4 days (shrimps) for the calculation of the lethal concentration (LC) values. Sea urchin embryos were exposed for 48 h and the size increase of larvae and their effect concentration (EC) values were calculated. Malformations were also

recorded and integrated in a Toxicity Index (TI), depending on the severity. Finally, the capacity to undergo the developmental program was studied by the application of different indexes. Based on the results obtained, the EC50 value obtained by the Microtox® assay was 3012.98 (CI: 2741.76 3311.035) mg/L, values much higher than environmentally relevant concentrations in oceans (several hundred µg/L). Copepods showed the highest sensitivity with an LC50 of 22.433 (CI: 11.508 38.942) mg/L after 48h. The EC50 values obtained for the sea urchin embryos revealed that the TI (43.629 (CI: 33.430 57.579) mg/L) presented a higher sensitivity than size increase (89.959 (CI: 58.437 136.266) mg/L). Finally, the development test results showed that high Li concentrations (233 and 610 mg/L) stopped development at morula, or even at cleavage stage (1597 mg/L). Upon lower levels (5, 13, 34 and 89 mg/L), more embryos reached pluteus stage, although malformations were detected, thus, sub-lethal levels should not be underestimated. These findings give insight into the toxicity of Li to different marine species and contribute to assess possible effects at different taxon to understand the sensitivity of species to this emerging pollutant. Moreover, the disparity in results between species shows the need to further investigate the effect of Li, as well as potential changes in sub-lethal/ chronic exposure scenarios.

Disclaimer/Disclosure: This work was funded by the Basque Government (Grant to Consolidated Research Group, CBET +, IT1743-22) and Laura Noguera is a recipient of a pre-doctoral grant from the University of the Basque Country (UPV/EHU).

2.07.P-Th078 Impact of Polycyclic Aromatic Compounds and Oil Exposure on the Righting Behavior of Two Gastropod Species
***Danielle Philibert**[1] and Benjamin Patrick de Jourdan[2], (1)Huntsman Marine Science Center, Canada, (2)Huntsman Marine Science Centre, Canada*
Of the 1000s of components within crude oil, polycyclic aromatic compounds (PACs) are thought to be the primary driver of toxicity. Due to the complexity of a crude oil spill, stakeholders must rely on mathematical models to predict and assess the impacts of a spill on aquatic life. Oil spill models rely on species sensitivity distributions (SSDs) to determine species at risk if exposed, and there is very limited data available on the sensitivity of gastropods to petroleum contaminants. Distributed throughout the North Atlantic, periwinkles snails are found in high numbers in intertidal zones, and field observations made during the Sea Empress and Amoco Cadiz oil spills suggest that they may be sensitive to hydrocarbon exposure. Abalone are a slow growing herbivorous gastropod that historically served as a subsistence food for indigenous peoples along the west coast of North America. Due to overfishing, and pressure from disease and predator population booms, populations of abalone have declined significantly, and there is limited data available to determine if PAC pollution could be an additional threat. The aim of the study was to generate toxicity data to determine the sensitivity of two gastropod species, the common periwinkle snail (*Littorina Littorea*) and the red abalone (*Haliotis rufescens*) to PACs using a sublethal behavioral endpoint, and to see if the effects observed in single compound exposures are predictive of whole oil effects. The PAC test solutions were generated using passive dosing with polydimethylsiloxane (PDMS) O-rings left to equilibrate in 1L glass jars for 24 hrs. For the oil exposures, water accommodated fractions (WAFs) of crude oil were prepared using a 1 g/L loading in natural seawater with 20 hrs mixing (20% vortex) and 4hrs settling. Adult snails and the juvenile abalone were then exposed for 24 hours in aerated 1L glass jars and were subject to a righting assay. For the righting assay, the gastropods were placed on their back in a crystalizing dish with clean seawater and left undisturbed for 1hr. Results suggests that righting behavior assay was a repeatable and reliable way to test PAC toxicity in gastropods. It was also very sensitive endpoint, and abalone were more sensitive to PAC exposure than the periwinkle snails. The data generated in this study can be used to better understand the sensitivity of gastropods to PAC exposure, and to assess the impact of oil spills on underrepresented test species.

2.07.P-Th079 Marine Environment Impacts from Space Launch Activity
***Imogen Bailes**[1], Isobel Shears[2], Anna Tuulikki Kukkola[2] and Christopher Green[3], (1)Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom, (2)Defra, United Kingdom, (3)DEFRA, United Kingdom*
In recent years, there has been a significant rise in global space launches, with rockets primarily delivering commercial satellite payloads into orbit. While the sector is currently dominated by the US and China, spaceports are emerging within the OSPAR region (North East Atlantic), with active or planned developments in the UK, Norway, Sweden, and other countries. By 2030, several spaceports could be operational, but the exact number remains to be determined. During launch, space launch vehicles jettison various components, such as stage 1 and 2 engines and nose cones (fairings), which can be deposited into the marine environment. Additionally, upon re-entry, further debris from rockets and payloads can be deposited into the ocean. Typically, these jettisoned parts are not recovered, and have the potential to

cause a range of environmental impacts. Current definitions of long-term space sustainability focus largely on the orbital environment, neglecting the Earth-based impacts, particularly those related to the marine environment. Evidence of the environmental effects of space launch activity, particularly concerning marine debris, remains limited and there are significant knowledge gaps. A literature review and interviews with experts in the industry was used to gather insights on the potential impacts from jettisoned rocket parts. Some of the identified impacts include: creation of marine litter from debris, release of contaminants such as fuel and other chemicals (some of which are Substances of Very High Concern under EU REACH), and smothering of organisms on the seabed. There is no global or regional reporting requirement for deposition of rocket parts into the ocean and international instruments such as OSPAR, London Convention/London Protocol and UNCLOS do not specifically address this issue. Options to improve information gathering, reporting, best practices to prevent and reduce marine environmental effects and international cooperation and information exchange should be considered.

2.07.P-Th080 Biomakers Assesment for Matrices Artificially Contaminated with Dichlofluanid

Ana Carolina Feitosa Cruz[1]*, Paloma Kachel Gusso Choueri*[2]*, Guacira de Figueiredo Eufrasio Pauly*[1]*, Bruno Galv o Campos*[1]*, Fernando Perina*[3]*, Ítalo Braga de Castro*[4] *and Denis Moledo de Souza Abessa*[1]*, (1)São Paulo State University - UNESP, Brazil, (2)Santa Cecilia University - UNISANTA, Brazil, (3)Aveiro University, Portugal, (4)Federal University of São Paulo - UNIFESP, Brazil*

Antifouling paints are used to combat biofouling on submerged surfaces. These paints contain biocidal compounds that can be extremely harmful to aquatic ecosystems. Among the different biocides present in antifouling paints, dichlofluanid stands out, also known as N-dichlorofluoromethythio-N', N'-dimethyl-N-phenylsulfamide ($C_9H_{11}Cl_2FN_2O_2S_2$). Little is known about how this active ingredient affect marine organisms. Therefore, it is important that studies on the topic are conducted to evaluate the biological effects of this contaminant. The aim of this study was to evaluate the effect of dichlofluanid at the cellular and biochemical level, using bivalves exposed to seawater and sediment contaminated with this biocide, while also considering sediments with two different concentrations of organic matter. Exposure tests were carried out in water with bivalves species Perna perna, and in sediment with the bivalve Anomalocardia flexuosa. The neutral red retention time assay was used in P. perna, while biochemical biomarkers such as DNA damage, LPO, GSH, GST, EROD, AChE and GPx were analyzed in both species. Particle size, carbonate content and organic matter analyzes were also conducted on the sediments. In water, an effect was observed at higher concentrations in the neutral red assay, indicating a loss of lysosomal stability. For biomarkers, changes were observed in the digestive glands and gills. In sediment, effects were noted in both organs, with more significant changes in sediments with higher levels of organic matter. Based on the results of these studies, environmental concentrations of dichlofluanid are likely to cause effects to the organisms studied.

Disclaimer/Disclosure: FAPESP (2016/02029-4; 2021/06167-0; 2023/09222-8)
FINEP (1111/13; 456372/2013-0).

2.08.P New Developments in Sediment Ecotoxicology and Risk Assessment

2.08.P-Mo157 Effect-Based Trigger Values for a Mixture of Aryl Hydrocarbon Receptor Agonists in Sediments Derived from In Vitro Bioassays

Jiyun Gwak[1]*, Jihyun Cha*[1]*, Junghyun Lee*[2] *and Seongjin Hong*[1]*, (1)Department of Earth, Environmental & Space Sciences, Chungnam National University, Republic of Korea, (2)Department of Environmental Education, Kongju National University, Republic of Korea*

Target chemical analysis is commonly used to monitor persistent toxic substances in the marine environment; however, it cannot assess contamination by unknown compounds. To address this limitation, effect-based monitoring (EBM) utilizes in vitro bioassays to evaluate the biological activity of environmental samples, including the mixture effects of known and unknown compounds. Implementing EBM requires the establishment of effect-based trigger values (EBTs) to differentiate between acceptable and unacceptable levels of persistent toxic substances. While EBTs studies have primarily focused on the water environment, research on sediments remains limited. This study aimed to derive appropriate EBTs for aryl hydrocarbon receptor (AhR) activity in sediments using H4IIE-luc bioassays and to evaluate AhR activity in highly industrialized coastal sediments based on the derived EBTs. The first EBTs method (Criteria 1) was to obtain instrumental analysis data, such as BaP equivalent concentrations, using the predicted no-effect concentration (PNECsediment) values and the relative potency values of 20 individual AhR agonists. The EBTs was calculated by dividing the sum of BEQs by the total number of compounds. PNECsediment values were determined using the KOC values of each AhR agonist and the minimum concentration inducing AhR-mediated potency. The second EBTs method (Criteria 2) was a value incorporating cytotoxicity, which was calculated using the predicted baseline toxicity (IC10) and EC10 values for 20 AhR agonists. The EBTs derived using Criteria 1 was 707 ng BaP-EQ g-1 dw, and the EBTs derived using Criteria 2 was 200 ng BaP-EQ g-1 dw. The AhR activity in sediments from South Korea were evaluated using these EBTs. The BaP-EQbio concentrations in sediments from Ulsan Bay, Lake Sihwa, Masan Bay, Yeongil Bay, and Busan Bay ranged from 610 12,000, 580 1,800, 33,000 45,000, 1,700 220,000, and 1,300 5,400 ng BaP-EQ g-1 dw, respectively. When evaluated using Criteria 1 EBTs, Ulsan Bay, Masan Bay, and Yeongil Bay sediments exceeded the threshold. On the other hand, when evaluated using the Criteria 2 EBTs, 14 coastal sediments exceeded the EBTs. These results suggest the need for further evaluation of AhR activity and continued monitoring of AhR agonists in these regions. Future efforts should include a broader range of AhR agonists in EBTs calculations, preceded by effect-directed analysis studies to identify and characterize additional AhR agonists in sediments.

Disclaimer/Disclosure: This study was supported by grants from the Ministry of Oceans and Fisheries of Korea (RS-2024-00417889).

2.08.P-Mo158 Toxicity Assessment of Freshwater Sediments: Proposing the European Amphipod *Gammarus fossarum* for the Development of New Standardised Bioassays

***Cecile Luc-Rey*[1]*, Anthony Gérard Edouard Mathiron[2], Benoit Ferrari[3], Helene Budzinski[4], Pierre-Louis Hombert[2], Nicolas Delorme[5], Olivier Geffard[5] and Guillaume Jubeaux[2], (1)Biomonitoring Aquatic Environment - BIOMAE and RiverLy - Fonctionnement des hydrosyst mes - INRAE, France, (2)Biomonitoring Aquatic Environment - BIOMAE, France, (3)Swiss Centre for Applied Ecotoxicology (Centre Ecotox), EPFL-ENAC-IIE-GE, Switzerland, (4)Environnements et Paleoenvironnements Oceaniques, Universite de Bordeaux, France, (5)RiverLy - Fonctionnement des hydrosyst mes - INRAE, France*

Freshwater sediments act as sinks for various contaminants, including metals, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and emerging pollutants like pharmaceuticals. These contaminants accumulate over time, posing risks to benthic organisms and creating challenges for sediment management. Addressing this issue is critical for understanding ecosystem health and improving sediment management practices.

This study aims to standardise bioassay protocols for assessing sediment toxicity using the European amphipod *Gammarus fossarum*. The goal is to evaluate the biological effects of contaminated sediments on feeding behavior and reproduction while considering confounding factors of sediments such as granulometry and organic carbon content.

To tackle these challenges, 140 sediment samples were tested for feeding rate, and 84 for reproduction, using protocols adapted from standardised methods. Physico-chemical analyses of sediments, including particle size distribution and contaminant concentrations, were conducted in parallel. Statistical analyses linked sediment characteristics to biological endpoints to derive threshold values and refine risk assessment.

Preliminary results show minimal influence of granulometry and organic carbon content on the endpoints, enabling threshold value proposals (2 g/gammarid/day for feeding, 10 embryos/female for reproduction). However, artificial sediment used as control showed reduced feeding and reproduction rates compared to uncontaminated natural sediments, raising concerns about their suitability. Feeding rate proved to be a more sensitive indicator of sediment toxicity than reproduction, although both endpoints complement each other in assessing impacts.

This research highlights *G. fossarum* as a promising bioindicator for sediment toxicity. The findings allow for the development of standardised bioassays and thresholds, contributing to sediment quality assessments. These insights can inform regulatory frameworks and sediment management strategies, advancing our understanding of freshwater ecosystem health and aiding in sustainable sediment management practices. Therefore, this work is aligned with the session 2.10 « New Developments in Sediment Ecotoxicology and Risk Assessment ».

2.08.P-Mo159 “In Vivo” ECOD Assay: A Proxy to Unveil Biotransformation in Sediment-Dwelling Invertebrates.

***Elettra D'Amico*[1]*, Martina Santobuono[1], Wing Sze Chan[1], Kevin Noort[2] and Henriette Selck[1], (1)Roskilde University, Denmark, (2)CEHAC, United Kingdom*

The ECOD (7-ethoxycoumarin-O-dealkylation) "in vivo" assay is a valuable tool for assessing the biotransformation capabilities of sediment-dwelling invertebrates, specifically focusing on Cytochrome P450 (CYP450) activity. This study presents an optimized method for performing the ECOD assay with sediment-associated hydrophobic compounds, using the polychaete Capitella teleta as a model organism.

The ECOD assay, traditionally used in "in vitro" setups, has been adapted for "in vivo" conditions to provide a more accurate quantification of CYP450 activity over time. This adaptation is particularly relevant for sediment-dwelling organisms, which are often exposed to contaminants through sediment ingestion rather than water.
C. teleta individuals were exposed to sediments spiked with a mixture of PCBs (#52, #153, #209) or Sertraline at concentrations of 50 and 100 µg/g, respectively. The exposure lasted for 14 days, after which the worms were transferred to a multi-well plate containing 7-ethoxycoumarin solution and spiked sediment for continuous exposure. Fluorescence detection was used to measure CYP450 activity, with samples collected every 15/30 minutes.
The optimized assay successfully measured CYP450 activity during sediment exposure, showing expected trends for the different contaminants. PCBs, known inducers of CYP450 activity, resulted in increased fluorescence detection compared to control values, while Sertraline, an inhibitor of CYP450, led to a decrease in activity. The results indicate significant differences in CYP450 activity among treatments, aligning with the known effects of the contaminants.
This study demonstrates that the "in vivo" ECOD assay can be effectively performed with sediment-associated hydrophobic compounds and sediment-dwelling organisms. The optimized method provides a powerful tool for time-dependent quantification of CYP450 activity and biotransformation rates in sediment. Further investigations with different species and contaminants are warranted to assess the broader applicability of the optimization.

2.08.P-Mo160 Overcoming Challenges in Chronic Toxicity Testing of Sediment-Dwelling Organisms: Validating Spiked Sediment Studies for a Variety of Species across Diverse Taxonomic Groups
Apostolos Koutsaftis[1] *and Stephanie Fritz*[2]*, (1)Environmental Resources Management (ERM), Netherlands, (2)Sumitomo Chemical AgroSolutions Division EMEA Region, France*
Under the EFSA Aquatic Guidance (2013), which has been noted and used since 2015 for the aquatic risk assessment of plant protection products (active substances, new and renewals; formulated products under zonal authorizations or country registrations) in the EU, there are various Tiers and options offered for testing and refinements for aquatic organisms exposed via the water phase.
However, for sediment dwelling organisms exposed to contaminated sediment, higher tier options for refinement are significantly limited in comparison. In practical terms, the Tier 3 mesocosm option is by default not realistic as such studies performed with spiked sediment to achieve a worst-case/realistic exposure regime are very challenging. Similarly, pulse exposure (Tier 2C) is also not a realistic refinement option due to the very nature of the exposure expected (accumulation in sediment). Therefore, the only practical options are based on additional single species laboratory testing followed by data analysis i.e., geometric mean approach (Tier 2A) or species sensitivity distribution (SSD) approach (Tier 2B). These approaches require a dataset of toxicity endpoints from different species preferably belonging to different taxonomic groups.
We are here discussing a case study demonstrating that even the above option is realistically very challenging: identifying a variety of sediment dwelling organism species and performing successful testing under GLP conditions that result in valid studies can be a complicated task. There are many factors contributing to this. Mainly, the lack of standardized methodologies, particularly for chronic/reproductive toxicity testing for various species and the need of adapting existing guidelines and relevant validity criteria to different species. In this case study the attempt to test 17 different sediment dwelling species (from insect, crustacean, polychaete, nematode and bivalve taxonomic groups) at three different contract research organizations is presented. All the practical problems encountered, such as acquisition of test organisms, success rate and the failures of validity criteria or the lack of possible valid adaptation and interpretation of existing guidelines are presented. With this presentation we hope that the necessity of further standardized methodology and guideline development is highlighted for sediment dwelling organisms (with spiked sediment) toxicity testing.

2.08.P-Mo162 Development of a Conceptual Model for Sediment Dynamics and Pollutant Distribution in a Connected Pond System
Sebastian Hoss[1]*, Ivonne Stresius*[2] *and Susanne Heise*[2]*, (1)Ecossa, Germany, (2)Hamburg University of Applied Sciences, Germany*
Reinfelder Teiche comprises a system of connected ponds which are located in the centre of the city of Reinfeld, Northern Germany. Surface run-off from urban areas and agricultural fields as well as emissions from domestic sewage treatment plants are likely to have an impact on the chemical quality of water and sediment and the biodiversity of the area. Various measures to improve the biodiversity of the pond system have been much debated but postponed up to now, because the impact of potential chemical,

biological and human stressors on the pond s ecosystem is not well known.
In order to better understand the dynamic of the accumulating sediment and its contamination, sediment cores have been taken at all ponds, profiles of heavy metal contamination and ecotoxicologial effects have been measured with depth. Chemical contamination was measured at the different water systems and sedimentation rates were determined. In each of the 5 most important ponds, the upper 3 cm of sediment surface layer of the 7 most important ponds was analysed by a set of 4 bioassays and a nematode-based in-situ index (NemaSPEAR[%]-index). A more detailed chemical analysis of sediment pollutants and dissolved pesticide concentrations and effects in inflowing waters, a conceptual model for the ponds will be set up to help improving system understanding and providing a first basis for targeted measures.

2.08.P-Mo163 Distribution of Potentially Toxic Elements in Sediments in Millstream Creek, Langford, BC, Canada

*Max Barker[1], **Matt Dodd**[2] and Brian White[1], (1)Royal Roads University, Canada, (2)School of Environment and Sustainability, Royal Roads University, Canada*

Westshore Motorsports Park (WMP) founded in 1954 near Victoria operated as a racing track until its closure in 2022. The area is currently being developed as a housing complex and business park. There is concern about its legacy in the form of potentially toxic elements (PTEs) such as arsenic, cadmium, chromium, copper, mercury, nickel, lean and zinc emissions from the motor cars that used to race on the tracks. Twenty-nine sediment samples were collected from Millstream Creek, which flows past the WMP, to assess how the surrounding land use influence metal distribution in the sediments. Samples were collected along the stream at locations upstream (Area A), immediately downgradient (Area B), and further downstream (Area C) of the WMP. Total metal concentrations were determined by x-ray fluorescence and the physicochemical properties of surface water were also evaluated. There was a statistical difference in pH with Area B, immediately downgradient of WMP having the highest mean concentration (pH = 7.63). The concentrations of the arsenic, cadmium, and mercury in all the sediment samples were below detection. Chromium, copper, and zinc in some of the sediments samples exceeded the Canadian Council of Ministers of the Environment (CCME) interim freshwater sediment quality guidelines (ISQG). The elevated chromium concentrations could be attributed to the relatively high chromium background concentrations on Vancouver Island. Copper, nickel, and zinc were comparatively higher in Area B with the mean concentrations of copper (49.6 mg/kg) and zinc (125 mg/kg) exceeding the CCME ISQG. The statistically significant higher concentrations in Area B could be attributed to impacts from the WMP, albeit the presence of a highly vegetated riparian zones may limit the migration of contaminants into the creek. The results of the human health and ecological risk assessment including the influence of a riparian zone along with an exploration of phytoremediation as a nature-based solution for easing the transition toward regenerative development will be presented.

2.08.P-Mo164 Influence of Sediments Spiked with “Smart” Anti-corrosion Nanoadditives in Hediste Diversicolor: Biomarkers and Bioaccumulation

***Mariana Bruni Marques do Prado e Silva**[1], Joana Figueiredo[2], Fernando Perina[3], Denis Abessa[4] and Roberto Martins[5], (1)University of Aveiro, Portugal, (2)Department of Biology, University of Aveiro, Portugal, (3)University of Aveiro, Aveiro, Portugal, (4)São Paulo State University "Julio de Mesquita Filho", Brazil, (5)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

The corrosion of immersed metallic structures generates a significant economic problem, which can be reduced using corrosion inhibitors (CI) that retard this process. However, most CIs are toxic to the biota, requiring eco-friendly alternatives. ZnAl layered double hydroxides (LDH) have been used to immobilize different CIs to develop smart or stimuli-responsive anti-corrosion nanoadditives that can reduce toxicity and increase corrosion protection over time. This study aimed to assess the toxicity of four CIs (2-mercaptobenzothiazole (MBT), benzotriazole (BTA), sodium gluconate (SG) and sodium nitrite (NaNO2)), the respective nanoform (LDH-MBT; LDH-BTA; LDH-SG; LDH-NO2), and the raw nanomaterial (LDH-NO3) through biochemical biomarkers and bioaccumulation in the polychaete Hediste diversicolor. The dissolution of nanomaterials was also quantified in artificial saltwater (ASW) and sediment. Juveniles of H. diversicolor were exposed individually in 200 mL flasks containing 6 cm of contaminated sediment in 3 different concentrations (0.2; 2; 20 mg kg-1) and 50 mL of ASW for 10 days. After the exposure, the organisms were preserved to biochemical biomarkers and bioaccumulation determination, while the sediment and water were appropriately stored for Zn2+ and Al3+ quantification. Acetylcholinesterase (AChE), lipid peroxidation (LPO), catalase (CAT), and glutathione-S-transferases (GST) were tested for all the nanostructured and soluble forms of the four CIs. The findings of the biomarkers indicated that MBT, LDH-MBT, LDH-BTA, and LDH-NO3 caused mainly neurotoxicity. Bioaccumulation of Al3+ and Zn2+ was observed for all nanoforms, apart from LDH-SG (not measured for technical reasons). In the overlying ASW, dissolved Zn was increased only in 20 mg kg-1 of LDH-MBT and LDH-BTA. Regarding dissolution in sediment, there was a decrease of Al in all concentrations of raw LDH-NO3, as well as of LDH-MBT, and LDH-NO2, in 0.2 and 2 mg kg-1 of LDH-SG and in 2 mg kg-1 of LDH-BTA. Reduced Zn concentrations were also observed in all concentrations of LDH-NO2 and LDH-NO3, while increased concentrations occurred in 20 mg kg-1 of LDH-SG and LDH-BTA, and no difference in LDH-MBT. These findings on the effects and bioaccumulation of such innovative smart nanomaterials and their dissolution in sediment demonstrate their potential as eco-friendly alternatives. Future studies must confirm these results in scenarios where the nanoadditives are incorporated into coatings.

2.08.P-Mo165 Hediste Diversicolor Model for the Evaluation of Estuarine Sediment Toxicity Impacted by Sewage Treatment Plants

Evgeni Bunin[1]*, Robert Duran*[2]*, Cristiana Cravo-Laureau*[2] *and Maren Ortiz-Zarragoitia*[3]*, (1)Universite de Pau et des Pays de l Adour, E2S UPPA, CNRS, IPREM, Institut des Sciences Analytiques et de Physico-chimie pour l Environnement et les materiaux; CBET Research Group, Dept. of Zoology and Animal Cell Biology, Faculty of Science and Technology, Spain, (2)Universite de Pau et des Pays de l Adour, E2S UPPA, CNRS, IPREM, Institut des Sciences Analytiques et de Physico-chimie pour l Environnement et les materiaux, France, (3)CBET Research Group, Department of Zoology and Animal Cell Biology, Faculty of Science and Technology, Research Centre for Experimental Marine Biology and Biotechnology PIE, University of the Basque Country UPV/EHU, Spain*

River estuaries are vital transitional ecosystems that experience significant anthropogenic pressure, leading to the accumulation of pollutants in sediments. While the ecological impacts of treated sewage discharges on river sediments have been previously studied, estuarine ecosystems pose additional challenges due to their dynamic physico-chemical properties. To address threats to ecosystem resilience posed by sewage treatment plant (STP) discharges, novel ecotoxicological models that provide realistic, multi-level responses are essential.

This study employed the endobenthic ragworm, Hediste diversicolor, a widely distributed model organism, to evaluate the impacts of different size STPs on river estuaries. Ragworms were exposed for seven days to air-dried estuarine surface sediments collected during two distinct seasons from upstream, discharge, and downstream sites. We assessed toxicity endpoints at multiple levels of ragworm biological organisation, including primary behavioural responses at the beginning of incubation and acute toxicity, cellular changes, and biochemical alterations after the end of incubation.

The results revealed heightened stress behaviours in ragworms exposed to sediments from all discharge sites. Coelomic amoebocyte viability was significantly reduced at discharge and downstream sites compared to upstream sites in one of the large estuaries under study, highlighting the impact of sediment-associated contaminants on the health of benthic organisms. Preliminary data from acute toxicity tests using sediment elutriates with rotifers and analyses of non-polar pharmaceutical residues further support these findings. Moreover, sediment sand content emerged as a key stressor, strongly correlating with weight loss and reduced amoebocyte viability in ragworms. Oxidative stress biomarkers cyclooxygenase, superoxide dismutase, glutathione S-transferase, and acetylcholinesterase exhibited changes among sites. The findings emphasise the utility of a multi-level approach in applying H. diversicolor as a model organism for environmental monitoring. This study demonstrates the potential of integrating sediment characterization and multi-biomarker responses to improve ecotoxicological assessments in estuarine environments.

Disclaimer/Disclosure: This work was supported by the Basque Government (ref. IT1743-22), French ANSES (n°2024/EST/218 ISMI) and the UPPA MESRI (AAP UPPA/UPV 2022) grants.

2.08.P-Mo166 Distribution Characteristics and Potential Toxicity of Dioxin-Like Chemicals in Sediments from Busan Bay, South Korea

Songyeon Lee[1]*, Jiyun Gwak*[1]*, Jihyun Cha*[1]*, Sunmi Yang*[1]*, Hyo-Bang Moon*[2] *and Seongjin Hong*[1]*, (1)Department of Earth, Environmental & Space Sciences, Chungnam National University, Republic of Korea, (2)Department of Marine Science and Convergence Engineering, Hanyang University, Republic of Korea*

This study investigates the contamination status of dioxin-like chemicals (DLCs) and their potential dioxin-like activities in sediments collected from Busan Bay, Korea. A total of 41 sediment samples were collected from North Harbor (n = 20), South Harbor (n = 12), and Gamcheon Harbor (n = 9). Of these, 5 sediment samples (N1, N2, N6, N7, and N10) exhibited significant AhR-mediated potency. The targeted 96 DLCs, including 17 polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs), 22 polybrominated diphenyl ethers (PBDEs), 22 polychlorinated biphenyls (PCBs), and 35 polycyclic aromatic hydrocarbons (PAHs) were detected at all sites. The concentrations of PCDD/Fs (17 210 pg g-1 dw) were the highest in Gamcheon Harbor, while North Harbor showed elevated levels of PBDEs (1.6 280 ng g-1 dw), PAHs (100 880 ng g-1 dw), and PCBs (0.42 360 ng g-1 dw) due to the influence of industrial complexes and port activities. To identify contamination sources, a positive matrix factorization (PMF) model and principal component analysis (PCA) were applied. The PMF model revealed that PAHs in Gamcheon and South Harbor originated mainly from petroleum, while those in North Harbor were attributed to diesel emissions. PCA results indicated that PCBs in the sediments were compositionally similar to industrial products such as Aroclor, Clophen A, and Kanechlor, and PCDD/Fs showed profiles similar to TPN 1993 and fly ash. Among the targeted DLCs, 35 specific compounds (17 PCDD/Fs, 7 PBDEs, 2 PCBs, and 9 PAHs) were detected in concentrations ranging from 43 to 160 ng g-1 dw. A potency balance analysis was performed by comparing bioassay-derived TCDD-equivalent concentrations (EQs) with instrument-derived toxic equivalents to determine the contribution of specific DLCs to total TCDD-mediated potency. The specific DLCs contributed 30% and 42% to bioassay-derived TCDD-EQs (TCDD-EQbio) in N2 and N7, respectively, and explained more than 100% of TCDD-EQbio in N1, N6, and N10. PAHs in sediments were the primary contributors to dioxin-like activities. Among the PAHs, benzo[b]anthracene was identified as a major compound exhibiting TCDD-like potency in sediments from Busan Bay. These findings provide useful baseline data on the distribution of DLCs, their potential dioxin-like activities, and the relative contributions of individual DLCs in sediments from Busan Bay.

Disclaimer/Disclosure: This study was supported by grants from the Ministry of Oceans and Fisheries of Korea (RS-2024-00417889).

2.08.P-Mo167 Exploring Coconut Husk as an Organic Matter Enrichment Alternative to Peat in Sediment Toxicity Test

Davide Asnicar *and Benjamin Patrick de Jourdan, Huntsman Marine Science Centre, Canada*

The utilization of standardized artificial sediment in toxicity assessments offers increased repeatability and enhances consistency across bioassays and laboratories. Artificial sediment is required for most OECD (Organisation for Economic Co-operation and Development) guidelines, particularly in studies assessing the impact of chemicals on benthic communities.

While peat is conventionally incorporated into artificial sediment formulations as the source of organic matter (OM), it is not a sustainable resource due to the long time it takes to form and the environmental impact of its extraction. Notably, peatlands, covering over 12% of Canada's land area, are pivotal in carbon sequestration, estimated to be 150-160 Gt of carbon. The extraction of peat leads to a carbon loss equivalent to 2.1 megatonnes of carbon dioxide emissions annually, accompanied by the potential release of other elements into the environment and aquifers. Consequently, the pursuit of less impactful alternatives is desirable, and aligns with the 2030 Agenda for Sustainable Development, endorsed by the OECD.

Here we investigated the viability of coconut husk as an alternative to peat in formulating artificial sediments for toxicity testing.

Juvenile Stage IV American lobsters (Homarus americanus) were exposed for 15 days in aerated 1L glass jars with 50 grams of test sediment (n = 6 per treatment). Test sediment was prepared with either peat or coconut husk as source of OM. Three OM levels were tested: 0.5, 2.3, and 5 % of sediment wet weight. Dry sediment was mixed with an antiparasitic drug, ivermectin (stock solution in acetone), to achieve 3 desired concentrations (nominal 40, 100, 400 ng/g DW).

Mortality assessment was carried out every day and a 15-day LC50 was calculated with measured concentrations of the compound tested. The test was replicated twice over two years.

There was no statistically significant difference in LC50s between the sediment prepared with peat or coconut husk.

The results indicate that the presence of coconut husk does not introduce toxicity effects of the tested chemicals, suggesting its suitability as a viable alternative for toxicity testing.

2.08.P-Mo168 Tubifex tubifex Bioturbation and Biotransformation Ability Determine the Distribution of Polycyclic Aromatic Hydrocarbons and Polychlorinated Biphenyls Mixtures in the Sediment.

Betty Chaumet[1], Henriette Selck[2] and ***Elettra D'Amico***[2]*, (1)Environmental Science, Stockholm University, Stockholm, Sweden, (2)Roskilde University, Denmark*

Bioturbation, the reworking of sediments by animals, plays a significant role in the distribution of contaminants in aquatic environments. The oligochaete Tubifex tubifex is known for its sediment reworking and flushing capabilities, which may reintroduce sediment-associated contaminants into the overlying water, as well as influence the bioavailability of these contaminants. Furthermore, T. tubifex

may biotransform organic contaminants, thus, impacting the fate of sediment-associated contaminants This study assessed the impact of T. tubifex bioturbation on the distribution of two organic and hydrophobic contaminant groups, namely Polycyclic Aromatic Hydrocarbons (PAHs; considered biotransformable) and Polychlorinated Biphenyls (PCBs; considered inert to biotransformation) mixtures in sediment and their release in the water.
Two experiments (expt. 1: PAHs, expt. 2: PCB mixture) were conducted: Both experiments included a control (i.e., uncontaminated natural sediment) with and without worms and spiked sediment with and without worms (n = 3 replicates, 4 worms per replicate. A polyethylene (PE) passive sampler was suspended in the overlying water in each replicate vial to assess the potential distribution of sediment-associated contaminants between the sediment and the overlying water. Contaminants were quantified in the sediments, worms, and passive sampler to determine their distribution and fate in the system.
The results provide insight into whether worm presence (bioturbation, biotransformation) created by the behavioral traits of T. tubifex, influences the distribution of sediment-associated contaminants, potentially altering their bioavailability in different compartments. This study's findings could advance our understanding of contaminant dynamics in aquatic systems and inform risk assessments and remediation strategies for polluted sediments.

2.08.P-Mo169 The Amphipod *Hyalella curvispina* as an Ecotoxicological Biotool for Environmental Risk Assessment of Sediments in Río de la Plata Ports, Buenos Aires, Argentina

Walter D. di Marzio*, Maria Elena Saenz, Jose Alberdi and Santiago Martinez, PRIET DCB UNLU CONICET, Argentina*

In this study, samples were collected from port areas of the Río de la Plata near the city of Buenos Aires. A native amphipod was used to evaluate ecotoxicity.
The sampling area covers zones for loading and unloading petroleum derivatives, as well as port activities related to the shipbuilding industry.
Previous studies on age sensitivity in sediments and reference toxicants were made.
Survival and growth curves were analyzed using individuals of *Hyalella curvispina* less than 7 days old and measuring 1.5 mm, exposed to the sediments for 10 15 days. The slopes of these growth curves were evaluated in relation to the characterization and petroleum hydrocarbon content of the samples.
Principal component analysis was used to map the port area based on its activity, defining buffer zones with lower impact. These zones will support future dredging strategies and the management of river sediments near the ports.

2.08.P-Mo170 Assessment of the Detergent Concentrations in Water and Sediments of the Papaloapan River, Veracruz, Mexico

***Alma Sobrino-Figueroa*[1]** *and Alberto Perez Rojas[2], (1)Alejandro Villalobos Laboratory. Autonomous Metropolitan University-Iztapalapa, Mexico, (2)Geology and LimnologyLaboratory. Autonomous Metropolitan University-Iztapalapa, Mexico*

The Papaloapan River is a system that receives a continuous contribution of toxic compounds due to domestic, industrial, agricultural and livestock activities that take place on its banks. This study evaluated the presence of detergents in water and sediment samples obtained from the riverbed and associated systems, to detect the areas with the highest degree of pollution. Ten samples were collected in the final part of the river (18° 18' - 18° 47′ north and 95° 44′ - 95° 51′ west) during the dry and rainy seasons for 7 years (2014, 2015, 2016, 2018, 2019, 2022 and 2023). The following parameters were evaluated in situ from the water samples: pH, conductivity, dissolved oxygen and temperature. In the sediments, ammonium, organic matter, conductivity, texture, and pH were evaluated in the laboratory. The evaluation of detergents was carried out using the SAAM technique. The concentrations of detergents in the water samples varied from 0.17 ± 0.072 to 0.438 ± 0.2 mg/L. In sediments, from 0.22 ± 0.088 to 0.736 ± 0.438 mg/L. The sediments with the highest concentration of detergents were obtained from areas close to urban areas and areas with low water circulation. Likewise, a higher concentration of detergents will be monitored in 2022 and 2023.

2.09 Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.09.T-01 Temporal Heterogeneity of Periphyton Microbial Activity and Photosynthesis Sensitivity to the Chemical Stress and its Environmental Drivers

***Lin Zi*[1]**, *Arthur Medina[2], Melissa Eon[2], Chloe Bonnineau[3], Nicolas Mazzella Di Bosco[2], Aurelie Moreira[2], Soizic Morin[3] and Nicolas Creusot[2], (1)INRAE, EABX, France, (2)INRAE EABX - Bordeaux Metabolome, France, (3)INRAE EABX, France*

Facing chemical contamination of aquatic ecosystems, it is crucial to better understand how fluctuation in structural and functional microbial biodiversity due to environmental conditions may modulate the sensitivity of microbiomes to chemical stress, as these communities play a significant role in ecosystem function and services. Among these communities, periphytons are complex assemblages of microorganisms that strongly contribute to primary production and biogeochemical cycles. Omics and their combination pave the way to new perspectives in microbial eco(toxi)cology to gain mechanism understanding of the response of microbial communities to their environments. Among others, untargeted metametabolomic provides a comprehensive picture of the microbial activ ity in response to the environment. This approach is complementary of others descriptors at the physiological/functional level that may lake of sensitivity regarding the chemical stress. In this context, the present study aims at characterizing the change of sensitivity to micropollutants of the periphyton at both the molecular and physiological level and unraveling external (water physico-chemistry) and the internal (metabolic and physiological status) factors contributing to such a shift. To do so, biofilms were colonized monthly on glass slides in a pond. At each month, a part of the collected biofilm was exposed during 4h to serial dilution of terbuthylazine (TBA) to assess the sensitivity to this herbicide at both the biochemical (metametabolome) and physiological (photosynthetic yield) levels. Our results showed a strong temporal heterogeneity in the sensitivity and response to the chemical stress of periphyton microbial activity (metametabolome) against a low one of the photosynthesis.This strenghens the relevance of the aggregated metametabolome response to provide an integrative picture of the periphyton sensitivity. This also suggests that quite similar physiological responses may arise from various molecular pathways, adding complexity to the underlying phenomenon. DIABLO analysis further hilighted the contribution of environmental conditions to the temporal dynamic of the basal microbial activity and its sensitivity, although the actual contribution of external vs internal factor in this sensitivity shift remains to be elucidated. Altogether, our results will support better understanding of potential functional impairment of microbiomes by the chemical stress in the global changes context.

2.09.T-02 Investigating the Impact of Herbicide Exposure on Macrophyte Community Composition and Long Term Recovery

***Isabel Navarro Law**[1], Colin Brown[2], Jason Snape[2], Rachel Samantha Benstead[3], Michael Fryer[4] and Isabelle Durance[5], (1)University of York, York, United Kingdom, (2)University of York, United Kingdom, (3)Fera Science Ltd., United Kingdom, (4)HSE, United Kingdom, (5)Cardiff University, United Kingdom*

Currently, UK regulatory assessments of risks from herbicides to macrophytes only investigate th e immediate, in-season impact of herbicide exposure to individual plants. This study investigates the impact of herbicide exposure on macrophyte community composition and long-term recovery, to understand whether risk assessments should incorporate community level impacts and the ability of individual plants to recover.

Nine mesocosm units were planted with a community of eight emergent macrophyte species in April 2024. Six mesocosms were dosed with metsulfuron-methyl in June 2024. Three of these received 1 µg/L and three received 10 µg/L. Three mesocosms were un-exposed controls. Eight endpoint measurements were recorded for 116 days. These include: Quantum Yield of PSII, length, width, number of leaves, stems and flowers and percent chlorosis and necrosis. Aerial photos of each mesocosm were taken and percent cover calculated in ImageJ. The mesocosms were flushed on day 33 to remove any herbicide. Water samples were collected throughout and analysed by LC-MS/MS to measure the concentration of metsulfuron-methyl.

Principal Response Curve analysis indicates that 93.6% of variation in community level effects between the 10 µg/L mesocosms and the controls can be explained by the treatment. As expected, most species were negatively impacted by herbicide exposure. However, Phalaris arundinacea was positively impacted by herbicide exposure, with the population covering a greater percent area in the 10 µg/L mesocosms after exposure compared to the controls.

Some species were able to recover after herbicide exposure. Myosotis scorpioides individuals exposed to 10 µg/L initially had a steep decrease in leaf number after exposure. After the flushing event, the number of leaves on these individuals began to increase. At the end of the study the individuals in the 10 µg/L mesocosms had more leaves than those in the controls. Other species, such as Potamogeton natans, did not recover after exposure. Individuals of this species exposed to 10 µg/L of metsulfuron-methyl started declining in leaf number 11 days after dosing. By day 74 there were no leaves remaining and these never recovered.

Results suggest that some macrophyte species have the capacity to recover from herbicide exposure, whilst others thrive in communities exposed to herbicide. This highlights the need for risk assessments to incorporate impacts on community composition and their ability to recover.

2.09.T-03 Overspray of Herbicides Poses Risk for Floating Aquatic Macrophytes
*Bastian H. Polst, Dick Belgers, Laura Buijse, Nina Jansen and **Gertie Arts**, Wageningen University and Research (WUR), Netherlands*
Herbicides from agricultural fields frequently impact edge-of-field aquatic systems via spray drift, drainage, or surface run-off, exposing and affecting aquatic macrophytes. Regulatory risk assessments, especially Tier 1 assessments following OECD guidelines, primarily consider herbicide exposure as occurring via dissolved chemicals in water, a scenario applicable to submerged macrophytes such as Myriophyllum spicatum. However, floating and emergent macrophytes, including Lemna minor and Glyceria maxima, are also subject to direct herbicide exposure via their leaves following deposition of drifting herbicide spray, a pathway not addressed in existing guidelines. Notably, for Lemna minor, only a single, limited study from 1989 has explored such overspray exposure, despite recent suggestions of its relevance e.g., in EFSA s recent peer review of glyphosate.
To address this gap, our study compares the effects of glyphosate exposure on Lemna minor through two exposure routes: overspray application on the leaf surface and conventional exposure via water. We hypothesized that overspray would result in an increased toxicity compared to exposure via water. Along a dose-response setup, we measured conventional endpoints such as dry weight, and frond number and derived EC50 values for comparison of toxicity between the two exposure routes.
As hypothesized, exposure via spray deposition on top of the leaves led to an increased toxicity across all endpoints measured in Lemna minor. Nevertheless, further uncertainties in the method need to be discussed to finally allow drafting a protocol for future standardized overspray testing of floating aquatic macrophytes.
Ultimately, our findings reveal key insights into the differential effects of herbicide exposure pathways on floating macrophytes, with implications for refining regulatory risk assessments and ensuring agricultural practices that better safeguard aquatic ecosystems.

2.09.T-04 Estimating Fifty Percent Effect Rates for Plant Visual Injury via a Decision Tree
***Gunther Ulric du Hoffmann**[1], Joshua R. Arnie[1], Patricia Lopez-Mancisidor[2], Rena Jutta Irene Isemer[3], Sebastian Fellmann[3], Jeffrey C. Wolf[4], Ashlee Kirkwood[5], Andreas Duffner[6], Markus Simon[7] and Jette Bramby-Gunary[8], (1)Eurofins EAG Agrosciences, United States, (2)Corteva Agriscience, Spain, (3)Bayer AG, Crop Science Division, Germany, (4)Experimental Pathology Laboratories, Inc., United States, (5)Smithers, United States, (6)Eurofins Agroscience Services Ecotox GmbH, Germany, (7)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (8)AgroChemex Environmental, United Kingdom*
For the authorization of plant protection products (PPP) in the European Union (EU), non-target terrestrial plants (NTTP) are tested for effects on seedling emergence, survival, biomass, growth and visual injures according to test guidelines (OECD 208 (2006a) and OECD 227 (2006b)). It has to be noted that plant visual injuries (PVI) (chlorosis, necrosis, wilting etc.) are based on subjective and non-standardized observations. Recently, the European Food Safety Authority (EFSA) requires that ER50s for qualitatively assessed PVI should be considered for the risk assessment as equal to endpoints derived from quantitatively determined parameters. However, the interpretation of the data in terms of an ER50 is related to several challenges as it has been discussed previously (Fellman et al; 2023; IEAM). Furthermore, there is no guidance available harmonizing the assessment method of PVI and the statistical interpretation of the data leading to a multitude of approaches being used. Regulatory Authorities from across the globe have attempted to provide some insight into methods used to evaluate endpoints for differing scoring systems (UBA, EFSA, USEPA. RIVM, HAWC) but no agreement has been reached so far. The PVI SETAC Working Group under the umbrella of the SETAC Plants Interest Group gathered several NTTP PVI data sets to identify the variability and quality of the data. The correct statistical model to be used depends on whether the data is defined as ordinal or continuous. This work aims to harmonize the statistical analysis of PVI data by addressing the various PVI assessment methods used in regulatory NTTP effect studies. It will provide recommendations for effectively analyzing and interpreting the data to enhance comparability with standard ER50s (biomass, survival etc.) in form of a decision tree to support risk assessors. As next steps, the SETAC PVI Working Group will focus on developing a new assessment methodology, a standardized PVI scoring system, which will be accompanied by an appropriate statistical analysis. This progress will require a ring test to investigate the viability of a new approach which requires time. Accordingly, the presented decision tree for choosing suitable statistical methods for PVI evaluation becomes more important as it helps in harmonizing PVI data interpretation as an interim step.

2.09.T-05 First Insights into Drift Capture Efficiency of Non-Target Terrestrial Plants
***Rena Jutta Irene Isemer**[1], Andrew C. Chapple[1], Clare Butler Ellis[2], Andrew Lane[2] and Christine O'Sullivan[2], (1)Bayer AG, Germany, (2)Silsoe Spray Applications Unit Ltd, United Kingdom*

Non-Target Terrestrial Plants (NTTPs) are, by definition, located in the off-field where they can unintentionally be exposed to plant protection products. In Europe, spray drift is considered to be the main exposure route for NTTPs and is therefore taken into account for the risk assessment. The extent to which NTTPs are expected to be exposed to drift is defined by drift value tables (Rautmann) which are based on drift field trials using petri dishes as collectors. Drift deposition to flat collectors such as petri dishes is a surrogate for determining spray drift to surface water. However, NTTP communities located in the off-field are 3D structures with variable characteristics such as porosity, size and surface structure (hairy, smooth, waxy, etc.). Accordingly, drift deposition is only covering part of the NTTP exposure and drift capture needs to be considered as well. This raises the questions as to which of the characteristics of the off-field vegetation are most important for determining its drift capture efficiency.
To obtain some first insights into the possible influence that the characteristics of the off-field vegetation have on drift capture efficiency, drift deposition on four species (oats, soya, oil seed rape, sunflower) representing different growth types and 3D structures was investigated with the plants arranged as single plants, rows (1 × 5 potted plants) and blocks (5 × 5 rows) in a wind tunnel. This early work has shown that rows of plants capture essentially the same spray drift as single plants but that blocks of plants differ significantly in the quantity captured. The front row of plants, unsurprisingly, captures the most spray drift whereas just a few rows back, the amount of spray drift captured falls off considerably. There are also differences in spray drift capture depending on plant type.
The results present a challenge to the current modus operandi for NTTP risk assessment, in that the standard horizontal collection of spray drift in trials is an oversimplification of the reality of spray drift capture by off-crop canopies.

2.09.P Aquatic and Terrestrial Plant Ecology, Ecotoxicology, and Risk Assessment

2.09.P-We087 Efficacy of Pseudomonas Fluorescens and Azospirillum Brasiliense Based-Biostimulant in Forage Plant Development in a Historically Contaminated Soil Under Climate Change Scenarios

*Sara Cristiana Lopes Peixoto[1], Jose Nereu Pinto[1], Marija Prodana[1], **Patrícia Veríssimo Silva**[1], Diogo Filipe Nunes Cardoso[1], M. Nazaret Gonzalez-Alcaraz[2], Susana Loureiro[1] and Ana Rita R. Silva[1], (1)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (2)Department of Agricultural Engineering of the E.T.S.I.A., Technical University of Cartagena, Spain*
Organic farming methods have been increasing in the quest for sustainable and eco-friendly agricultural practices. As an example, microbial biostimulants (mPB) are currently applied in organic agriculture as potential substitutes for chemical fertilizers. Their primary goal is to improve plant growth, mainly by increasing nutrient availability in the soil. However, information on their efficacy under adverse anthropogenic pressure and climate change conditions is limited. This study aimed to evaluate the efficacy of a commercial mPB (comprising Pseudomonas fluorescens and Azospirillum brasiliense) in a historically contaminated soil with metals/metalloids (e.g., Hg, As, Pb) and under simulated climate change influence. For this, short-term toxicity tests were conducted on two forage plant species the lucerne Medicago sativa and the ryegrass Lolium perenne. The contaminated soil was collected from an area impacted by industrialization and agriculture (Estarreja, Portugal). The test was conducted under elevated atmospheric carbon dioxide (CO2) and temperature conditions (800 ppm atm. CO2 and temperature ramp of 20 30 °C) to simulate a forecasted climate change scenario and control climate conditions (approx. 400-500 ppm atm. CO2 and 23 °C). For comparison purposes, tests were also conducted with an uncontaminated soil (Lufa 2.2, control) under both climate conditions. Three days after seed germination, the recommended mPB application rate (5 L/ha) was applied to both soils (Estarreja and Lufa 2.2), regardless of the climate conditions tested. After 9 days, soil pH, electrical conductivity, susceptibility profiles of soil bacterial communities to Hg (disk diffusion method), Hg concentration in soils and plants and plant size and biomass were measured. The application of this mPB under distinct climate scenarios did not significantly alter soil pH, electrical conductivity, or mercury levels. M. sativa plants grown in Estarreja soil were the only ones showing a significant increase in size and biomass when mPB was applied, regardless of the climate conditions tested. For L. perenne, plant size and biomass were similar across both conditions (soil type and climate scenario). This study highlights the positive impact of mPB on plant growth under anthropogenic pressure and adverse climate conditions, especially for M. sativa. The observed difference in responses between M. sativa and L. perenne reinforces the relevance of testing different plant species.

2.09.P-We088 How to Address Herbicide Effects in Lotic Ecosystems – A Test System with Benthic Algal Communties

***Silke Classen**[1], Eric Bruns[2], Katrin Gergs[1], Jutta Hager[2] and Johannes Witt[2], (1)gaiac Research Institute, Germany, (2)Bayer AG, Germany*
In chemical risk assessment, microalgae like *Raphidocelis subcapitata* are tested as representatives for primary producers. However, this planktonic species might be only of little relevance for lotic ecosystems (streams) where mostly benthic algae communities are present. They consist of taxa with different needs regarding environmental conditions and thus also different physiological characteristics. As already shown in several studies for aquatic invertebrates, a similar ecotoxicological response of planktonic and benthic communities and species has not necessarily to be expected.
Thus, to better address the effects of chemical contaminants on benthic algal communities, we developed a test system with natural periphyton that can be exposed under defined laboratory conditions. The tested community develops from a field collected inoculum and contains usually at least 30 60 taxa. So far, diatoms have always dominated in biomass as well as in taxonomic richness both in laboratory culture and in comparative studies in the field. These organisms show, different to planctonic standard species, no exponential growth under laboratory conditions simulating realistic environmental growth. As exponential growth is a pre-requisite for the use of growth rate related figures, the data are evaluated based on biomass related numbers.
During exposure, the development of the periphyton in terms of change in biomass and the composition of the three main algal classes green algae, blue-green algae and diatoms are monitored fluorometrically as chlorophyll-a content. Furthermore, effects on single species are addressed by determination and counting using a microscope at specific timepoints. With an exposure time of up to 14 days, the control variability is low, so that substance effects could be derived well in previous studies. The sensitivity of the investigated biocoenosis differs in part from the results of planktonic single species studies.

2.09.P-We089 Late Nights and Early Mornings; Impacts on Freshwater Algal Morphology
***Zoe Leanne Parker-Crosse**[1], Nadine S Taylor[2], Marie Brown[1], Ellie Welch[1], Katie Smith[1], Cameron Swain[1] and Scarlett Sturt[1], (1)Cambridge Environmental Assessments, United Kingdom, (2)Cambridge Environmental Assessments, Boxworth, United Kingdom*
Freshwater algal species are morphologically very diverse. Among the different taxa they vary in size, shape, colour and structure, making manual identification challenging, thus requiring specialist training. Identification of algal species becomes more challenging during reproduction where algae cells can change in structure and appearance, masking or altering identifiable features. For example, some species release daughter cells, which are miniature clones of themselves, while others surround themselves in a mucilage (palmella stage) in unfavourable conditions and lose identifiable features like flagella. The palmella stage can subsequently become easily confused with species that form colonies contained in a mucilage, like sphaerocystis schroeteri. Reproduction is thought to occur mostly during dawn and dusk in the natural environment, therefore the timing of sampling and preservation of algae samples from the field or mesocosm studies may impact the structure and stages of the algae cells collected. Subsequently this has the potential for misidentification of species collected from the in-life samples. In addition, when conducting mesocosm studies focussed on herbicides, where algae are known to be focal sensitive taxa, the timing of application(s) within these studies may also disrupt these reproductive cycles. Understanding biological processes, such as reproduction, can therefore aid the interpretation of sensitivity observed in specific taxa and help contextualisation of results within mesocosm studies.
In this poster we will investigate how species of algae change appearance in our outdoor mesocosm system during dawn and dusk sampling. With the aim of advancing and improving taxonomic identification techniques and expanding our understanding of potentially sensitive life stages in algae cells.

2.09.P-We090 Combined Effects of Methylmercury and Temperature in *Chlamydomonas reinhardtii*
***Claudia Cosio**, Universite de Reims Champagne-Ardenne, UMR-I 02 SEBIO, France*
Mercury (Hg) is a legacy pollutant that still currently threatens environmental and public health, because of the biomagnification of methyl-Hg (MeHg) in food chains. Microalgae are the major entry pathway of MeHg in food webs. Because environmental and biogeochemical processes are dynamic, understanding the time progression of toxic effects is instrumental for a more in-depth examination of the threat to microalgae fitness in environmentally relevant conditions. This project aims to improve our knowledge on the transfer and toxic effects of MeHg in a warming context using flow cytometry (FCM) to obtain novel insights into the cellular basis underlying the responses to MeHg.
Two incubation temperatures with a 6°C difference based on IPCC projections for 2100, namely 24°C and 30°C, were used. Two exposure conditions were applied for 72h: a control and a 7 ng/L MeHg, corresponding to 1/10 of the maximum MeHg concentration in French continental waters.
In terms of growth, algae incubated at 30°C grew faster regardless of their treatment with MeHg.

Similarly, temperature appeared to play a more significant role than MeHg in altering median levels of chlorophyll autofluorescence and ROS production. Conversely, mortality seemed to be more affected by MeHg treatment, independent of the incubation temperature. Furthermore, temperature did not appear to be a determining factor in the bioaccumulation of Hg. In addition, two cell types emerged in the cytograms of algae incubated at 30°C. Microscopic analysis showed that the algae divided both conventionally and in the form of palmelloids that appeared to secrete more ROS over time.
In the ecotoxicology field, dose responses have been more often studied than toxicokinetic, but the former obviously misses some part of the information to assess the physiology and survival of the target biological model over time. Kinetic knowledge is instrumental to better predict effects at higher levels of biological organization and long-term impacts of pollution to propose rational environmental risk assessment in the changing aquatic environment. I FCM was very efficient, as only small volumes are required for the analysis of several endpoints simultaneously making subsampling in the same small vials for all time points and concentrations possible.

Disclaimer/Disclosure: The authors thank funding by Fondation Rovaltain and URCATech Mobicyte Platform for equipment availability and Ondine Thouard for technical help.

2.09.P-We091 Assessment of the Effects of Metformin on the Macrophytes *Lemna gibba* and *Egeria densa*

***Alma Sobrino-Figueroa*[1]**, *Sergio Alvarez Hernandez[2] and Alberto Perez Rojas[3], (1)Alejandro Villalobos Laboratory. Autonomous Metropolitan University-Iztapalapa, Mexico, (2)Applied Phycology Laboratory. Autonomous Metropolitan University-Iztapalapa, Mexico, (3)Geology and LimnologyLaboratory. Autonomous Metropolitan University-Iztapalapa, Mexico*

Metformin is a drug used to treat diabetes. It is a drug widely consumed by the population in Mexico and sold without a prescription. Metformin has been detected in wastewater and natural waters at concentrations of 1 to 47 g/L. Because the effects of Metformin on aquatic organisms are not fully known, the objective of this study was to evaluate the effects of this drug on the macrophytes *Lemna gibba* and *Egeria densa* on their growth, their pigment and macromolecule content, and their oxidative effect. A bioassay was performed where the macrophytes were exposed to five concentrations of the drug (10, 20, 30, 40, 50, 100 mg/L), for 96 hours, to determine the EC50 using the Probit method. Subsequently, a 10-day sublethal bioassay was performed, where 3 sublethal concentrations (EC10, EC5 and EC1) were tested to evaluate the content of pigments, macromolecules and their oxidizing effect. The Effective Concentration 50 (EC50) values (96 h) obtained are in the range of 10 mg L^{-1} 100 mg L^{-1} indicating that Metformin is a harmful compound for macrophytes (GHS, UN 2011). In the sublethal tests, a decrease of between 15% and 46% in the concentration of total chlorophylls was observed. An increase of up to 80% in the carotene content was detected. The chlorophyll a / chlorophyll b ratio values were lower than those obtained in the controls, indicating that the macrophytes exposed to the drug were in a state of stress. Metformin had harmful effects on macrophytes at concentrations present in aquatic systems.

2.09.P-We092 Effects of Cosmetic Products on Photosynthetic Active Organisms in Freshwater Systems

*Sara Cuellar[1], **Guido Gonsior**[2], Maren Dill[1] and Gundula Gonsior[1], (1)GG BioTech Design GmbH, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany*

The negative impact of sunscreens on marine ecosystems, especially coral reefs, is currently being discussed. One focus is on the effects on the endo-symbiotic algae in corals. However, in addition to the widespread symbiosis with algae, the number of non-symbiotic algae is many times higher. In addition to these microalgae, there are also a large number of macroalgae in the marine environment.
In contrast to marine ecosystems with large amounts of water and a high dilution potential, many freshwater systems, especially lakes, are heavily stressed during the summer months. High concentrations of chemicals were measured, particularly during dry periods.
In fresh water, the function of macroalgae is usually performed by higher aquatic plants. For this reason, the influence of sunscreens on aquatic plants was investigated. We present data collected according to international guidelines. The focus was on the OECD guideline 239 on aquatic plants in a water-sediment system.

2.09.P-We093 The Effect of Elevated Temperature on Pesticide Terbuthylazine-induced Changes in Duckweed Lemna Minor Growth and Oxidative Stress Levels

***Diana Miškelytė*[1]**, *Jurate Zaltauskaite[2] and Levonas Manusad ianas[1], (1)Laboratory of Ecotoxicology, Nature Research Centre, Lithuania, (2)Department of Environmental Sciences, Vytautas Magnus*

University, Lithuania
Anthropogenic chemical pollution has the potential to pose one of the largest environmental threats to humanity. Water pollution becomes alarming since anthropogenic activity results in the contamination of water bodies with various chemicals, which in turn reduces ecosystem functioning. Pesticides stand out for their widespread occurrence in water bodies and highly diverse biological effects. They can enter adjacent water bodies through different ways and their residues may lead to chronic lethal and sublethal effects in non-target organisms. In the European Union, herbicide terbuthylazine (TBA), a member of the chloro-s-triazine group, has emerged as one of the most frequently detected herbicides in water bodies. However, TBA toxicity to aquatic plants is poorly documented. Climate change is an increasingly urgent problem with potentially far-reaching consequences for life on Earth. There is growing importance to understand the effects of changing environmental factors on pollutants ecotoxicity to aquatic organisms. To address this knowledge gap, we aimed to test the influence of elevated temperature (23º C vs 27º C) on ecotoxicological effects of pesticide terbuthylazine to Lemna minor growth and oxidative stress levels. L.minor morphological indicators (fresh weight, frond area), biochemical indicators (enzyme activity and metabolites) as well as oxidative stress damage (lipid peroxidation) were measured.

2.09.P-We094 Extraction and Quantification of Caulerpin in Different Caulerpa Species
Sara Cuellar[1]*, Gundula Gonsior*[1]*, Maren Dill*[1]*, Lara Stuthmann*[2]*, Andreas Kunzmann*[2]*, Hermann Bozler*[3] *and Guido Gonsior*[4]*, (1)GG BioTech Design GmbH, Germany, (2)Leibniz Centre for Tropical Marine Research (ZMT), Germany, (3)biochemA GmbH, Germany, (4)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany*
Green algae of the genus Caulerpa are found in shallow tropical and subtropical marine environments. About 160 species have been reported; two of the most common species are *Caulerpa lentillifera* and *Caulerpa racemosa*, known as sea grapes or green caviar. These species are edible, and their commercialization is an important economic activity in Indo-Pacific regions. There are, however, other species, e.g., *Caulerpa taxifolia* and *Caulerpa cylindracea*, that are considered invasive due to their fast adaptation and rapid expansion that threatens local marine environments. Caulerpin is a secondary metabolite found in the Caulerpa species. Concerns have been reported about the risk of the accumulation of Caulerpa metabolites, such as caulerpin, in fish tissue and other species of the trophic chain. However, some studies reported that caulerpin caused no harm; specifically, studies on zebrafish have shown increased food intake and improved fish reproductive performance. In addition, in other studies, the antimicrobial and anti-inflammatory properties of caulerpin have been reported, highlighting its bioactivity potential to be yet exploited. However, few studies have focused on extracting and comparing caulerpin content among different Caulerpa species. In this work, we present data comparing different extraction methods and quantification of caulerpin in six different Caulerpa species.

2.09.P-We095 Identification of Negative Influence of Pharmaceuticals on the Biodiversity of Freshwater Ecosystems with Focus to Water Plant Communities
Guido Gonsior*, Maren Dill, Gundula Gonsior and Sara Cuellar, GG BioTech Design, Germany*
The interaction of several species in the ecosystem prevents the risk of biological collapse. Aquatic plants are able to stabilise freshwater ecosystems in a significant way. Further, it is now very evident that climate change is significantly affecting most ecosystems, leading to potentially dramatic changes in food webs. All photosynthetic organisms that can store carbon from the atmosphere therefore have a central role to play. It is therefore important to identify potentially toxic substances on aquatic plants and to clarify the effects under laboratory conditions. We are currently working on the identification of stressors for macrophytes. It is becoming clear that even pharmaceuticals that have not been tested for their effect on rooted macrophytes could reduce plant communities. Here we present data to clarify the impact of pharmaceuticals on aquatic plants.

2.09.P-We096 Comprehensive Analysis of Water Hyacinth Biomass for use as an Agricultural Soil Regenerator
Ignacio Pinheiro[1]*, Rodrigo Neves*[1]*, Carla Patinha*[2]*, Solange Magalhaes*[3]*,* ***Isabel Lopes***[4] *and Catia Venancio*[4]*, (1)Department of Biology, University of Aveiro, Portugal, (2)GEOBIOTEC, Geosciences Department, University of Aveiro, Portugal, (3)University of Coimbra, CERES, Department of Chemical Engineering, Portugal, (4)Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal*
Water hyacinth (WH; Eichhornia crassipes) is one of the most problematic invasive aquatic species worldwide, causing significant ecological and socioeconomic impacts. Its control and minimization of costs associated to its removal may rely on the valorization of WH biomass. Accordingly, this study aimed to characterize WH biomass (morphology and biochemistry) with the aim of incorporating it as an

agricultural enhancer. For this purpose, a multidisciplinary approach was taken, including: (1) sample collection in six strategic locations [Estação Experimental António Teixeira (EEAT), Praia de Coruche (PRAIA), Vila Valente (VV), São João de Loure (SJL), and two points in Pateira de Fermentelos, Aveiro - Observatório Bico (Bico), and Estalagem (PF)], (2) plant biometric measurements, (3) sugar and lipid quantification, (4) pigment extraction and quantification, (5) aqueous extracts conductivity and pH, (6) chemical composition through FTIR; and (7) cellulose, hemicellulose, and glucose levels. The morphometrics and biochemical characteristics of the biomass collected at different locations correlated well with the environmental parameters of each location with plants collected at sites with high input from agricultural activities (EEAT) being larger with a smaller root extension, whereas plants at less urbanized sites were smaller with very dense root systems, which may be related to the availability of nutrients in the water courses. Water extracts pH of each of the biomasses was distinct from those of agricultural zones (EEAT, PRAIA, VV, and SJL, ranging from 6.8 to 8.1) to less urban zones (Bico and PF values of 5.9 and 5.3, respectively), whereas the conductivity values of the WH water extracts were above 6 mS/cm. Water bodies (sampling sites) with a more neutral pH and high conductivity may indicate a higher concentration of dissolved salts and potential contamination from other sources. FTIR analyses indicated the presence of a large area under the absorbance ranges of 2850-3000 cm-1 and 3000-3100 cm-1, indicating the potential presence of aromatic compounds, alcohols, N-H-containing amines or amides, or carboxylic acids. Around 48-63% of the biomass was lignin and hemicelluloses, and glucose levels were above 0.53 µg/g dry weight. Overall, the characterization of WH biomass makes it a promising environmentally friendly resource for agricultural applications through a value-added chain, while designing a sustainable solution to control WH.

2.09.P-We097 Species Sensitivity Distribution for Aquatic Macrophytes: Species and Distribution Selection

***Anastasia Del Signore**, Corteva Agriscience, Germany*

In the EU, a risk assessment for plant protection products (PPP) is required under Regulation (EC) 1107/2009. Referring to the EFSA (2013) aquatic guidance, a tiered risk assessment can be followed where Species Sensitivity Distributions (SSDs) are proposed as a higher tier option for a refined risk assessment. SSDs are crucial tools for deriving the hazardous concentration for 5 % of species (HC5) to predict a regulatory acceptable concentrations (RAC). This can then to be compared to modelled or predicted environmental concentrations (PEC) for authorization of PPP. In the current research project, we focus on the selection of macrophytes species and underlying distribution models for constructing SSDs. EFSA (2013) aquatic guidance notes that in SSDs, all species have equal weight and thus are considered of equal importance in assessing the ecotoxicological risks. But what species of aquatic macrophytes should be included in the SSD? With this question in mind, we investigate what species are actually possible to test in laboratory conditions to fulfil existing validity criteria of OECD test guidelines. The analysis is based on accepted studies as evaluated at the EU level during (re-) authorisation of active substances. We look at how and why some species are excluded from constructing an SSD.We also identify which macrophyte species grow in edge-of-field water bodies (ponds, streams and ditches) and which species can be considered as characteristic species. The characteristic species show a large overlap with the species typically used in the SSD approach.
EFSA (2013) aquatic guidance also states that While it is typically assumed that SSDs follow a normal distribution, significant deviation from normality (..) should be a trigger for trying other distributions, (e.g., Burr type III, Weibull) that may provide a better goodness of fit . Do the users of SSD often check the goodness of fit of the dataset for a particular PPP? We explore the evaluated active substances at the EU level to identify what distribution models have been typically used and whether goodness of fit was verified. We analyze whether other models would fit the datasets better and how the selection of underlying distributions may influence the agreed RAC. In addition, we explore the ready to use tools that allow a goodness of fit check and selection of distributions, e.g., ETX, Seb Dalgarno (2018) ssdtools, UBA R-based excel tool.

2.09.P-We098 Aquatic Macrophyte Toxicity: Water Phase vs Overspray Application

*Dirk Scheerbaum[1], **Jorn Rosner**[2], Kirsten McVean[1], Janis Fuller[1] and Antonia Maess[3], (1)Noack Laboratorien GmbH, Germany, (2)DHD-Consulting GmbH, Germany, (3)NOACK Laboratorien GmbH, Germany*

Following the data requirements (Commission Regulation (EU) 284/2013) for plant protection products with an herbicidal mode of action, effects on emergent (or floating) macrophytes (e.g., *Lemna gibba*) shall be assessed following test guideline OECD 221 (standard aqueous exposure). As most herbicides are applied by spraying, the member states of the Central Zone are of the opinion that (direct) exposure of floating macrophytes by spray drift should be considered as an additional scenario in the risk-assessment

in case of unexpected low toxicity (ExC50 > 1 mg/L) for the aqueous route.
Spray drift exposure can be recreated by an overspray-design in the laboratory. While this design is nowadays a common experimental procedure for terrestrial ecotox-studies, no guideline or validated test protocols are available to test aquatic macrophytes.
We herein present our developed and established test system to facilitate an overspray exposure scenario for *L. gibba*. Performance criteria have shown to be passed with high repeatability as well as precision and the results of initial investigations with an exemplary commercial herbicide comparing the two modes of exposure are presented.

2.09.P-We099 Comparing the Suitability of Non-Destructive Macrophyte Endpoints
Isabel Navarro Law[1]*, Colin Brown*[2]*, Jason Snape*[2]*, Rachel Samantha Benstead*[3]*, Michael Fryer*[4] *and Isabelle Durance*[5]*, (1)University of York, York, United Kingdom, (2)University of York, United Kingdom, (3)Fera Science Ltd., United Kingdom, (4)HSE, United Kingdom, (5)Cardiff University, United Kingdom*
Endpoint measurements are commonly used to assess the impact of chemical exposure on plant health. However, there is little research focusing on the reliability of endpoint measurements, meaning that commonly used endpoints may not always be an accurate reflection of plant health. In this study we compare the reliability and sensitivity of eight commonly used non-destructive endpoint measurements and suggest improvements to future plant ecotoxicology studies.
Eight emergent macrophyte species were selected for a long-term mesocosm study investigating the impact of 10 µg/L of metsulfuron-methyl on aquatic plants and their recovery. Eight endpoint measurements were selected: number of leaves, flowers and stems, length, width, quantum yield (QY) of PSII (a measure of photosynthetic efficiency, measured using a fluorometer) and percent necrosis and chlorosis (both separate and combined). These were recorded weekly for four weeks after dosing and fortnightly for a further fourteen weeks. The mesocosms were flushed on day 33 to remove any herbicide. Water samples were collected throughout and analysed by LC-MS/MS to measure the concentration of metsulfuron-methyl.
Focusing on just one of the species, results from Myosotis scorpioides demonstrated that whilst measuring necrosis and chlorosis poses issues with subjectivity, it is sensitive to changes in plant health. For instance, 46 days after exposure the individuals in the treated mesocosms had between 45 and 80% necrosis, significantly ($p < 0.05$) greater than the individuals in the controls (which all had 5% necrosis). However, both the width and the QY of PSII remained statistically similar across time between the control and treated individuals. The latter may be because only the healthiest part of the healthiest leaf was selected, meaning that if a plant only had one healthy leaf remaining, the results from QY of PSII could make the whole individual plant appear healthier than it is. The individuals in the treated mesocosms had significantly ($p < 0.05$) less stems and leaves than the controls 46 days after dosing, however after the chemical exposure was removed they had significantly ($p < 0.05$) more stems and leaves by day 116.
Our results suggest that relying on one endpoint measurement alone can provide unreliable results. In order to fully understand how chemical exposure impacts plant health and their ability to recover, multiple endpoints should be used in conjunction with one another.

2.09.P-We100 Approaching a Harmonized Assessment of Phytotoxicity in Aquatic Plants
Katrin Kuhl[1]*, Bastian H. Polst*[2]*, Gertie Arts*[2]*, Sarah Hartmann*[1]*,* ***Eric Bruns***[1] *and Andreas Solga*[1]*, (1)Bayer AG, Crop Science Division, Germany, (2)Wageningen University & Research Team Environmental Risk Assessment, Netherlands*
Visual injuries (phytotoxicity) in aquatic plants gain an increasing attention in the risk assessment of plant protection products, despite the lack of a clear validated evaluation/assessment scheme. So far mainly qualitative assessments of observed phytotoxicity effects in the registration studies have been performed. The assessed symptoms (if assessed at all) are often difficult to classify in their severity (e.g., minor, major) and prevalence (share of plants affected). Consequently, a statistical evaluation is hardly possible - if at all. In addition, it is not known which effect at which severity may cause the death of the plants or a significant impact on growth. Even if such data are recorded and assessed, comparison of phytotoxic effects between different labs or even different time periods remains difficult due to the use of individual and non-standardized assessment schemes.
Our goal is to develop and propose a harmonized assessment approach for different types of phytotoxicity symptoms in aquatic plants. In a first step we collect all available data from our studies (approximately 550 Lemna and 50 Myriophyllum studies), to evaluate the data and to find correlations between observed phytotoxic and conventional endpoints. In further steps we plan to propose an assessment scheme and evaluation process for phytotoxicity in different plant species. By performing lab experiments using chemicals covering a range of different modes of action, we aim to evaluate approaches regarding feasibility, reliability and reproducibility and ultimately define our scheme for assessment of phytotoxic

effects in aquatic macrophytes.
In our poster presentation we give an overview of our first results of the evaluation of our available aquatic plant studies based on our approach.

2.09.P-We101 Extending the Standard Lemna Growth Inhibition Test According to OECD 221 with Quantitative Phytotoxicity Assessments

*Daniel Stengel[1], Patrick Renner[2], **Katharina Pelka**[3] and Daniel Ruf[3], (1)Rifcon GmbH, Germany, (2)Biochem Agrar, Germany, (3)RIFCON GmbH, Hirschberg, Germany*

Authorities frequently request the inclusion of phytotoxicity-related parameters in endpoint derivation for aquatic macrophyte pesticide risk assessment in Europe. However, regulatory documents on phytotoxicity and guidance for scientifically sound assessments are scarce. In fact, assessment is only detailed for non-target-terrestrial plants. For aquatic macrophytes, relevant technical guidelines OECD 221 and OECD 239 from 2006 and 2014 mention phytotoxicity solely as data to be noted. Phytotoxicity assessment in current ecotoxicity studies remains inconsistent and mostly semi-quantitative, leading to evaluator-dependent variability and limiting reliability. Therefore, additional plant specific parameters such as chlorophyll content might be more promising for a quantitative and same time more reliable phytotoxicity evaluation. For this, a proof-of-principle study has been conducted to evaluate the feasibility of phytotoxicity assessment via Chlorophyll-a (hereafter Chl-a) quantification. In a standard study conducted with *Lemna gibba* following OECD 221 guidelines, with an herbicidal formulation containing two active substances, effects on phytotoxicity (i.e., chlorosis and root length) have been detected. These phytotoxicity effects were found at concentrations below the determined endpoints based on growth rate. Subsequently, a further OECD 221 study modified by a method for chlorosis quantification based on Chl-a extraction and spectrophotometric determination has been conducted.
Chl-a measurements indicated effects at lower concentrations than standard chlorosis assessment, making Chl-a inhibition as expected a more sensitive and reliable indicator of treatment-related phytotoxicity than standard visual semi-quantitative chlorosis assessment. However, it was not possible to calculate definitive endpoints needed for the risk assessment (i.e., EC10 or EC50) for Chl-a as the chosen concentration range did not cover the full scope of effects on Chl-a content. In analyzing dose-response pattern, no clear correlation was observed between Chl-a and growth rate or yield inhibition.
In conclusion, Chl-a content analysis has shown potential as a reliable method for assessing phytotoxicity. We, therefore, suggest addressing phytotoxicity with quantifiable methods such as Chl-a content analysis to reduce phytotoxicity related uncertainty in pesticide risk assessment in Europe.

2.09.P-We102 Elevated Temperature and CO2 Conditions Attenuate the Toxicity of Sulfamethoxazole on Barley Plants at Low Concentrations but Exacerbate It at Higher Levels

*Austra Diksaityte, Giedre Kaciene, Irena Januskaitiene, Diana Miškelytė, Gintare Sujetoviene and **Jurate Zaltauskaite**, Vytautas Magnus University, Lithuania*

Sulfonamides (SAs) are the oldest and still one of the most widely used antibacterial agents in veterinary medicine, owing to their low cost and relative efficacy against some common bacterial diseases. However, due to poor metabolization in animals, a large portion of the administered amount is excreted, entering the environment through field fertilization with animal manure and slurry. Accumulated in the soil, SAs can be absorbed by plants, posing a potential threat to human health through the food chain. While the use of antibiotics continues to increase, the effects of these pharmaceuticals on plants are still poorly understood, especially under changing climate conditions. The toxicity mechanisms of sulfamethoxazole (SMX) at different concentrations (0, 1, 10, 25. and 50 mg kg 1) on pot-grown barley (Hordeum vulgare L.) plants were investigated in this study under ambient and elevated temperature and CO2 conditions (ATC, 21/14 °C, 400 ppm vs. ETC, 25/18 °C, 800 ppm, respectively). It was found that ETC conditions increased the photosynthetic efficiency and growth of barley and attenuated the toxic effects of SMX at low concentrations (1 mg kg 1) but exacerbated its toxicity at higher levels. The main mechanism by which SMX affected barley s growth was the closure of photosystem II reaction centers, with a rate increasing with increasing concentration, resulting from functional impairment in the activity of oxygen-evolving complex and non-photochemical quenching. This led to a considerably decreased utilization of excitation energy in photochemical reactions, resulting in almost complete growth retardation at 50 mg kg 1 SMX treatment under ETC conditions. Thus, the worrying effects of SMX on crop production could become even more pronounced with the changing climate conditions.

2.09.P-We103 Ecotoxicological Test Protocol for the Assessment of Reproductive Endpoints in Non-Target Terrestrial Plants under Greenhouse Conditions

Andreas Duffner[1]*, David Mark Olszyk*[2]*, Bianca Flickinger*[3]*, Fernando Huerta*[4]*, Holger Teresiak*[5]*, Joanna Davies*[6]*, Lucia Privitera*[7] *and Christine Mihan*[8]*, (1)Eurofins Agroscience Services Ecotox GmbH, Germany, (2)U.S. Environmental Protection Agency, United States, (3)BASF SE, Germany, (4)Eurofins Trialcamp S.L.U., Spain, (5)agro-check, Dr.Teresiak & Erdmann GbR, Germany, (6)Syngenta, United Kingdom, (7)Greenhouse Team, AgroChemex Environmental, United Kingdom, (8)Bayer AG, Crop Science Division, Germany*

Ecotoxicological testing to assess the effects of plant protection products on non-target terrestrial plants (NTTPs) under greenhouse conditions is conducted according to standard guidelines (e.g., OECD 208 and OECD 227). EFSA s Scientific Opinion of 2014 on the risk assessment of plant protection products (PPP) for non-target terrestrial plants raised awareness of a potential need to assess effects on plant reproduction. Literature reviews and experimental studies evaluated the feasibility and relevance of plant reproductive endpoints. In summary, it can be concluded that (a) assessment of reproductive endpoints in selected plant species is in principle feasible, (b) there is no clear trend that reproductive endpoints are more sensitive than vegetative ones, and (c) cases may occur where reproductive endpoints appear to be more sensitive depending on, e.g., mode of action of a plant protection product and/or test species.

For cases where effects on reproductive endpoints need to be assessed for regulatory purposes, a standard test protocol is required.

A working group within the SETAC Plant Interest Group collected and analyzed relevant and available data and experiences to provide an ecotoxicological test protocol for the assessment of reproductive endpoints in Non-Target Terrestrial Plants under greenhouse conditions.

This poster will provide an overview of the protocol and will highlight the challenges and special considerations such as test duration, plant species and endpoint selection as well as statistical evaluation.

2.09.P-We104 Environmental Risk Assessment of Plant Protection Product Residues on Imported Cut Roses

Daphne de Roode*, Joost Meekes and Marca Schrap, Office for Risk Assessment & Research (BuRO), Netherlands Food and Consumer Product Safety Authority, Netherlands*

In the EU, the use of plant protection products is restricted to approved active substances in authorised products based on EU legislation. In addition, maximum residue levels on food & feed apply to both locally grown and imported crops. This is not the case for imported cut flowers, which must however comply with phytosanitary requirements. High levels of residues, including substances that are not approved in the EU, have been found on imported cut flowers, but thus far, environmental risks from these residues remain unknown.

Waste of cut flowers may be discarded through green waste and then get composted. Through composting, residues from cut flowers may reach the environment. As the soil is the primary receiving compartment of compost, we conducted an environmental risk assessment for soil organisms and bees exposed to compost that contains residues from imported roses. Bees were included as they may be exposed via plants and the residues encountered in our study include many insecticides, some of which are neonicotinoids.

Roses imported from outside the EU were sampled and subjected to chemical analysis using a QuEChERS extraction followed by GC- or LC-MSMS. Concentrations were then modelled using Bayesian techniques to estimate mean and 95th percentile concentrations on imported roses. These were compared to safe concentrations in soil, which were derived from ecotoxicological endpoints for soil organisms and bees, and from environmental quality standards for soil and surface water. Safety factors used to calculate safe concentrations in soil from endpoints for plants, soil micro-organisms, earthworms, springtails, soil mites and other soil insects were taken from ECHA and RIVM guidance and were affected by data availability. Safe concentrations for bees were calculated using the scenario for sludge application (ECHA guidance) and using safety factors comparable to those for soil organisms. Environmental quality standards for soil were used as such, while environmental quality standards for surface water were recalculated to safe concentrations in soil using equilibrium partitioning. The lowest safe concentration for each substance was used for the risk characterisation, where P95 and mean concentrations in roses were divided by safe concentrations in soil. The resulting risk ratios varied between <1 and nearly 1000,000, indicating a potential risk to soil organisms and/or bees resulting from imported roses in green waste.

2.09.P-We105 Zn-Al-NO3 Layered Double Hydroxide as Potential Innovative Zn Nanofertilizer: An Integrated Assessment of its Efficacy and Environmental Safety

Catarina Correia de Lemos Malheiro[1]*, Marija Prodana*[2]*, Diogo Filipe Nunes Cardoso*[1]*, Rui G. Morgado*[3] *and Susana Loureiro*[4]*, (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)CESAM and Department of Biology, University of Aveiro, Portugal,*

(4)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal
The United Nations predicts the world population will reach 11 billion by 2100. Agricultural production must ramp up to cope with the expected increased food demand. Fertilizers, widely used to enhance plant productivity, often cause soil degradation. Thus, developing innovative products with improved efficacy and environmental safety is crucial. Nanotechnology has shown potential for agricultural use as it is expected to optimize agricultural practices while reducing environmental impacts. Among the several classes of nanomaterials, layered double hydroxides (LDHs) have been receiving increasing attention. Still, considering their novelty, more information on their effects on different terrestrial organisms must be available. To overcome this gap, an integrated assessment was conducted, focusing on the evaluation of the effectiveness of Zn-Al-NO3 LDH as an innovative nanofertilizer to a target species (maize) and safety to non-target species (enchytraeids and collembolans), along with the exposure chemical assessment. Results indicated that soil fertilization with LDH at a recommended dose, aligned with maize nutritional needs, enhanced plant emergence and shoot length compared to a conventional fertilizer (ZnSO4). While Zn accumulated in maize roots with low translocation to shoots, root morphology remained unaffected. Comparing the release of Zn, ZnSO4 was more effective in the immediate Zn supply, while LDH controlled the release of Zn throughout time. In addition, the environmental safety of the nanofertilizer was evaluated by assessing its effects on the avoidance behaviour, survival and reproduction of enchytraeids and collembolans. The results showed that both enchytraeids and collembolans could detect the LDH in soil. Comparing both species, enchytraeids were more sensitive to their presence, likely due to organisms different exposure routes. Reproduction was the most sensitive endpoint, followed by avoidance and survival, indicating a potential risk, as the concentrations usually not perceived as harmful might induce a chronic effect, such as affecting reproduction success and the future of the population. The quantification of Zn in the soil pore water showed that LDH underwent changes and released Zn, which could be responsible for the observed effects on soil organisms. Overall, this study showed that Zn-Al-NO3 LDH has the potential to replace Zn conventional fertilizers since its application rate does not exceed toxicity thresholds.

2.10 Integrative Approaches to Biomonitoring and Wildlife Toxicity: Improving the Assessment of Exposure and Effects of Legacy and Emerging Contaminants.

2.10.T-01 Brown Rat (*Rattus norvegicus*) Metabolic Adaptation to High Rodenticide Usage in the Sewer System of the City Core of Madrid

***Azucena Bermejo-Nogales**[1], Jose Maria Camara[2], Agustin Cordobes[3], Maria Santos[4], Begona Aguado[4], Bruno Hernaez[4], Antonio Alcam[4] and José María Navas[1], (1)Instituto Nacional de Investigacion y Tecnolog a Agraria y Alimentaria (INIA-CSIC), Spain, (2)Madrid Salud. Department of Vector Control of the City Council of Madrid, Spain, (3)Lokimica, Madrid, Spain, (4)Centro de Biolog a Molecular Severo Ochoa (CSIC-UAM), Spain*
The impressive adaptability of the commensal brown rat (*Rattus norvegicus*) metabolism could explain the wide presence of this species in the sewer system of cities as one common urban pest. Anticoagulant rodenticides (ARs) are used for control of rat populations and multiple studies have shown that rat populations can exhibit resistance to ARs associated with nonsynonymous substitutions in the vitamin K epoxide reduc-tase complex subunit 1 (vkorc1) gene. However, few studies explore other resistance pathways. The metabolic hypothesis suggests that increasing metabolism (and detoxi-fication processes) in rodents can lead to a reduction of the half-life of rodenticides in the organism provoking, a resistance phenomenon. Therefore, identifying genes associ-ated with this adaptive metabolism could provide valuable information for the complex networks underlying variations in resistance. The aim of this study was to detect the metabolic (including detoxification) pathways involved in rodent resistance by means of RNA sequencing. We explored the transcriptome of rats captured in an area of high ro-denticide usage in the sewage system of Madrid. We obtained RNA post-mortem samples of rat tails with high quality (RIN scores >8) for total RNA sequencing library preparations. In total, we obtained 57-79 million high-quality paired reads per sample with a mean alignment rate to reference of 58.2%, after discarding a sample due to low alignment rate (<15%). Samples were stratified according to the number of SNPs and normalized counts of the vkorc1 gene to define a threshold to group samples into SNP (SNP>5, ncounts>400) and noSNP (SNP < 5, ncounts < 400) groups for differential ex-pression analysis. The number of differentially expressed genes (DEGs) detected ranged from 5,359 to 7,106 depending on analysis, of which 4,081 were common to all analysis performed. From the Salmon-based DEGs, 557 also presented SNPs in their coding se-quence. These SNP presenting DEGs were used for Gene-Set Enrichment Analysis (GSEA) on KEGG pathways, showing 6 positively and 18 negatively related enriched categories. Thus, the SNP group had higher expression of the complement and coagula-tion cascades and lower expression of

xenobiotic, drug or retinol metabolism related genes. Integrated interpretation of both total SNP and differential gene expression will elucidate Adverse Outcome Pathways related with metabolic resistance in rodent popu-lations adapted to a high rodenticide use.

2.10.T-02 Dermal Pesticide Exposure of Sand Martins (*Riparia riparia*) and Barn Swallows (*Hirundo rustica*) as a Potential Cause for their Acute Death

***Aafke Saarloos*[1]**, *Maarten Schrama[2], Henrik Barmentlo[2], Judith van den Brand[3], Natashja Ennen-Buijs[3], Reina Sikkema[4], Tijs van den Berg[5] and Nico van den Brink[1], (1)WUR, Netherlands, (2)CML, Leiden University, Netherlands, (3)DWHC, Netherlands, (4)Erasmus Medical Center, Netherlands, (5)WRS de Haar, Netherlands*

The current study investigates two spontaneous mass mortality incidents in two different swallow bird species in the Netherlands. The first incident was observed in a sand martin (*Riparia riparia*) colony near Utrecht and occurred during bird ringing. More than 30 individuals showed direct mortality, plus an additional of 15 individuals that died soon after being caught. The affected sand martins exhibited remarkable symptoms of neurological behavior: proptosis, hypotonia and ataxia. A second comparable case was observed in barn swallows (*Hirundo rustica*) in Noord-Holland. To determine the potential cause of death for these two cases, dead swallows were collected, necropsied and samples were taken for a virological, pathological and pesticide exposure assessment. The virological and pathological examination is work in progress, but the 650 pesticides screening of brain, feather, liver and stomach samples revealed the ubiquitous presence of the pyrethroid insecticides permethrin and tetramethrin. Only traces were detected for some other pesticides, but most pesticides were not detected. The average concentration of permethrin and tetramethrin in barn swallow feathers was 18.6 ug/g feathers (0.8 to 46 ug/g) and 0.7 ug/g (0.05 to 1.5 ug/g) feathers, respectively. The average concentration of permethrin and tetramethrin in sand martin feathers was 62.7 ug/g (11.7 to 137.3 ug/g) and 8.7 ug/g (1.9 to 19.9 ug/g) feathers, respectively. Remarkably, permethrin and tetramethrin concentrations were absent or detected at relatively low levels in liver and stomach samples. An unexpected result based on the available toxicity data for these compounds and the birds remarkable acute neurotoxicological symptoms. These observations suggest that the main route of exposure may not have been oral, but via acute dermal pesticide exposure. A suggestion that is supported by the observed high concentrations of permethrin and tetramethrin in feather samples, and its presence in some brain samples. This finding could potentially help to explain their neurological behavior (work in progress, will elaborate on this more during presentation). Concerning is that current environmental risk assessment of chemicals does often not adequately consider the impact of direct pesticide exposure to wildlife, and knowledge on potential effects of this exposure route is lacking. However, the results of the current study suggest that dermal exposure is the exposure route of relevance.

2.10.T-03 Developing Non-invasive Tools for Monitoring Pharmaceutical Exposure in Avian Scavengers

Nelly Arlot[1], ***Marta Herrero-Villar*[1]** *and Rafael Mateo[2], (1)Institute for Game and Wildlife Research (IREC-CSIC-UCLM-JCCM), Spain, (2)Institute for Environmental Assessment and Water Research (IDAEA-CSIC), Spain*

Pharmaceuticals are now a well-known environmental concern. Veterinary drugs can reach avian scavengers through the trophic chain when consuming previously treated livestock with potential negative consequences. The most dramatic example of this was the devastating effect that had diclofenac, a non-steroidal antinflammatory drug (NSAID) in Gyps vultures from Asia. Residues of this NSAID in the carcasses easily reached vultures resulting in an acute renal failure and extended visceral gout. Other NSAIDs have also been identified as highly toxic to avian scavengers, such as flunixin, ketoprofen, nimesulide or carprofen. NSAID intoxications with diclofenac and flunixin have already been detected in Spain, which hosts the biggest European vulture population. Several studies have confirmed the presence of NSAIDs and other pharmaceuticals such as antibiotics, antiparasitic drugs or barbiturates in avian scavengers and livestock carcasses from Spain. Even though, these methods require strong sampling efforts. Therefore, here we developed a non-invasive method to monitor these compounds using pellets as a matrix to collect information on exposure to pharmaceuticals in sites surrounding vulture feeding stations. For this we sampled pellets (n = 292) from vulture roosting sites among different regions in Spain during 2021, 2022 and 2024. We analysed 49 compounds that included 13 NSAIDs, 32 antibiotics, 3 antiparasitic drugs, and 1 anticholinergic drug, using a liquid chromatography coupled with electrospray ionization mass spectrometry (LC-ESI-MS/MS). Additionally, a subsample was taken from each pellet for identification of the main prey to study their association with the presence of pharmaceuticals. Veterinary pharmaceuticals were detected in 44.2% of pellets: 43.5% with antibiotics, 2% with NSAIDs and 1.4% with both. Regarding the diet, pellets containing only domestic livestock hair showed the highest prevalance (49.5%) for pharmaceuticals, followed by mixed pellets (38.6%), and pellets of wild animals (33.3%). Our results state that vultures in Spain are exposed to a wide variety of pharmaceuticals. We found that certain levels of compounds are influenced by the type of livestock ingested previously by the scavengers such as pig and chicken. Therefore, we emphasize that the disposal of carcasses for avian scavenger feeding must be closely monitored and consider the potential risks posed by veterinary pharmaceutical residues, notably NSAIDs.

2.10.T-04 A Bat-Barber for Metal Exposure?

Annalisa Zaccaroni[1], *Rebecca Andreini*[1], *Marina Silvi*[1], *Federico Plazzi*[2], *Manuel Spinola Parrallada*[3] *and Karen Daniela Sibaja-Morales*[4], *(1)Department Veterinary Medical Sciences, University of Bologna, Italy, (2)Department of Biological, Geological and Environmental Sciences (BiGeA), University of Bologna, Italy, (3)Instituto Internacional en Conservacion y Manejo de Vida Silvestre, National University of Costa Rica, Costa Rica, (4)Universidad Estatal a Distancia (UNED), Costa Rica*

Bats represent a fundamental part of the Costa Rican ecosystem, characterized by varied diets and food sources. They are also susceptible to numerous exogenous stressors, making them critical environmental indicators. Collecting Chiroptera biological samples can be a valuable tool for better understanding bat populations' health status and the environment's ecotoxicological condition. Sampling from wild bats can be complex due to their size and ecological characteristics. Furthermore, the less invasive method of collection is required to minimize stress and potential physical damage to the subjects. The value of hair as a reliable sample for metal detection and quantification is well documented in the literature. Despite this, little research on trace elements in bat hair has been conducted in Costa Rica. In this study, we analyzed trace element concentration in the hair of 23 different bat species (320 animals in total) from Costa Rica in the geographic area of Sarapiqui, including frugivorous, nectarivorous, insectivorous, and hematophagous bat species. Bats' hair was collected by capturing subjects using 8 mist nets. Each bat was taxonomically identified on external physiologic characters and shorn in the lumbosacral portion of the back to collect hair using ordinary scissors, and then bats were released. Trace elements (As, Cd, Cr, Hg, Ni, Pb, Co, Cu, Fe, Mn, Se, and Zn) were analyzed using an Inductively Coupled Plasma-Optic Emission Spectrometry (ICP OES) technique on a Perkin Elmer Optima 2100 DV couple with a CETAC U5000AT+ ultrasound nebulizer for mercury. The distribution of heavy metals in bats highlighted no particular differences in the accumulation among species, while differences were found among sampling sites. Cd, Cr, Pb, and As were among the metals showing the highest concentrations, and PCA analysis also revealed that the analyzed elements form, on the totality of the samples, into two groups, one represented by Zn, Ni, Pb, and Hg, the second by the remaining elements. This allows us to infer that diet is not the primary source of metals but rather a deposition at the environmental level, and anthropogenic activities cause the difference in the latter at the various sites sampled. The obtained results prove the effectiveness of hair for non-invasive monitoring of contaminants and the importance of collecting and integrating all possible data in the analysis and interpretation of research outcomes to get to more reliable conclusions.

2.10.P-We115 Monitoring Chemicals Exposure and Mixture Effects in Terrestrial Food Chains in Europe

Paola Movalli[1], *Georgios Gkotsis*[2], *Reza Aalizadeh*[2], *Nikolaos Boinis*[3], *Antigoni Konomi*[2], *Faidra-Angeliki Mourtzoukou*[2], *Eleni Panagopoulou*[4], *Nikiforos Alygizakis*[5], *Guy Duke*[5], *Peter Fantke*[5], *Peter Oswald*[5], *Martina Oswaldova*[5], *Jaroslav Slobodnik*[5], *Koos Biesmeijer*[1], *Aglaia Bouma*[1], *Becky Dejardins*[1], *Barbara Gravendeel*[1], *Liselotte Rambonnet*[1], *Tom M. Nolte*[1], *Vincent van de Pas*[1], *Jan Wieringa*[1], *Henrik Barmentlo*[6], *Philipp Kropf*[7], *Olivier Jolliet*[8], *Susan Oginah*[8], *Laura Scherer*[6], *Martina G. Vijver*[6], *Romana Hornek-Gausterer*[9], *Oliver Machate*[10], *Gabriele Treu*[10], *Sofia Gomes*[11] *and Nikolaos S. Thomaidis*[2], *(1)Naturalis Biodiversity Center, Netherlands, (2)National and Kapodistrian University of Athens, Greece, (3)Chemistry, National and Kapodistrian University of Athens, Athens, Greece, (4)National and Kapodistrian University of Athens, ., Greece, (5)Environmental Institute, Slovakia, (6)CML, Leiden University, Netherlands, (7)CLM, Leiden University, Netherlands, (8)Technical University of Denmark, Denmark, (9)German Environment Agency (UBA), Austria, (10)German Environment Agency (UBA), Germany, (11)Institutw of Biology, Leiden University, Netherlands*

We have insufficient knowledge of exposure of terrestrial biota to anthropogenic chemicals in the environment, and of effects on terrestrial biodiversity and ecosystem services. TerraChem is carrying out research on monitoring exposure and mixture effects in wildlife food chains in order to: (1) detect and determine chemicals, and predominant chemical mixtures, in selected apex species food chains in

representative terrestrial ecosystems across Europe; (2) better understand exposure including routes and extent of trophic transfer; (3) explore patterns for individual contaminants and predominant mixtures in the selected food chains; (4) elucidate toxic effects of chemical mixtures on vertebrates; and (5) collate secondary data on contaminants along trophic chains in terrestrial ecosystems in Europe. We implemented a pan-European case study (barn owl Tyto alba food chain in 6 countries) and six single-country case studies on apex mammal species food chains. In each country, for each case study, we gathered samples from six apex species territories. We gathered one apex species liver sample per territory. Four samples of each type of food chain sample were pooled to give, for each territory: 1 pooled vertebrate prey species A (e.g., wood mouse *A. sylvaticus*) soft body tissues sample; 1 pooled vertebrate prey species B (e.g., field vole *M. agrestis*) soft body tissues sample; 1 mixed invertebrate species group A (herbivore/fungivore/ detritivore) sample; 1 mixed invertebrate species group B (omnivore/carnivores) sample; 1 mixed plant species leaves sample; 1 bulk soil sample. For each territory, food chain samples were collected within a short time-frame for temporal co-location. Samples will be analysed using: (1) instrumental analysis with ultra-high performance LC-HRMS and GC-HRMS for identification of c. 2,500 known emerging substances and suspect screening of >100,000 substances; (2) sensitive targeted methodologies for the determination of legacy substances. Additional analyses will include: (1) CALUX bioassays for analysis of mixture effects; (2) stable isotope analysis to inform analysis of routes of transfer and trophic magnification; (3) metabarcoding of soil and invertebrate samples to support source-to-damage modelling and work on prevention and mitigation of risks. The presentation will include discussion and conclusions on the design of a sampling regime and preliminary results from the target analyses and non-target screening.

2.10.P-We119 Legacy and Emerging Poly- and Perfluoroalkyl Substances (PFAS), and Non-Target Screening in Marine Mammals Stranded around the UK

Imogen Bailes[1], *Jonathan Barber*[2], *Sara Losada.*[2], *Rob Deaville*[3], *Rosie Williams*[3], *Andrew Brownlow*[4], *Lee Walker*[5], *Shinji Ozaki*[5], *Christopher Green*[6] *and Andrew Sweetman*[7], *(1)Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom, (2)Cefas, United Kingdom, (3)Zoological Society of London, United Kingdom, (4)University of Glasgow, United Kingdom, (5)UKCEH, United Kingdom, (6)DEFRA, United Kingdom, (7)Lancaster University, United Kingdom*

Poly- and perfluoroalkyl substances (PFAS) are a large group of chemicals that display unique properties due to combined oil and water repellence, extreme stability, and hence are used in a wide range of industrial processes and consumer products. These chemicals can be problematic in the environment due to their potential to undergo long-range transport, persistence and toxicity. However, only some of these substances have been regulated by the Stockholm Convention and other international regulations. Beyond these known PFAS, numerous other related chemicals remain undetected due to the limitations of traditional targeted analyses. Non-targeted screening allows for the identification of both known and previously unrecognized contaminants.

We analysed the liver tissue of 200 individuals from a variety of species stranded between 2012 and 2022, collected by the UK Cetacean Strandings Investigation Programme (CSIP). We employed an ultra-performance liquid chromatograph coupled to a high-resolution mass spectrometer (Orbitrap) to analyse a range of both legacy and emerging PFAS including 11 PFCAs (C4-C14), 9 PFSAs (C4-C10), 3 FASAs, 3 PFPiAs and 6 fluorotelomer acids, among others in mammal liver tissue. Further, we ran pooled extracts using data-dependent acquisition to generate MS2 spectra. CompoundDiscoverer software was used to identify chemicals present.

We report high total PFAS concentrations in a range of species of marine mammals collected around the UK. Concentrations of different compounds vary highly within species, but most species tend to be dominated by PFOS and long chain PFCAs. Total PFAS concentrations had an average of ~ 200 ng/g ww between species, with bottlenose dolphins having the highest total PFAS concentrations. Total PFAS concentrations decreased in our study period (2012 and 2022) for both cetaceans and seals which could be as a result of global restrictions such as the Stockholm Convention. Preliminary results from non-target screening in this study have revealed the presence of a range of active pharmaceutical ingredients and potentially narcotic substances. This study highlights the importance of continued biomonitoring and underscores the complementary use of targeted and non-target screening approaches.

2.10.P-We136 Metal Contamination and Ecological Niche Variations in Sea Turtles of São Tomé and Príncipe

The São Tomé and Príncipe archipelago hosts nesting sites for four of the seven existing and threatened sea turtle species. Due to their wide distribution, long lifespan, and diverse feeding behaviours, sea turtles often accumulate pollutants, such as metals and metalloids, throughout their complex life cycle. This study investigated metal contamination and isotopic signature in three sea turtle species *Chelonia mydas*, *Eretmochelys imbricata*, and *Lepidochelys olivacea* comparing two different life stages (nesting females, males, and juveniles) from São Tomé Island. Additionally, nesting females green (*C. mydas*) and hawksbill (*E. imbricata*) sea turtles from Príncipe Island were analysed to compare contamination levels and isotopic niches between the two islands. Female olive ridley turtles (*L. olivacea*), which nest exclusively on São Tomé Island, showed higher levels of several elements (e.g., Ca, Fe, K, Zn, Se, Cd), which could reflect natural physiological levels, contamination and/or unique dietary sources. Additionally, green and hawksbill sea turtle populations, including both adults and juveniles, showed elevated concentrations of elements such as S, Cs, and Pb. Moreover, differences in chemical elements contamination were observed between female green turtles across the two islands, despite their similar isotopic signatures. On São Tomé Island, isotopic niche analysis revealed variations in ?^{1}?N and ?^{13}C values, suggesting that green, hawksbill and olive ridley turtle populations differ in their ecological niches and/or exhibit dietary habitats, both across species and between developmental stages. This study provides insights into chemical element contamination and ecological niches across sea turtle species in the archipelago, highlighting species-specific and life-stage variations that reflect differences in diet, ecology, and environmental contamination. Furthermore, these findings enhance understanding of contamination dynamics, providing insights that can help local NGOs design targeted conservation strategies and inform policy decisions.

Disclaimer/Disclosure: This study had the support of Fundação para a Ciência e a Tecnologia (FCT) through the Strategic Project granted to MARE Marine and Environmental Sciences Centre (doi.org/10.54499/UIDB/04292/2020 and doi.org/10.54499/UIDP/04292/2020), the project granted to the Associated Laboratory ARNET (doi.org/10.54499/LA/P/0069/2020), the grants awarded to IM (doi.org/10.54499/PD/BD/1505 62/2019) and to MIL (doi.org/10.54499/UI/BD/150956/2021) and the contracts to FC (DL57/2016/CP1370/CT90) and SN (doi.org/10.54499/CEECINST/00060/2021/CP2902/CT0007). We are thankful to all the members of NGO Programa Tatô, NGO Fundação Príncipe and research assistants that helped us in the field under challenging conditions.

2.10.P Integrative Approaches to Biomonitoring and Wildlife Toxicity: Improving the Assessment of Exposure and Effects of Legacy and Emerging Contaminants

2.10.P-We106 Chemical Profiling of Hydrophobic Organic Compounds in Terrestrial Mammals at High Trophic Levels Using Silicone Chemometers

Caglar Akay[1]*, Elisa Rojo-Nieto*[1]*, Claudia A. Szentiks*[2]*, Ursula Siebert*[3] *and Annika Jahnke*[4]*, (1)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Department of Wildlife Diseases, Leibniz Institute for Zoo and Wildlife Research, Germany, (3)Institute for Terrestrial and Aquatic Wildlife Research, University of Veterinary Medicine Hannover, Germany, (4)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ) & Institute for*

Environmental Research (IFER), RWTH Aachen University, Germany
Passive equilibrium sampling using silicone chemometers is an effective tool for sampling and assessing hydrophobic organic compounds (HOCs) in biota. Silicone chemometers have been applied to evaluate HOCs in lipid tissues of various marine mammal species; however, their use for the bioaccumulation assessment of pollutants in terrestrial mammals remains largely underexplored. Here, we address this gap by characterizing the chemical exposome of four terrestrial and two semi-terrrestial mammal species, representing different feeding habits and habitats.
We used silicone chemometers to extract and analyze approximately 100 legacy and emerging HOCs from 83 lipid-rich blubber samples collected from nutria (n = 10), otter (n = 10), fox (n = 3), raccoon dog (n = 20), raccoon (n = 10), and wolf (n = 30). Targeted chemical analysis was performed using gas chromatography coupled with high-resolution mass spectrometry (GC-HRMS Orbitrap Q-Exactive), covering polybrominated diphenyl ethers (PDBEs), polychlorinated biphenyls (PCBs), chlorinated hydrocarbons (CHCs), and organochlorine pesticides (OCPs), polycyclic aromatic hydrocarbons (PAHs), pyrethroids, musks and other industrial compounds. Here we focus on PBDEs, PCBs, OCPs, and CHCs, as data evaluation for the other HOCs is ongoing.
We identified 19 out of 37 target compounds in at least one of the 83 blubber samples, while 18 were absent from all samples. PCBs and OCPs were the most frequently detected HOCs across all species. Furthermore, PCB153, PCB170 and PCB180 were present at elevated concentrations compared to other PCBs. The metabolite 4,4 -Dichlorodiphenyldichloroethylene (DDE) was determined in all otter samples (up to 119 pg/mgPDMS), half of the raccoons (up to 36 pg/mgPDMS), and 12 wolves (up to 22 pg/mgPDMS) but was absent in nutria. The presence of DDE indicates historical contamination with 4,4 - Dichlorodiphenyltrichloroethane (DDT), with DDE being detected five times more frequently than its precursor. Higher concentrations and detection frequencies of HOCs in otters than in other species investigated in our study suggest distinct exposure through their diet and habitat.
Overall, our findings highlight the persistence and bioaccumulation of legacy pollutants, such as PCBs and DDE, in high trophic level terrestrial mammals, despite regulatory bans on these HOCs. Future work will expand the range of HOCs and explore patterns across terrestrial mammals, marine mammals, and humans in our HGF project EXPOSO-METER.

2.10.P-We107 Enhancing the Risk Assessment of Pesticides on Bats: A Case Study from the SYBERAC Horizon Project

***Berta Perez Vazquez**, Silvia Lacorte and Ana Lopez-Antia, IDAEA-CSIC, Spain*

Bats are an order of mammals that might be especially vulnerable to contaminants due to their unique characteristics as high metabolic rate and k-selected reproduction. In addition, they are particularly susceptible to dermal exposure because of their large and highly vascularized wing surface.
Since bats inhabit and forage in farmlands, they are at risk to pesticide exposure, nevertheless, recent research questions if bats are adequately covered by the current European Food and Safety Authority (EFSA) guidance for risk assessment for birds and mammals from plant protection products (PPP). On the other hand, this guidance excludes rice fields scenarios due to its cultivation in water. This research aims to investigate the exposure to pesticides of the bat species Pipistrellus pygmaeus and Pipistrellus nathusii foraging in the rice fields of Ebro Delta (Spain), and the direct and indirect effects that they might pose.
In the present study, nearly 60 bat boxes are included, placed near rice fields with an ascendent gradient of synthetic pesticide usage: from 0, in organic fields, up to 14 active substances along the rice growing season.
To estimate the exposure to contaminants, samples of blood and faeces of bats as well as samples of arthropods will be collected along the rice growing season and analysed by LC-(HR) MS/MS.
In order to assess the potential direct effects at an apical level, the corporal condition of each specimen sampled will be determined. Bats behaviour will be studied by analysing the differences in foraging activity, which will be quantified with ultrasonic recording devices. In addition, reproductive success will be investigated. The indirect effects will be assessed by studying the abundance and diversity of arthropods that constitute bat s food supply. The characteristics of the landscape surrounding the rice fields will be taken into account, as presence and quality of field margins or the proximity to natural areas. This study will provide necessary information about exposure and sensitivity of bats to pesticides, helping to conduct an improved Environmental Risk Assessment (ERA) for bats in agricultural environments. Ultimately, it will assist in proposing measures towards the alienation of rice production and biodiversity conservation.
This research is one of the study cases of the SYBERAC Horizon Project, which aims to better understand the chemical impacts on biodiversity and ecosystem services.

2.10.P-We108 Immunoglobulin G Characterisation in Iberian Hare Inhabiting Agricultural Landscapes and Exposed to an Infectious Disease

*Clara Munoz-Hernandez[1], Marinela Contreras-Rojo[1], Beatriz Cardoso[1], Ignacio Garcia Bocanegra[2], Isabel G. Fernandez de Mera[1], Jose Alberto Vinuela[3], Pelayo Acevedo[1] and **Monica Martinez-Haro**[4], (1)Institute for Game and Wildlife Research (IREC, UCLM-CSIC-JCCM), Spain, (2)Departamento de Sanidad Animal, Grupo de Investigacion en Sanidad Animal y Zoonosis (GISAZ), Universidad de Cordoba, Spain, (3)CIAPA de Marchamalo, Instituto Regional de Investigacion y Desarrollo Agroalimentario y Forestal de Castilla La Mancha (IRIAF), Spain, (4)Institute for Game and Wildlife Research (IREC, UCLM-CSIC-JCCM); CIAG del Chaparrillo, Instituto Regional de Investigacion y Desarrollo Agroalimentario y Forestal de Castilla La Mancha (IRIAF), Spain*

During the 20th century agricultural landscapes have undergone major alterations due to agricultural intensification, which has been linked to population decline of plants, arthropods, birds and mammals. Agricultural intensification has led to a significant homogenisation of the landscape due to land consolidation, and to the entry of more and more chemical pesticides and fertilisers into the environment. Pesticides directly and indirectly destroy many target organisms for which they were designed, altering the food chains in natural ecosystems. But they also have lethal and sub-lethal effects on non-target organisms. Sub-lethal effects are related to chronic exposures and can have consequences in the health status of individuals, being able to affect the immune system. The immune system is particularly relevant to protect organisms against pathogens such as those that cause infectious diseases. A good study model of this relationship is found in the lagomorphs of the Iberian Peninsula, as the Iberian hare (Lepus granatensis) and the effect of myxoma virus (MYXV, genus Leporipoxvirus, family Poxviridae). For that, blood samples were collected from hunted animals during the 2021/22 hunting season in the southwestern Spain from animals with and without lesions compatible with myxomatosis. For this study the levels of immunoglobulin G, together with MYXV antibodies in serum, and viral presence, were analysed for a first immune system characterisation in animals from pesticides-treated and untreated areas. Overall, the results show that hares from treated areas have lower mean IgG concentrations than those from untreated areas. In addition, the results show particularly low IgG concentrations in animals with lesions, viral presence, and absence of antibodies, suggesting that this disease may be occurring more severely in individuals living in areas treated with pesticides.

Disclaimer/Disclosure: Project funded by the Junta de Comunidades de Castilla-La Mancha and the European Regional Development Fund (SBPLY/21/180501/000182).

2.10.P-We109 Assessment of Environmental Contamination and Pathogens in the Conservation of Bats in Wetland National Parks in Spain – QUIROTOXPATH Project

***Monica Martinez-Haro**[1], Ana M Rubio Polonio[1], Marta Rafael[1], Alberto Moraga Fernandez[1], Jesus Nogueras[2], Carlos Ibanez[2], Javier Juste[2] and Isabel G. Fernandez de Mera[1], (1)Institute for Game and Wildlife Research (IREC, CSIC-UCLM-JCCM), Spain, (2)Do ana Biological Station (EBD, CSIC), Spain*

Bats provide essential services for the balance of ecosystems, contributing greatly to their health. However, the scarcity of research on this group means that there is still a significant lack of knowledge about the current status of the populations for most species, making it difficult to prioritise and plan actions for their conservation. This project aims to address, from a multidisciplinary approach, the repercussions of exposure to environmental pollutants and the circulation of pathogens, both individually and synergistically, on the conservation of bats in wetland National Parks (Doñana and Tablas de Daimiel), characterised by being surrounded by large areas of intensive cultivation where the use of pesticides is abundant. In this context, the proposed objectives are: (1) to determine the level of exposure to environmental pollutants; (2) to identify and characterise the groups of pathogens present in the populations, as well as the ectoparasites they carry; (3) to determine the potential effects of oxidative stress and genotoxic effects triggered by environmental pollutants; (4) to determine the immunological status of the populations; and finally (5) to assess the potential association between exposure to environmental pollution and the presence of pathogens/ectoparasites. The results of the project will serve as a basis for the sustainable management of chiropteran populations and contribute to their conservation.

Disclaimer/Disclosure: Project funded by the Spanish Ministry for the Ecological Transition and the Demographic Challenge (MITECO), National Parks Autonomous Agency (OAPN) (Ref: 3201/2024).

2.10.P-We110 PharmaBat: Investigating Bat-Mediated Transfer of Aquatic Pharmaceuticals to Terrestrial Ecosystems and Implications for Bat Health

***Natalia Ivone Sandoval Herrera**[1], Erin McCallum[2], Daniel Cerveny[2] and Tomas Brodin[3], (1)Department*

of Wildlife, Fish, and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden
Pharmaceutical pollution poses a growing threat to wildlife, with traces of medicines detected in nearly all parts of the world. While much research has focused on the impact of pharmaceuticals on aquatic organisms, their transfer to terrestrial ecosystems remains largely unexplored. Insectivorous species like bats, which feed in areas bordering water bodies, could be key players in moving these contaminants from water to land. This pollution can harm bats' health, potentially affecting their immune system, stress response, and ability to transmit diseases. Given bats' role as carriers of various pathogens, some of which can be transmitted to humans, understanding how pharmaceutical pollution affects these species is crucial. PharmaBat is a global-scale project that aims to shed light on the impacts of pharmaceuticals on bats and their ecosystems using an integrative approach. Specifically, we are investigating if bats are exposed to pharmaceuticals through their diet, and how the contaminants' load could influence their overall health including the presence of viruses to ultimately link this with their ability to spread infectious diseases. We optimized pharmaceutical quantification using Dried Blood Spot (DBS) a minimally invasive and field-friendly technique. This method has a substantial potential to advance the field of wildlife ecotoxicology with numerous applications to evaluate wildlife health and contaminant exposure. Here, we present preliminary results of pharmaceutical contaminants found in riparian bats in Sweden using DBS and highlight the potential for improving pharmaceutical monitoring exposure in wildlife.

2.10.P-We111 Bat Activity in Agricultural Land

Charles Hazlerigg[1]*, Mark Whittingham*[2] *and Amy C. Brooks*[3]*, (1)Enviresearch Ltd, United Kingdom, (2)Newcastle University, United Kingdom, (3)Cambridge Environmental Assessments (RSK ADAS), United Kingdom*
Bats are prevalent across Europe, roosting in trees and buildings, foraging in woodland and agricultural land. They are indicator species of a productive habitat. However, bat populations are falling in many areas, with the use of pesticides one suspect as the cause of these declines. This led, in 2019, to the European Food Safety Authority assessing whether the potential risks to bats from pesticides were currently adequately captured within the current regulatory scheme. Their conclusion: they were not. However, no further progress has been made since on establishing a suitable approach to ensure the protection of bats in the future. The first step in developing such an approach is understanding which species are potentially susceptible to exposure to pesticides. To address this, we have conducted an acoustic monitoring study of bat activity in farmland in Northern England from May 2022 to the present. Bat detectors were deployed for one week every month at five different sites across a single farm. The sites were associated with grassland, woodland (control) and three arable fields (growing winter and spring cereals, oil-seed rape and legumes). The crop growth stages (BBCH) were assessed each month. The data was analysed to explore the bat activity and species diversity associated with each site across the study. Early results show that although bats hibernate, some bats were active during the winter period (though at a much lower level than in the summer months), indicating that potential pesticide exposure may still occur year-round. Furthermore, whilst nine species of bat were detected, certain species dominated the recordings (i.e., Pipistrellus pipistrellus, Pipistrellus pygmaeus) which may be relevant when considering focal species selection for risk assessment scenarios and potential refinement options (e.g., proportion of time foraging in a given field; equivalent to the PT refinement in the birds and mammals guidance document). Given the potential confounding variables (e.g., temperature, rainfall), further analysis will be performed and presented to account for these and assess whether bat activity / diversity differs with crop type and crop growth stage. These results will then be compared against pesticides commonly used on these crops.

Disclaimer/Disclosure: Funded by UKRI MR/V025570/1.

2.10.P-We112 Hops in Crops: Monitoring Lagomorphs in Agricultural Landscapes

Tina Grimm[1]*, Imme Katzschner*[2]*, Kaat Brulez*[2] *and Martin Vallon*[1]*, (1)RIFCON GmbH, Hirschberg, Germany, (2)Rifcon GmbH, Germany*
"Brown hares (Lepus europaeus) and European rabbits (Oryctolagus cuniculus) commonly occur in agricultural landscapes across Europe and are potentially exposed to pesticides mainly via their herbivorous diet including many crop plants. Both species are regularly discussed as potential focal species for the evaluation of associated risks within the European risk assessment framework for pesticides. Understanding their population dynamics, utilisation of agricultural fields and general movement patterns based on robust data from the field is thus crucial for conducting informed risk assessments. Here we want to present comprehensive approaches for monitoring free ranging lagomorph

populations, with a focus on methods that are particularly relevant for assessing pesticide exposure risk, as outlined in the recently noted revised EFSA Guidance Document on Risk Assessment for Birds and Mammals coming into place in 2025.
We present a combination of direct and indirect monitoring techniques, including but not limited to:
- visual observations using night-vision and thermal imaging cameras from elevated locations for documenting general lagomorph activity
- stationary and moving wildlife and drone-mounted cameras
- options for detailed tracking of individual movement patterns and habitat preferences such as VHF- or GPS-based radio tracking

For rabbits in particular, a critical challenge in monitoring this species in crops lies in the spatial relationship between the location of their burrow and the surrounding agricultural fields, and whether the crop of interest is available at known rabbit sites having the rather small activity ranges of rabbits in mind. The selection of monitoring sites thus requires careful consideration of this species-specific ecological trait.
In line with the Bird and Mammal Guidance Document, which highlights the need for robust and case-specific field data, this overview of methods provides valuable options for assessing ecological data for the use in risk assessments of lagomorphs. By integrating multiple monitoring techniques, the application of the given methods contributes to a better understanding of their potential exposure pathways in agricultural environments, and at the same time to a knowledge gain in farmland ecology of these species. We will present examples of more than 10 years of experience in lagomorph field studies in European farmland.

2.10.P-We113 Linking LIFE APEX Data on Chemicals in Wild Biota in Europe with the Distributed System of Scientific Collections (DiSSCo), for Research and Regulatory Applications
***Paola Movalli*[1]*, Eva Alonso*[1]*, Nikiforos Alygizakis*[2]*, Sharif Islam*[1]*, Dimitris Koureas*[1]*, Jaroslav Slobodnik*[2] *and Guy Duke*[2]*, (1)Naturalis Biodiversity Center, Netherlands, (2)Environmental Institute, Slovakia*
DiSSCo (The Distributed System of Scientific Collections) is the new world-class Research Infrastructure (RI) for Natural Science Collections. It aims to digitally unify all European natural science assets, in a pan-European digital collection sharing common access, curation, policies and practices across countries, ensuring that all data complies with FAIR and CARE principles. DiSSCo also links data on digital specimens in participating collections with related infrastructures such as the Global Biodiversity Information Facility (GBIF), International Barcode of Life Data System (iBOLD), and European Nucleotide Archive (ENA). The EU-funded LIFE APEX project (2018-2022) analysed chemicals in apex predators and their prey from across Europe using non-target screening (>65,000 substances), wide-scope target analyses (>2300 substances) and other target analyses. The resulting data is stored in the LIFE APEX Knowledgebase which is integrated into the EMPODAT database (target analyses data) and the DFSP database (non-target screening data) on the NORMAN Platform. A similar database, also to be integrated with EMPODAT and DFSP, is under construction by the Horizon Europe project TerrraChem (2023-26) which will analyse chemicals in terrestrial food chains across Europe. LIFE APEX and TerraChem will together provide >7.5 M data points on chemicals in wild biota. The EMPODAT and DFSP databases are in this respect well placed to contribute to the proposed EU Common Data Platform for Chemicals. The purpose of this study is to develop and test data pipelines to connect DiSSCo architecture with the LIFE APEX Knowledgebase with a view to extending this to the TerraChem Database and other data on chemicals in biota within EMPODAT and DFSP. Such connections will benefit various end users (e.g., researchers, regulators) for a range of applications e.g., locating matched chemical exposure and species richness data to derive species sensitivity distributions for modelling of chemical effects on species richness. We will develop a suite of user stories that identify potential users and prioritise use cases, align data standards between the LIFE APEX database and DiSSCo s Digital Specimen architecture (DiSSCo DS), and enable DiSSCo users to retrieve data from the LIFE APEX database and DiSSCo DS through APIs. This poster will report on preliminary results of this project including user stories developed, any challenges identified in establishing the link and next steps.

2.10.P-We114 Generating Spatially and Temporally Matched Data at Pan-European Scale on Chemicals Exposure and Species Composition in Soils and Invertebrate Communities to Build Species Sensitivity Distributions

Paola Movalli[1]*, Koos Biesmeijer*[1]*, Vincent Merckx*[1]*, Elaine van Ommen Kloeke*[1]*, Georgios Gkotsis*[2]*, Reza Aalizadeh*[2]*, Nikolaos Boinis*[2]*, Antigoni Konomi*[2]*, Faidra-Angeliki Mourtzoukou*[2]*, Eleni Panagopoulou*[2]*, Nikolaos S. Thomaidis*[2]*, Nikiforos Alygizakis*[3]*, Peter Oswald*[3]*, Martina Oswaldova*[3]*, Jaroslav Slobodnik*[3]*, Sofia Gomes*[4] *and Guy Duke*[3]*, (1)Naturalis Biodiversity Center, Netherlands, (2)University of Athens, Greece, (3)Environmental Institute, Slovakia, (4)Institute of Biology, Leiden University, Netherlands*
In order to build species sensitivity distributions (SSDs) to train models on effects of chemicals on terrestrial species composition, we need matched data on (a) exposure to chemicals and (b) species composition, for the same place and time. There is at present very limited availability of such matched data for the terrestrial environment, in particular across trophic levels, and in particular at pan-European scale. This study aimed to generate such matched data for multiple locations across Europe for both soil microbiota and invertebrates and was performed under the Horizon Europe project TerraChem. Co-located soil and invertebrate samples were collected as part of 12 case studies, six on the barn owl Tyto alba food chain (in Netherlands, Germany, Spain, Portugal, Greece, Romania - which together form a pan-European case study) and six single-country case studies (stone marten Martes foina, Netherlands; grey wolf Canis lupus, Germany; European badger Meles meles, Spain; Egyptian mongoose Herpestes ichneumon, Portugal; northern white-breasted hedgehog Erinaceus roumanicus, Greece; red fox Vulpes vulpes, Romania). For each case study, we gathered six replicate sample sets, one set within the assumed territory of each apex species specimen (roadkill). Each set comprised: one apex species liver sample, eight mammalian prey species samples (in most cases, rodent soft body tissues), four mixed species invertebrate samples, four mixed species plant leaf samples and four bulk soil samples. For each territory, we derived two pooled prey samples, one pooled herbivorous invertebrate sample, one pooled non-herbivorous invertebrate sample, one pooled plant leaf sample and one pooled soil sample. Lyophilised samples will be analysed using HRMS-based wide-scope target screening (>2,500 substances), suspect screening (>100,000 substances) and additional target analyses (the latter for persistent organic pollutants). Each of the pooled soil samples was analysed by metabarcoding for microbial species composition (bacteria, fungi, eukaryotes) in collaboration with the Dutch national research infrastructure eDentity. Each of the pooled invertebrate samples was analysed by metabarcoding for invertebrate species composition in collaboration with the Dutch national research infrastructure ARISE. Matched data on chemical residues and species composition will be used to build SSDs. The poster will present preliminary results and conclusions.

Disclaimer/Disclosure: This work is funded by the European Union. Views and opinions expressed are however those of the authors only and do not necessarily reflect those of the European Union or European Research Executive Agency. Neither the European Union nor the granting authority can be held responsible for them.

2.10.P-We115 Monitoring Chemicals Exposure and Mixture Effects in Terrestrial Food Chains in Europe

Paola Movalli[1]*, Georgios Gkotsis*[2]*, Reza Aalizadeh*[2]*, Nikolaos Boinis*[3]*, Antigoni Konomi*[2]*, Faidra-Angeliki Mourtzoukou*[2]*, Eleni Panagopoulou*[4]*, Nikiforos Alygizakis*[5]*, Guy Duke*[5]*, Peter Fantke*[5]*, Peter Oswald*[5]*, Martina Oswaldova*[5]*, Jaroslav Slobodnik*[5]*, Koos Biesmeijer*[1]*, Aglaia Bouma*[1]*, Becky Dejardins*[1]*, Barbara Gravendeel*[1]*, Liselotte Rambonnet*[1]*, Tom M. Nolte*[1]*, Vincent van de Pas*[1]*, Jan Wieringa*[1]*, Henrik Barmentlo*[6]*, Philipp Kropf*[7]*, Olivier Jolliet*[8]*, Susan Oginah*[8]*, Laura Scherer*[6]*, Martina G. Vijver*[6]*, Romana Hornek-Gausterer*[9]*, Oliver Machate*[10]*, Gabriele Treu*[10]*, Sofia Gomes*[11] *and Nikolaos S. Thomaidis*[2]*, (1)Naturalis Biodiversity Center, Netherlands, (2)National and Kapodistrian University of Athens, Greece, (3)Chemistry, National and Kapodistrian University of Athens, Athens, Greece, (4)National and Kapodistrian University of Athens, Greece, (5)Environmental Institute, Slovakia, (6)CML, Leiden University, Netherlands, (7)CLM, Leiden University, Netherlands, (8)Technical University of Denmark, Denmark, (9)German Environment Agency (UBA), Austria, (10)German Environment Agency (UBA), Germany, (11)Institutw of Biology, Leiden University, Netherlands*
We have insufficient knowledge of exposure of terrestrial biota to anthropogenic chemicals in the environment, and of effects on terrestrial biodiversity and ecosystem services. TerraChem is carrying out research on monitoring exposure and mixture effects in wildlife food chains in order to: (1) detect and determine chemicals, and predominant chemical mixtures, in selected apex species food chains in representative terrestrial ecosystems across Europe; (2) better understand exposure including routes and extent of trophic transfer; (3) explore patterns for individual contaminants and predominant mixtures in the selected food chains; (4) elucidate toxic effects of chemical mixtures on vertebrates; and (5) collate secondary data on contaminants along trophic chains in terrestrial ecosystems in Europe. We implemented a pan-European case study (barn owl Tyto alba food chain in 6 countries) and six single-country case studies on apex mammal species food chains. In each country, for each case study, we gathered samples

from six apex species territories. We gathered one apex species liver sample per territory. Four samples of each type of food chain sample were pooled to give, for each territory: 1 pooled vertebrate prey species A (e.g., wood mouse A. sylvaticus) soft body tissues sample; 1 pooled vertebrate prey species B (e.g., field vole M. agrestis) soft body tissues sample; 1 mixed invertebrate species group A (herbivore/fungivore/ detritivore) sample; 1 mixed invertebrate species group B (omnivore/carnivores) sample; 1 mixed plant species leaves sample; 1 bulk soil sample. For each territory, food chain samples were collected within a short time-frame for temporal co-location. Samples will be analysed using: (1) instrumental analysis with ultra-high performance LC-HRMS and GC-HRMS for identification of c. 2,500 known emerging substances and suspect screening of >100,000 substances; (2) sensitive targeted methodologies for the determination of legacy substances. Additional analyses will include: (i) CALUX bioassays for analysis of mixture effects; (ii) stable isotope analysis to inform analysis of routes of transfer and trophic magnification; (iii) metabarcoding of soil and invertebrate samples to support source-to-damage modelling and work on prevention and mitigation of risks. The presentation will include discussion and conclusions on the design of a sampling regime and preliminary results from the target analyses and non-target screening.

Disclaimer/Disclosure: This research is funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or of the Research Executive Agency. Neither the European Union nor the granting authority can be held responsible for them.

2.10.P-We116 Free and Open Source Databases on Terrestrial Pollution of Wild Apex Predators

*Tom M. Nolte[1], Philipp Kropf[2], Henrik Barmentlo[2], Gabriele Treu[3], Nikiforos Alygizakis[4], Susan Oginah[5], Peter Fantke[4], Georgios Gkotsis[6], Nikolaos S. Thomaidis[6], Martina G. Vijver[2], Jaroslav Slobodnik[4], Guy Duke[4], Koos Biesmeijer[7] and **Paola Movalli**[7], (1)Naturalis Biodiversity Center, Netherlands, (2)Leiden University, Netherlands, (3)German Environment Agency (UBA), Germany, (4)Environmental Insitute, Slovakia, (5)DTU, Denmark, (6)National and Kapodistrian University of Athens, Greece, (7)Naturalis, Netherlands*

Pollutants affect environmental health. As field monitoring/sampling can be cumbersome and costly, linking pollutants to effects on biodiversity may be facilitated by complementing chemical analysis with existing data. As the field is >50 years old, there is a legacy of biomonitoring of wildlife. This poster presents collated and curated existing data on pollutants in terrestrial apex wildlife species. From the literature we aggregated data on organohalogens like dioxins, PCBs, PDBEs, PAHs, pesticides, heavy metals and metalloids in wild biota. The species covered included Canidae, Strigidae and Tytonidae, Mustelidae, Procyonidae, Erinaceinae, Herpestidae, Ursidae and Suidae. In total, we extracted data from ~1500 papers.

As an example, for metals, we report 20000 values for residue concentrations in 28 different biological matrices, organs and tissues (liver, kidney, bone, brain, etc.). These biomonitoring data on metals cover 32 owl, 18 canid and 22 mustelid/procyonid species in 58 countries, from 1829-2024. We covered a large geographical distribution and contaminant levels to aid modelers and assessors to benchmark risks across time and space. Globally, residue levels in liver, hair, feather, etc., increase with their local levels in soil, but remain subject to many other local factors. We applied rudimentary regression to obtain relationships in time and space and interpreted pollutant abundances by describing data in terms of presumed driving factors, pollutant source, (trophic) niche, geography and background levels.

The data will become open access via open source data management platforms (e.g., NORMAN) and we anticipate may support future risk assessment and modeling. We also anticipate that the work can inform future monitoring of chemical exposure in terrestrial species. Importantly, of the 40 fields for meta-data (unit, matrix, geocoordinates, etc.) about 50% of cells were not filled due to reporting lacunae (e.g., detection limits). As papers screened span varying scientific fields (ecology, analytical chemistry, etc.) and decades, terminology and reporting schemes differ vastly, which complicates data compilation, curation and standardization. This presentation will discuss lessons learned to facilitate data compilation and curation. Lastly, we will use the data to interpret new empirical exposure monitoring in European terrestrial species and food chains (e.g., barn owl, red fox) under the Horizon project TerraChem and related projects.

2.10.P-We117 Monitoring Based Substance Prioritization – Tracing Chemical Pollution Through Apex Predators

***Dominik Nerlich**[1], Oliver Machate[2], Peter Von der Ohe[2], Reza Aalizadeh[3], Georgios Gkotsis[3], Nikolaos S. Thomaidis[3], Nikiforos Alygizakis[4], Jaroslav Slobodnik[5], Henner Hollert[6] and Gabriele Treu[2], (1)German Environment Agency (UBA)| Department Evolutionary Ecology & Environmental Toxicology (E3T),* *Faculty Biological Sciences, Goethe University Frankfurt, Germany, (2)German Environment Agency (UBA), Germany, (3)Laboratory of Analytical Chemistry, Department of Chemistry, National and Kapodistrian University of Athens, Greece, (4)Laboratory of Analytical Chemistry, Department of Chemistry, National and Kapodistrian University of Athens, Slovakia, (5)Environmental Insitute, Slovakia, (6)Department Evolutionary Ecology & Environmental Toxicology (E3T), Faculty Biological Sciences, Goethe University Frankfurt, & Department Environmental Media Related Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany*

The One Health approach pursued by the European Commission to protect humans, wildlife and ecosystems from the harmful effects of chemicals tries to address the problem of global chemical pollution. Increasing production volumes of a constantly increasing number of unregulated chemicals lead to an urgent need for both improved risk assessment strategies and regulatory action. However, major challenges such as the limited amount of systematically collected effect and emission data, the limited consideration of long-term, mixture and biodiversity effects as well as the absence of field comparison for prospective effect analysis currently limit the available assessment and prioritization tools. Using chemical monitoring data from apex predators, such as marine mammals, terrestrial mammals and raptors, provides a potential breakthrough.

Apex predators enable a long-term assessment of chemical exposure as a consequence of accumulation in food webs. Systematically collected monitoring data could be used in multiple ways to identify and prioritize substances in need of regulation, real-world environmental exposure assessment, field extrapolation or effectiveness evaluation of risk management measures. Despite being explicitly addressed in the REACH regulation and its technical guidance documents, they have hardly been systematically used in the environmental risk assessment so far, e.g., as an additional line of evidence for increased bioaccumulation potential in REACH.

This poster illustrates how chemical monitoring data derived from High-Resolution Mass Spectrometry (HRMS)-based suspect screening analysis in various European apex predator species could be used to identify and prioritize chemicals requiring further regulatory action. The developed decision flowchart combines artificial intelligence (AI)-supported assessments of persistency (P), bioaccumulation (B), mobility (M) and toxicity (T) with cross-checked exposure data, yielding a list of Europe s top apex PBT and PMT substances.

Disclaimer/Disclosure: The authors thank Prof. Nikolaos S. Thomaidis for giving the opportunity to contribute to the study which has received funding from the EU-funded projects TerraChem (project number: 101135483) and LIFE APEX (project number: LIFE17 ENV/SK/000355).

2.10.P-We118 In Utero Maternal Transfer of Environmental Pollutants in Long-Finned Pilot Whale Mother-Foetus Pairs

***Katrin Hoydal*[1] *and Halla Weihe Reinert*[2]*, (1)Environmental Protection, Faroese Environment Agency, Faroe Islands, (2)Faroese Environment Agency, Faroe Islands*

Long finned pilot whales from the North Atlantic are highly exposed to environmental pollutants such as heavy metals (mercury, Hg and cadmium, Cd) and persistent organic pollutants (POPs) like PCBs and PFASs. High levels of these contaminants have been associated with negative effects on bodily functions such as reproduction, the immune system and the central nervous system in marine mammals. Continuous high contaminant loads in the tissues of these animals can thus have severe effects on the pilot whale population. The high contaminant exposure in pilot whales leads to concern for females transferring the chemicals to their offspring during pregnancy and lactation, resulting in the offspring being highly exposed at a vulnerable developmental stage.

Tissues from pilot whale mother-foetus pairs were analysed for heavy metals (Hg and Cd), PCBs and PFASs. Muscle samples were analysed for Hg, liver samples for PFASs, Hg and Cd, blubber samples were analysed for PCBs, and kidney samples for Cd.

The metal analysis showed Hg being transferred to both liver and muscle of the foetus, although lower concentrations were found in the foetus compared to the mother. The Hg concentrations in mothers and foetuses were not correlated in either liver or muscle, but the mother-foetus ratios were negatively correlated with foetus length, reflecting the increased transfer Hg with gestation time. Cd was not detected in foetus kidney or liver, indicating no or very low transfer of Cd from mother to foetus.

PCB levels in foetus blubber were correlated with maternal blubber concentrations when expressed as lipid weight, and levels were less influenced by gestation time.

The PFAS mother-foetus concentration ratios were correlated with foetus length rather than maternal concentrations, indicating an increased contaminant transfer with gestation time. The relative concentrations of PFASs in foetuses varied with the congeners, with some showing higher concentrations in the foetus than in the mother (PFOSA: foetus/mother ratios of 2.6 - 7.3), with the highest relative

concentrations in the largest foetuses.
The results show that the relative maternal transfer of contaminants varies between the different pollutant groups. Especially concerning is the PFAS exposure which appears to be transferred from the mother to the foetus at a high rate.

2.10.P-We119 Legacy and Emerging Poly- and Perfluoroalkyl Substances (PFAS), and Non-Target Screening in Marine Mammals Stranded around the UK
***Imogen Bailes**[1], Jonathan Barber[2], Sara Losada[2], Rob Deaville[3], Rosie Williams[3], Andrew Brownlow[4], Lee Walker[5], Shinji Ozaki[5], Christopher Green[6] and Andrew Sweetman[7], (1)Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom, (2)Cefas, United Kingdom, (3)Zoological Society of London, United Kingdom, (4)University of Glasgow, United Kingdom, (5)UKCEH, United Kingdom, (6)DEFRA, United Kingdom, (7)Lancaster University, United Kingdom*
Poly- and perfluoroalkyl substances (PFAS) are a large group of chemicals that display unique properties due to combined oil and water repellence, extreme stability, and hence are used in a wide range of industrial processes and consumer products. These chemicals can be problematic in the environment due to their potential to undergo long-range transport, persistence and toxicity. However, only some of these substances have been regulated by the Stockholm Convention and other international regulations. Beyond these known PFAS, numerous other related chemicals remain undetected due to the limitations of traditional targeted analyses. Non-targeted screening allows for the identification of both known and previously unrecognized contaminants.
We analysed the liver tissue of 200 individuals from a variety of species stranded between 2012 and 2022, collected by the UK Cetacean Strandings Investigation Programme (CSIP). We employed an ultra-performance liquid chromatograph coupled to a high-resolution mass spectrometer (Orbitrap) to analyse a range of both legacy and emerging PFAS including 11 PFCAs (C4-C14), 9 PFSAs (C4-C10), 3 FASAs, 3 PFPiAs and 6 fluorotelomer acids, among others in mammal liver tissue. Further, we ran pooled extracts using data-dependent acquisition to generate MS2 spectra. CompoundDiscoverer software was used to identify chemicals present.
We report high total PFAS concentrations in a range of species of marine mammals collected around the UK. Concentrations of different compounds vary highly within species, but most species tend to be dominated by PFOS and long chain PFCAs. Total PFAS concentrations had an average of ~ 200 ng/g ww between species, with bottlenose dolphins having the highest total PFAS concentrations. Total PFAS concentrations decreased in our study period (2012 and 2022) for both cetaceans and seals which could be as a result of global restrictions such as the Stockholm Convention. Preliminary results from non-target screening in this study have revealed the presence of a range of active pharmaceutical ingredients and potentially narcotic substances. This study highlights the importance of continued biomonitoring and underscores the complementary use of targeted and non-target screening approaches.

2.10.P-We120 Transcriptional Biomarkers of Metal-Induced Stress Contamination in the Critically Endangered Burrunan Dolphin (*Tursiops australis*)
*Iara Cruz[1], Chantel Sarah Foord[2], **Tiago Filipe da Silva Simoes**[3], Sara Novais[3], Marco F.L. Lemos[3], Dayanthi Nugegoda[4], Damien Nzabanita[4] and Kate Robb[2], (1)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (2)Marine Mammal Foundation, Australia, (3)MARE- Marine and Environmental Sciences Centre & ARNET Aquatic Research Infrastructure Network Associated Laboratory, ESTM, Polytechnic of Leiria, Portugal, (4)Ecotoxicology Research Group, School of Science, Royal Melbourne Institute of Technology, Australia*
Marine ecosystems are increasingly threatened by chemical pollutants, including metals, which persist in the environment, bioaccumulate, and pose risks to both marine organisms and human health. In Victoria, Australia, Burrunan dolphins (*Tursiops australis*), a critically endangered and endemic species, are especially susceptible to metal pollution due to their strong site fidelity to regions like Port Phillip Bay and Gippsland Lakes areas heavily impacted by urban, industrial, and agricultural runoff. Notably, these areas are associated with some of the highest recorded mercury (Hg) concentrations globally. Previous studies have shown elevated levels of Hg in deceased Burrunan dolphins, which further underscore the need to investigate the impact of such contamination in live populations. Furthermore, little is known about how metals may be affecting these populations, and looking at their molecular responses, particularly gene expression changes, may be valuable in identifying stress and compromised health.
Thus, this study aimed to investigate metal accumulation in Burrunan dolphins and its potential effects on their molecular stress responses and overall health. By examining the expression of genes involved in key biological processes such as detoxification, antioxidant defenses, immune function, and oxidative stress, the research aimed to identify molecular biomarkers indicative of contamination. Skin biopsy samples were collected from free-ranging individuals using minimally invasive methods. These samples were

preserved in RNAlater and stored at -80°C until RNA extraction and gene expression analysis using quantitative real-time PCR (qPCR). Simultaneously, metal concentrations were quantified using inductively coupled plasma mass spectrometry (ICP-MS). Results showed significant correlations between expression of some genes and metal contaminant levels, pinpointing some candidate genes to be used as biomarkers of interest for biomonitoring campaigns. This study highlights the urgent need for measures to mitigate pollutant exposure in habitats critical to Burrunan dolphin populations and contributed with information and tools that have the potential to be used to advance conservation strategies for safeguarding this species and for the preservation of marine ecosystems affected by metal pollution.

2.10.P-We121 A Dynamic Energy Budget Model for the Wood Mouse (*Apodemus sylvaticus*), an Important Focal Species for ERA

*Thomas Martin[1], Alexander Singer[2], **Oliver Jakoby**[2] and Nika Galic[3], (1)Effect Modelling, Rifcon GmbH, Germany, (2)RIFCON GmbH, Germany, (3)Syngenta, United Kingdom*

"Environmental risk assessment (ERA) estimates the risk from pesticide exposure to populations of non-target species based on individual level laboratory data for a test species. This complex task of ERA has traditionally been approached in a simplistic way, with the toxicity exposure ratio (TER) only accounting for differences in (average) daily individual exposure. Five to ten-fold safety factors aim to ensure a low risk of individual and, by extension, population level effects. At higher tiers, field studies are used to provide a more realistic assessment of potential effects, thereby reducing uncertainty, but are resource-intensive and have known limitations.

Various mechanistic methods have been developed to reduce uncertainty in ERA. Population modelling uses dose-response curves and estimated exposure to project effects within a simulated population of the focal species. Dynamic energy budget (DEB) modelling can add realism by simulating the sub-individual processes that lead to growth, maturation and reproduction. Further, a DEB model coupled with a toxicokinetic-toxicodynamic module (DEB-TKTD) can mechanistically simulate individual level toxic effects. A validated DEB-TKTD model can then be used to predict the effects of realistic exposure in the field, differences in species traits can be accounted for by substituting the DEB model for that of a real focal species used in ERA.

High-quality DEB models for focal species can therefore have a clear role in a mechanistic ERA framework. We have developed a DEB model for the wood mouse (*Apodemus sylvaticus*), an important focal species in European ERA (population model also under development). The previous DEB model for the species in the Add my Pet (AmP) library was based on very limited data. Following an extensive literature search by the authors, high-quality data were gathered describing:

2.10.P-We122 Diet Specialization on Earthworms in European Bird and Mammal Species – A scientific Perspective

*Christian Imholt[1], Kaat Brulez[2], **Frank Staab**[1], Kristof Brenzinger[1], Felix von Blanckenhagen[2], Jochen Gerlach[2] and Barbara Birk[3], (1)BASF SE, Germany, (2)Rifcon GmbH, Germany, (3)BASF SE, Germany*

Earthworms can represent a significant fraction of the diet of various bird and mammal species. Therefore, their role in mediating the transfer of plant protection products (PPP) through trophic interactions is a critical concern in pesticide risk assessments for birds and mammals in Europe. Earthworms can uptake PPPs from contaminated soil or water, which are then transferred to higher trophic levels through predation. To accurately estimate the risk to birds and mammals through secondary poisoning via consumption of earthworms on treated agricultural fields, it is essential to assess the spatial and temporal factors that influence prey availability. The quantity of earthworms in the diet might change with several species-specific factors. Such factors include: (i) varying degrees of diet specialization, (ii) seasonal variations in diet composition reflecting breeding patterns or (iii) habitat suitability for earthworms mediating prey availability for birds and mammals. So far, no concise reviews are available regarding proportions of, and changes in, earthworms within the diet of bird and mammal species, within the context of PPP risk assessments.

The aim of this study is to identify relevant literature that characterizes the consumption and proportion of earthworm-type diet by European wild bird and mammal species. The focus will be on identifying relevant species as well as accompanying covariates like, time of year, breeding status or habitat of the respective wild bird and mammal species.

A meta-analysis of literature results revealed species-specific differences in the quantity of earthworms in the respective diet, but also a strong seasonality in the consumption of earthworms across species. These results will contribute to identifying relevant species for the risk assessment of secondary poisoning, but also provide additional ecological background regarding the trophic interactions that underlie this risk assessment.

2.10.P-We123 Do We Need an Update on Inhalation Risk Assessment for Wildlife?

Martin Vallon[1]*, Katja Henkes*[2]*, Jens Schabacker*[3]*, Amelie Ochs*[3]*, Felix von Blanckenhagen*[3] *and Daniel Ruf*[1]*, (1)RIFCON GmbH, Hirschberg, Germany, (2)Rifcon GmbH, Germany, (3)Rifcon GmbH, Germany*

In the European pesticide registration scheme the risk assessment for birds and mammals assumes dietary exposure as main route of exposure to pesticides for wildlife after application in field. However, free ranging animals in farmland can also be exposed to pesticides by inhaling. Volatile agricultural pesticides, such as soil fumigants, are of particular concern, although they are injected into the soil, but can be released into the air during application due to their physico-chemical properties, like high vapour pressure. Known potential effects range from mild and reversible (e.g., eye irritation) to more serious and irreversible effects (e.g., lung necrosis), depending on the fumigant and the level of exposure. Therefore, within the European pesticide registration scheme, an inhalation risk assessment for birds and mammals is required for such substances and becomes a more common case in recent years.

However, there were no recommendations in the current, and even are no recommendation in the new and revised EFSA Bird and Mammal Guideline for pesticides coming into place in 2025 on how to conduct an inhalation risk assessment. Thus, inhalation risk assessments for birds and mammals are still based on the requirements according to an EPPO guideline dated 1994 based on the ratio of the predicted maximum inhalation dose and the relevant inhalation toxicity endpoint. This partly based on physiological allometric data on avian respiratory variables from the 1970s and were already recognised at that time as a preliminary analysis of the relationships between avian respiratory variables and body weight. A revision and reformulation of the procedures, still followed today, is therefore needed. This work provides an update on the subject, considering developments since the 1970s and more recent data. It also reviews the avian and mammalian toxicological inhalation studies and the resulting endpoints and examines the extent to which they can be used for realistic inhalation risk assessment in wild vertebrates.

2.10.P-We124 Evaluating Whether Modern Environmental Contaminants Have the Potential to Cause Eggshell Thinning

Jacob Frederick Ian Parkman[1]*, Karl L Evans*[1]*, Nicola Hemmings*[1]*, M. Gloria Pereira*[2] *and Andrew Sweetman*[3]*, (1)University of Sheffield, United Kingdom, (2)UK CEH, United Kingdom, (3)University of Lancaster, United Kingdom*

Avian population declines arising from eggshell thinning induced by chemical exposure is now typically regarded as an historical threat. Evidence has started to emerge, however, that a wide range of pollutants are abundant in the environment that could generate eggshell thinning. These include historical legacy pollutants and more novel emergent pollutants. Using a systematic literature review approach we provide an assessment of the potential for six main chemical groups, those being DDT and its metabolites, PCBs, PBDEs, PFASs, NSAIDs and neonicotinoid pesticides, to induce eggshell thinning. Assessment of the quantity and quality of evidence highlight that whilst much additional research is needed a number of these pollutants, in addition to DDT, have potential to induce avian eggshell thinning with potential demographic consequences.

2.10.P-We125 Navigating the Complexity of Bird Life History Traits to Better Evaluate Exposure to Environmental Chemicals

Sandrine Estelle Deglin[1]*, Adriana C. Bejarano*[2]*, Markus Deutsch*[3] *and Mark S. Johnson*[4]*, (1)Health and Environmental Sciences Institute (HESI), United States, (2)National Oceanic and Atmospheric Administration, United States, (3)Umweltbundesamt, Germany, (4)Retired, United States*

As part of a constant effort to protect wildlife, risks from exposures to environmental chemicals should be evaluated as accurately as possible. This is a formidable challenge to tackle, considering the number of species involved, and their complex interactions with each other, and with their environment.

Consequently, exposure evaluations must often be simplified, using a series of approximations. In many cases, some assumptions are necessary to compensate for species-specific data gaps, but also to simplify calculations used in a screening approach. Consequently, exposure estimates rarely represent actual field conditions.

More specifically, characterizing exposure of birds to environmental chemicals is particularly challenging given their species diversity, ecological and physiological plasticity, complex seasonal life histories and seasonal niche partitioning, and physiological variations. Part of this complexity is reflected in EFSA s recent regulatory guidance, which accounts for parameters such as foraging guild or habitat preference to refined exposure evaluations in higher tiers of the risk assessment (EFSA 2023). Furthermore, efforts using models that increase realism that include habitat preferences in spatial environments have been shown to result in more realistic exposure estimates that can be verified. However, in both cases, species-specific data such as food and water ingestion rates, food choices, and habitat preference, are important and yet, are rarely available.

To address this issue, and advance knowledge in this space, a HESI Technical Committee is working on establishing a state of the science on the influence of birds' life history traits on chemical exposure. We explore the value of integrating species-specific traits and behaviors, that can modulate chemical exposure and biological responses. We also developed a database of life history traits to identify potential impactful data gaps, and establish trait-dependent commonalities among birds to help more accurately characterize their exposure to various types of contaminants. Based on species vulnerability, we propose a prioritization strategy for life history traits to help determine which ones have the greatest influence on chemical exposure predictions. We provide a qualitative analysis of behavioral and life history parameters most useful in providing greater precision to exposure estimates and highlight areas in need of additional research.

2.10.P-We126 Modeling Chemical Bioaccumulation in Black-Tailed Godwits: Analyze the Extra Risk of Migratory Birds and Identify High-Risk Sites Along Migration Routes

Evangelia Alexandri[1] *and Andreas Focks*[2]*, (1)Greece, (2)Institute of Mathematics, Osnabrück University, Germany*

Animals are increasingly exposed to chemical substances that do not occur in their natural habitats. Such chemicals are continuously introduced into the environment, for example as a result of agricultural and industrial activities. Large predators generally have a high potential for bioaccumulation, as they can ingest large amounts of chemicals with their prey. For large migratory bird species, the risk can even be higher as they need to consume lots of prey as they need to increase their body weight for their migration flights. One of the most prevalent shorebird species is the Black-tailed Godwit (Limosa limosa) which migrates to north African countries for the European winter months and forages at different places such as estuaries, rice fields and grasslands during winter or migration. We are developing a model to describe the body weight dynamics of godwit individuals, and the bioaccumulation of chemicals that the godwit consumes with their feed. The combination of body weight dynamics and chemical bioaccumulation allows us to analyze the dynamics of internal concentrations, which can increase during periods of intense energy consumption, such as migration flights, even without ingestion of chemicals. The model is used to integrate data on contaminant exposure and uptake, chemical kinetics, and physiological processes to analyze the accumulation of chemicals in black-tailed godwits across spatial scales. Our aim is to analyze the extra risk migratory bird species may be exposed to, to identify high-risk sites along migration routes, and to understand long-term consequences of contaminant exposure. The research results could serve as a basis for conservation strategies for migratory species, including black-tailed godwits, by establishing a connection between their health condition and environmental quality.

2.10.P-We127 Factors to Consider for Future Assessment of Effects of Pesticides on Avian Reproduction

Diana Temple[1]*, Ryan Davis*[1]*,* ***Gunther Ulric du Hoffmann***[1]*, Carsten Lange*[2] *and Thomas Bean*[3]*, (1)Eurofins EAG Agroscience, United States, (2)BASF SE, Germany, (3)BASF Corporation, United States*

Protocols for conducting avian reproduction studies based on the OECD 206 (1984) and OCSPP 850.2300 (2012) guidelines typically use 144 adult birds and ~2000 offspring during the test. This poster examines the feasibility of two ways that vertebrate use could be reduced (1) the number of species tested, and (2) by reducing the number of animals within or eliminating a concurrent control group in every test. For the global registration of a pesticide, a reproduction study is required for two gamebird species: an upland species (typically Northern bobwhite, *Colinus virginianus*) and a waterfowl species (Mallard, *Anas platyrhynchos*). In Europe, data in only one species (an upland gamebird) are required but data for a second species (a waterfowl species) are often available as they are generated if a product is also registered in North America, and thus are also considered in the risk assessment. This has led to questions around whether additional protection is being achieved by testing in the mallard vs testing in bobwhite alone. Secondly, there is a growing trend towards virtual control groups in mammalian toxicity testing as a way of reducing vertebrate testing, but to our knowledge this has yet to be explored for birds. In this poster presentation we evaluate and apply learnings from an analysis of Eurofins historical control data as well as the authors experiences working on these studies to provide factors that should be considered for future testing that could help reduce the number of animals used. The questions evaluated will include (1) would the same level of protection be achieved if only one species were tested? (2) could virtual control groups that are constructed from historical control data be used to reduce bird numbers needed for testing? The data presented will subsequently be of interest to regulators, industry and those working on animal alternatives. It is suggested that it may be possible in future avian reproduction study protocols to reduce vertebrate usage per test by mining information from historical control data, but it should be recognized that valuable additional information for the risk assessment is generated by testing in mallard in addition to the Northern bobwhite.

2.10.P-We128 Anticoagulant Rodenticides, Hemorrhages and Fractures in Red Kite (*Milvus milvus*): Nine Years Retrospective Study in France

Philippe Jacques Berny*[1] *and Irene Valverde*[2]*, (1)VETAGRO-SUP, France, (2)Vetagro sup, Toxicology, France

Second generation anticoagulant rodenticides (SGARs) have been widely used in France for many years against rodents and voles in agriculture. The Red kite (*Milvus milvus*) is an opportunistic raptor species which makes it vulnerable to poison. The Red kite is resident or partial migrant in France.
A 9-year retrospective study was carried out between the years 2014-2023 in the Laboratory of Toxicology VetAgro Sup (Lyon). The aim of this study is to assess the concentrations of AR in Red kite in France and, their relationship with two main signs found in necropsy: hemorrhages and fractures.
A total of 110 individuals were studied. 74% of the positive analysis to SGARs were received in 4 years (2017, 2020, 2021, 2022). From 2017, individuals with multiple SGARs were detected, and from 2020 these individuals represented more than 50% of the total individuals analyzed. Bromadiolone (n = 42, 32%) and brodifacoum (n = 37, 29%) were the most detected SGARs. Followed by difenacoum (n = 25, 19.2%) and difethialone (n = 23, 18%). Positive analyses to SGARs came from 52 different departments in France, mainly from the Pyrénées-Atlantiques (39%) in the southwest of France.
Positive SGARs individuals with hemorrhages (n = 21, 19%) and fractures (n = 18, 16%) showed median concentrations (min-max) of 0.13 (0.01-0.7) and 0.05 (0.003-0.44) µg/g, respectively. Moreover, a threshold value was calculated to predict the presence of hemorrhages or fractures caused by the presence of SGARs in Red kite. This value may be used as a support tool in the investigation of cause of death in Red kite.

2.10.P-We129 Current Status of Lead Exposure in the Marbled Teal (*Marmaronetta angustirostris*) in El Hondo Natural Park.

***Pablo Sanchez Virosta*[1]*, Sofia Gonzalez-Gallego Martin-Pozuelo*[2]*, Pilar Gomez-Ramirez*[2]*, Francisco Botella*[3] *and Juan Manuel Peerz-Garcia*[3]*, (1)NTNU, Norway, (2)University of Murcia, Spain, (3)Universidad Miguel Hernandez, Spain*

The marbled teal (*Marmaronetta angustirostris*) is one of the most endangered ducks in Spain, as it is exposed to various threats, one of them being contamination caused by lead shot accumulation from hunting activities. In this study, blood samples were taken from 48 marbled teals in El Hondo Natural Park and Clot de Galvany (Alicante) and the concentrations of lead, chromium, manganese, nickel, copper, selenium, arsenic and cadmium were analyzed using ICP-MS. Additionally, 4 animals were tagged with GPS transmitters to evaluate potential exposure sources. No differences in lead concentration were found between the sampling locations, nor sex or weight, despite hunting having been banned in Clot de Galvany for over 2 decades. This could be explained by the insufficiency of the lead ammunition ban, the lack of time after the banning and, above all, the persistence of lead shots in the soil over time. Other results showed higher manganese and nickel concentrations in Clot de Galvany (more urbanized area) and higher selenium and arsenic concentrations in El Hondo (more agricultural area).

Disclaimer/Disclosure: Funded by: Grant FJC2019-042357-I funded by MCIN/AEI, Generalitat Valenciana, LIFE Cerceta Pardilla.

2.10.P-We130 Bioaccumulation of Persistent Organic Contaminants in the Complex Marine, Aquatic and Terrestrial Ecosystem of an Avian Top Predator, the Bald Eagle

***John E. Elliott**, Environment and Climate Change Canada, Environment and Climate Change Canada (ECCC), Gatineau, Canada*

We used the bald eagle (Haliaeetus leucocephalus), a top predator, as a sentinel species of exposure and effects of POPs in the Salish Sea region of North America. Blood samples were collected from 91 bald eagle nestlings (n = 64 nests) across eight regions of the Canadian areas of the Salish Sea basin and a reference area on the outer Pacific coast of Vancouver Island. Samples were analyzed for a suite of legacy and emergent contaminants, stable isotopes, and fatty acids. Plasma ?13C, ?34S, and ?15N values revealed clear spatial patterns reflecting dietary transitions, from marine-derived diets on the outer coast to more terrestrial and freshwater diets in the Thompson River, Fraser Valley, and Fraser delta regions. The isotope data contextualize broad dietary patterns, while the fatty acid ratios provide finer-scale resolution, revealing aquatic versus terrestrial dietary sources. Higher ?Omega3:Omega6 ratios observed from the outer coast (4.4) compared to the interior river system (0.5) aligned with isotope signatures, reinforcing a marine-dominant diet versus freshwater/terrestrial. Relative compositions of perfluoroalkyl substance (PFAS) were generally similar across regions and were dominated by PFOS (22-84%) and PFUdA (1-32%). ?PFAS levels were highest in urbanized areas of the Fraser Delta (57 ng/g wet weight) and the South Salish Sea (44 ng/g), associated with proximity to airports, wastewater treatment plants, and landfills. ?PFAS were lower in less urbanized areas (15 and 18 ng/g, respectively). Flame retardants (FRs) were uniformly low, with the highest levels observed in Delta (2 ng/g) and the South Salish Sea (3.2 ng/g). Legacy contaminants, including organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs), were elevated in the North and South Salish Sea (?OCPs: 17 and 15 ng/g; ?PCBs: 6 and 14 ng/g, respectively), likely due to historical use and some ongoing contaminant release. With the exception of PFAS, all contaminant groups were positively correlated with ?13C, ?15N, and ?34S (R2 = 0.2-0.3), underscoring the role of diet and foraging behavior in driving exposure levels, and the importance of ecological variables in understanding contaminant dynamics within this complex marine to freshwater ecosystem.

2.10.P-We131 Evaluating Pesticide Risks in Rice Fields: A Field Study

Ana Lopez-Antia *and Silvia Lacorte, IDAEA-CSIC, Spain*

Field studies are essential to assess the effects of pesticides (individually or in mixtures) on populations, communities, and ecosystems under natural conditions. However, this step is still lacking in risk assessment schemes. Post-registration studies are especially urgent in rice fields, a unique and ecologically valuable crop that has received little attention from European regulatory authorities, as shown by the lack of guidance for assessing risks to birds and mammals in these environments.

We conducted our research in the Ebro Delta (Catalonia, Spain), an area dedicated to rice cultivation and an important region for waterbird conservation. Surveys were conducted among farmers to gather information on pesticide use, including the types, quantities, timing, and target pests. This data helped design a sampling strategy involving 35 fields (6 organic and 29 conventional) representing different levels of pesticide use. In these 35 experimental units and 9 natural areas, we conducted biological and physicochemical measurements and collected environmental (water) and biological samples (chironomid larvae, bird blood, and crop and gizzard contents).

Using HPLC-Q-ToF, we identified 24, 22, and 21 compounds in the waters of conventional, ecological, and natural areas, respectively, with bentazone, penoxsulam, azoxystrobin, carboxin, acetamiprid, and chlorantraniliprole at higher concentrations. Further analysis is needed to understand the influence of treatment, sampling dates, and temporal dynamics across different environments.

In the analysis of crop and gizzard contents, we found that difenoconazole, pendimethalin, chlorantraniliprole, fludioxonil, and azoxystrobin were the most prevalent and present at higher concentrations. A first-tier risk evaluation of these compounds, particularly those used as seed treatments, indicated a high risk of long-term effects, which should be confirmed by higher-tier (field) studies. The method will also be applied to chironomid larvae and the blood of moorhens (herbivores) and black-winged stilts (insectivores), species that breed and feed in rice fields. These samples were collected from the controlled rice fields in the study.

We present a field ecotoxicological study on pesticide use, concentrations in water, and exposure in indicator organisms. We also explore how landscape and agronomic factors influence exposure, aiming to propose a management model that balances productivity and biodiversity conservation.

2.10.P-We132 Lesser Flamingo Eggs: A 'Lesser' Indicator of Metal Pollution

Nicole Van Gesselen[1] *and Hindrik Bouwman*[2]*, (1)North-West University, South Africa, (2)Zoology, North-West University, South Africa*

Flamingos are long-lived birds likely to accumulate metals from the highly saline waters they feed in. Concentrations of 24 elements in egg contents and eggshells from abandoned eggs from Lesser Flamingo Pheoniconaias minor breeding at Kamfers Dam, Northern Cape, South Africa, suggest metal pollution. The considerable variation in metallic element concentrations between eggs may reflect the nomadic movements of the birds over their lifetimes. Strontium concentrations in eggshells exceeded toxic reference values, and copper concentrations in egg contents may contribute towards reproductive stress. Flamingo chicks consume eggshells, which may remobilise metals such as additional Sr and Cu. Given the longevity of P. minor (up to 50 years), the metal concentrations were lower than expected, especially mercury. This may be due to a combination of excretion via eggs, salt glands, uropygial glands, feathers, and crop milk (among others). Selenium, known to detoxify mercury, had no association between the two element concentrations. However, the mean molar ratio was 8.2, suggesting a highly protective effect afforded by Se. Concentrations and relative compositional differences of metals show that eggshells are not a proxy for egg contents. We conclude that neither P. minor egg contents nor eggshells are good indicators of environmental metal pollution; feathers, blood, organs, or other species should be used. This is the first report of metallic element concentrations in egg contents of any flamingo species. Our study identified various mechanisms that may protect the embryo from metals, highlighted the contribution that eggshell and crop milk consumption may make post-hatching, and suggests the hatchling, nestling, and fledgling stages as perhaps the more sensitive development stage than the embryo. Our findings contribute towards informing a more nuanced approach to protecting Phoenicopteridae from pollution.

2.10.P-We133 POPs Concentrations: Egg Sizes of 15 Bird Species do not Matter

***Hindrik Bouwman**[1], Velesia Lesch[1] and Rialet Pieters[2], (1)Zoology, North-West University, South Africa, (2)North-West University, South Africa*

POP concentrations in bird eggs have been used for decades for monitoring and hazard assessment, published in hundreds of articles and reports. Yet, most papers considered eggs concentrations of only one or few species from a limited sample range, often with a small set of POPs classes. We investigated the effect of egg sizes (mass) of 80 eggs of 15 different species for a wide range of chlorinated, fluorinated, and brominated POPs (60+ individual compounds) collected over a large area, analysed by two different laboratories, published in two different papers. Egg masses ranged from 1.9 g for sparrows to 62 g for the African Sacred Ibis. Despite the order of differences in compound class concentrations, there was no association with egg mass, expressed as near horizontal regression slopes. The regression lines for the compound classes differed with regard to Y-intercepts but the slopes themselves did not differ between the classes. Fifteen different bird species from the same area eat different things, live in terrestrial, wetland, and aquatic habitats, have very different life histories, experience different conditions, come into contact with POPs in many different ways, differ how they metabolise POPs, and differ in how they deposit POPs into their eggs. The same goes for the chemical life histories of POPs. They have diverse sources and release pathways, differ in how they distribute between various environmental compartments even on a congener level, differ in half-lives in different compartments, and differ in bioavailability. The widely differing chemical and biological behaviours shapes the uptake and accumulation of POPs. However, as to why there was no association between independently produced and released POPs classes with bird egg mass, we have yet no answer.

2.10.P-We134 Anticoagulant Rodenticides in Eurasian Eagle Owls: Environmental Exposure and Risk in Semi-Arid Ecosystems

*Livia Spadetto[1], **Pilar Gomez-Ramirez**[1], Mario Leon-Ortega[2], Antonio Zamora-Lopez[3], Sarah Diaz-Garcia[2], Jose Manuel Zamora-Marin[4], Fernando Tecles-Vicente[5], Luis Pardo-Marin[5], Jose Fenoll[6], Jose Francisco Calvo[7] and Antonio Juan Garcia-Fernandez[1], (1)Area of Toxicology, Faculty of Veterinary, Campus de Espinardo, University of Murcia, Spain, (2)ULULA Association for Owl Study and Conservation, Spain, (3)ULULA Association for Owl Study and Conservation; Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Spain, (4)ULULA Association for Owl Study and Conservation; Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia; Department of Applied Biology, Centro de Investigacion e Innovacion Agroalimentaria (CIAGRO-UMH), Miguel Hernandez, Spain, (5)Interdisciplinary Laboratory of Clinical Analysis (Interlab-UMU), Veterinary School, Regional Campus of International Excellence 'Campus Mare Nostrum', University of Murcia, Spain, (6)Instituto Murciano de Investigacion y Desarrollo Agrario y Alimentario, IMIDA, Spain, (7)Department of Ecology and Hydrology, Faculty of Biology, University of Murcia, Spain*

Anticoagulant rodenticides (ARs) are widely used toxic agents in rodent control, authorized for both professional and public use. Their extensive environmental presence poses a risk to non-target species, particularly birds of prey, which are vulnerable to AR contamination due to their feeding habits and high trophic level. This study assesses AR exposure in Eurasian eagle owl (*Bubo bubo*) nestlings within the Region of Murcia (southeastern Spain), an area where these nocturnal raptors exhibit high population densities across natural habitats as well as near potential AR sources, such as landfills and urban areas. This setting provides an opportunity to evaluate the influence of environmental factors on exposure risk. Blood samples were collected from 106 individuals across 34 territories in 2021 and 2022, and residues of 10 ARs were analysed using HPLC-TQ. In addition, prothrombin time (PT) was analysed (n = 62) as a biomarker of effect. Mixed linear models were employed to explore associations between selected environmental variables (human population density, land use, presence of landfills, livestock farming, proximity to watercourses) with AR concentrations and prevalence. The findings indicate a high prevalence of ARs (91.5%), with multiple ARs detected in 70.8% of samples, suggesting repeated and widespread exposure. Although detected levels were low (median ?ARs 0.77 ng ml?¹), chronic low-level exposure may pose long-term health risks. Analysis of environmental factors associated with AR contamination showed higher concentrations in more urbanized areas and near landfills, likely due to greater AR use and increased availability of target prey, such as rats. Moreover, the prevalence of two ARs (brodifacoum and difenacoum) correlated positively with proximity to watercourses, implying potential accumulation in aquatic ecosystems, particularly in semi-arid regions where water scarcity limits contaminant dilution. We observed a positive but not significant association between PT and ?ARs (Rho = 0.04; p = 0.49), suggesting that adverse effects on coagulation can be ruled out in the short term. This study emphasizes the significant prevalence and diversity of ARs detected in this species, highlighting the persistent contamination risk for raptors, which can act as sentinel species for environmental pollution. The results emphasize the need for improved regulation of ARs and for long-term monitoring of their effects on vulnerable species populations.

2.10.P-We135 Inorganic Elements in Blood, Eggs and Embryos of Olive Ridley Turtles (*Lepidochelys olivacea*) from the Sanquianga National Natural Park, Colombian Pacific

*Laura Nathalia Hurtado-Sierra[1], Alan Giraldo[1], **Pilar Gomez-Ramirez**[2], Emma Martinez-Lopez[3], Juan Jose Gallego-Zerrato[1] and Adriana Azucena Cortes-Gomez[4], (1)Universidad del Valle, Facultad de Ciencias Naturales y Exactas, Departamento de Biolog a, Grupo de investigacion en Ecolog a Animal, Colombia, (2)Area of Toxicology, Department of Health Sciences, Faculty of Veterinary Medicine, University of Murcia, Spain, (3)Area of Toxicology, Department of Health Sciences, Faculty of Veterinary Medicine, University of Murcia, Murcia, Spain, Oceanosphera Laboratory. University of Murcia, Murcia, Spain, Spain, (4)SEE Turtles, Portland, Oregon, United States*

Lepidochelys olivacea is the most abundant species of sea turtle worldwide and in Colombia. In this country, the beaches of the Sanquianga National Natural Park (SNNP) are considered among the most important for its nesting. However, due to artisanal gold mining and cocaine hydrochloride extraction activities carried out there, it is possible that nesting females, eggs and embryos of *L. olivacea* that use these beaches are affected by exposure to inorganic elements. For this reason, in this study, eight inorganic elements (As, Cd, Cr, Cu, Hg, Pb, Se and Zn) in blood (nesting females), eggs, embryos and sand from *L. olivacea* nests in the SNNP (Colombian Pacific coast) were analysed for the first time. The samples were analysed by mass spectrophotometry with inductively coupled argon sputum, after dehydration and acid digestion by microwave. According to the results obtained, all elements were identified in all samples, and as expected, essential elements showed the highest concentrations, with Zn, Cr and Se being the most abundant elements. On the other hand, sand and embryo shells were the samples with the highest concentrations. In addition, positive correlations were identified between the elements, most of them being reported for the first time in the species. The Se:Hg molar ratio was less than 1 in most samples, indicating that not all Se is bound to Hg, due to the low concentrations of Hg present in the samples, and therefore, no negative effects on health status are expected. Likewise, there were five correlations associated with the embryo shell and none with sand, suggesting contamination by maternal transfer with higher values than those reported by other authors for the same and other sea turtle species. The results obtained provide novel information on exposure to inorganic elements in nesting sea turtles in the eastern tropical Pacific. Also reference values on the toxicological status of the *L. olivacea* population present in the SNNP are provided, which will allow future follow-up studies in this population, as an integral part of the management and conservation actions implemented in this natural area and in other areas present in the Colombian Pacific.

2.10.P-We136 Metal Contamination and Ecological Niche Variations in Sea Turtles of São Tomé and Príncipe

The São Tomé and Príncipe archipelago hosts nesting sites for four of the seven existing and threatened sea turtle species. Due to their wide distribution, long lifespan, and diverse feeding behaviours, sea turtles often accumulate pollutants, such as metals and metalloids, throughout their complex life cycle. This study investigated metal contamination and isotopic signature in three sea turtle species *Chelonia mydas*, *Eretmochelys imbricata*, and *Lepidochelys olivacea* comparing two different life stages (nesting females, males, and juveniles) from São Tomé Island. Additionally, nesting females green (*C. mydas*) and hawksbill (*E. imbricata*) sea turtles from Príncipe Island were analysed to compare contamination levels and isotopic niches between the two islands. Female olive ridley turtles (*L. olivacea*), which nest exclusively on São Tomé Island, showed higher levels of several elements (e.g., Ca, Fe, K, Zn, Se, Cd), which could reflect natural physiological levels, contamination and/or unique dietary sources. Additionally, green and hawksbill sea turtle populations, including both adults and juveniles, showed elevated concentrations of elements such as S, Cs, and Pb. Moreover, differences in chemical elements contamination were observed between female green turtles across the two islands, despite their similar isotopic signatures. On São Tomé Island, isotopic niche analysis revealed variations in $?^{1}?N$ and $?^{13}C$ values, suggesting that green, hawksbill and olive ridley turtle populations differ in their ecological niches and/or exhibit dietary habitats, both across species and between developmental stages. This study provides insights into chemical element contamination and ecological niches across sea turtle species in the archipelago, highlighting species-specific and life-stage variations that reflect differences in diet, ecology, and environmental contamination. Furthermore, these findings enhance understanding of contamination dynamics, providing insights that can help local NGOs design targeted conservation strategies and inform policy decisions.

Disclaimer/Disclosure: This study had the support of Fundação para a Ciência e a Tecnologia (FCT) through the Strategic Project granted to MARE Marine and Environmental Sciences Centre (doi.org/10.54499/UIDB/04292/2020 and doi.org/10.54499/UIDP/04292/2020), the project granted to the Associated Laboratory ARNET (doi.org/10.54499/LA/P/0069/2020), the grants awarded to IM (doi.org/10.54499/PD/BD/1505 62/2019) and to MIL (doi.org/10.54499/UI/BD/150956/2021) and the contracts to FC (DL57/2016/CP1370/CT90) and SN (doi.org/10.54499/CEECINST/00060/2021/CP2902/CT0007). 2.10.P-We137 Ecological Risk Assessment of Endocrine Disrupting Chemicals Based on the Fish Physiologically-based Toxicokinetic Model

Yiping Xu[1], *Ruili Xie*[1], *Mei Ma*[1], *Kaifeng Rao*[2] *and Zijian Wang*[2], *(1)Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences; University of Chinese Academy of Sciences, China (Mainland), (2)Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, China (Mainland)*
Endocrine disrupting chemicals (EDCs) have been widely detected in various mediums due to increasing industrial and agricultural activities, which can interfere with human and animal endocrine systems and thus adversely affect human and ecosystem health. High-throughput in vitro assays combined with in vitro-in vivo extrapolation (IVIVE) leverage in vitro responses to predict the corresponding in vivo exposures and thresholds of concern. The integrated approach is also expected to offer the potential for efficient tools to provide estimates of chemical toxicity to various wildlife species instead of animal testing. However, developing wildlife physiologically based toxicokinetic (PBTK) models for IVIVE in ecological applications are challenging, especially for plausible estimation of internal effective dose (biological equivalent concentration, BEC) linked with complicated biological pathways and adverse outcomes (AO) of EDCs. Fish are most frequently used vertebrate models for ecotoxicological studies and play a key role in freshwater ecosystems. In our study, a fish PBTK model linked with IVIVE approach was established, with parameter optimization of chemical unbound fraction, pH-dependent ionization and hepatic clearance, and integration of temperature effect and growth dilution. The fish-PBTK-IVIVE approach provides not only more precise estimation of tissue-specific concentrations but also a reasonable

approximation of BEC targeting estrogenic potency of EDCs. Both predictions were compared with in vivo data and were accurate for most indissociable/dissociable chemicals. In addition, the in vivo dose-response for adverse vision and swimming disorder outcomes was also approximately characterized by BEC derived from in vitro fish assays. Furthermore, the model can help determine cross-species variability and sensitivity among various fish species. Using the available IVIVE-derived BEC with target pathways is helpful to develop predicted no-effect concentration for chemicals with similar mode of action. Due to the limited in vitro activity data available and the limited number of fish species used in the present study, results of the species sensitivity extrapolation may not accurate enough. We conclude that the proposed fish PBTK-IVIVE approach can provide useful information for screening-level ecological risk assessment of EDCs, support the chemical environmental exposure assessment for rigorous prioritization in testing and monitoring

2.10.P-We138 Assessing Pesticide Contamination in Freshwater Fish Along the Po River (Piedmont, Italy)

***Alice Gabetti*[1]**, *Roberta Giugliano[2], Barbara Vivaldi[2], Valentina Ciccotelli[2], Camilla Mossotto[3], Alessandra Maganza[3], Theo Deremarque[4], Marine Combe[4], Rodolphe Gozlan[4], Marino Prearo[1] and Paolo Pastorino[1], (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy, (2)The Veterinary Medical Research Institute for Piedmont, Italy, (3)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua); Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (4)ISEM, University de Montpellier, CNRS, IRD, France*

Pesticides used in agriculture and urban areas can enter freshwater ecosystems through sewage, runoff, and rainfall. Aquatic organisms are therefore exposed to a variety of these contaminants. Fish are good bioindicators and can provide information about pesticide contamination in the ecosystem due to the different roles they play in trophic networks. In this study, fish were collected along the Po River (Piedmont, Italy) to assess the level of contamination by pesticides. Three sampling sites were selected in the metropolitan area of Turin: in the municipality of Moncalieri (260 m a.s.l.), in the centre of Turin (Murazzi) (239 m a.s.l.) and downstream of the San Mauro dam (210 m a.s.l.). All the stations have in common a certain degree of anthropogenic impact. Fish were caught by semi-quantitative sampling using electrofishing in August 2024. Barbus sp., Salmo trutta, Telestes muticellus, Silurus glanis, Rhodeus amarus, Squalius sp., Padogobius bonelli, Lepomis gibbosus, Cobitis bilineata, Pseudorasbora parva, Leuciscus sp., *Gobio gobio*, Perca fluviatilis, Carassius carassius were sampled, measured, and weighed, and classified according to feeding ecology and trophic level. After dissection, the dorsal part of the muscle samples (including skin) was stored at -20 °C until contaminant determination. A total of 95 pesticide compounds were screened for in muscle using gas chromatography mass spectrometry, the limit of quantification ranged from 0.002 to 0.005210 g/kg. The most common contaminants found in fish samples were bifenthrin and byphenyl, while only traces of DDT P-P' were found at all sites. The Moncalieri site showed lower contamination with no traces of endrin, endrin ketone and HCB. Traces of HCB were found only at the San Mauro and Murazzi sites in Barbus sp. and Lepomis gibbosus. The data also suggest that Rhodeus amarus, Barbus sp. and Padogobius bonelli accumulated more different classes of contaminants compared to the other species. These results show a disparity in contamination levels between species and contaminants, indicating possible differences in ecological or trophic exposure. The risk of ingesting contaminants through food is likely to be greater for benthivorous fish, which feed more heavily on sediment. This study highlights the importance of considering the spatial ecology and trophic role of different species when assessing pollution levels in freshwater ecosystems.

Disclaimer/Disclosure: This study was funded by Bio Threats Project (21C09).

2.10.P-We139 Assessing the Long-Term Impact of a Freshwater Oil Spill on Riverine Fish

***Jack Hamm*[1]**, *Markus Brinkmann[1,2], Alex Pelletier[1], Jillian Papke[1], Paul Jones[1], and Timothy Jardine[1,2], (1) Toxicology Centre, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, (2) School of Environment and Sustainability, University of Saskatchewan, Saskatoon, Saskatchewan, Canada*

In 2016, over 225,000 L of crude oil entered the North Saskatchewan River (NSR) in one of the largest freshwater oil spills in Canadian history. This study aims to evaluate the long-term impact of this oil spill by determining if riverine fish are still being exposed to oil constituents and whether exposure is mediated by consumption of migratory insect prey from outside the river. The primary constituent of concern is polycyclic aromatic hydrocarbons (PAHs) which are known carcinogens with toxicity mediated by the aryl hydrocarbon receptor. Fish may feed on riverine prey exposed to the spill or a migrating species of aquatic insect called water boatmen (Corixidae). Corixidae migrate from lentic wetlands to lotic river systems in the fall for overwinter survival and are high in omega-3 polyunsaturated fatty acids (n-3 PUFAs). N-3 PUFAs are critical components of overwinter survival in fish and thus Corixidae consumption could play a major role in offsetting PAH exposure and toxicity in fish. We caught five target species of fish using gill nets at five different sites along the NSR that range in their distance downstream from the original spill site. Fish were dissected and given internal and external health exams. PAH metabolite concentrations will be determined by analyzing bile with high performance liquid chromatography (HPLC) and synchronous fluorescence spectroscopy (SFS). Fatty acids will be determined by Gas-Chromatography/Tandem Mass Spectrometry (GC-MS/MS). Bile PAH metabolite concentrations will then be related to corixid consumption by examining the gut contents of each individual. Corixidae consumption will be further related to total lipid content and n-3 PUFA concentrations in muscle and liver. This process will be repeated over three sampling seasons in October, December, and March to track diet, lipid content and PAH exposure through the winter. Based on previous data obtained immediately following the oil spill, elevated PAH levels in fish are unexpected. However, Corixidae consumption could play a major role in the overwinter survival of fish and limit the long-term effects of the PAHs in fish exposed to contaminated sediment or prey.

2.10.P-We140 Retrospective Temporal Trend Analysis of Gene Expression Changes in Bream Livers from River Rhine (Koblenz)

Holger Kissel[1], Uwa Steve Ayobahan[1], Bernd Gockener[1], Christoph Schafers[1], Jan Koschorreck[2] and ***Sebastian Eilebrecht**[3]*, *(1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Federal Environmental Agency Germany (UBA), Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Anthropogenic substances can enter aquatic environments through emissions from urban and industrial wastewater treatment plants, leading to both short- and long-term environmental impacts. The German Environmental Specimen Bank (ESB) operates 17 sampling sites along major German rivers, collecting and storing samples, including blood, liver, and fillet from Abramis brama (bream) at ultra-low temperatures since the 1990s. This pilot project applied toxicogenomic methods to detect not the pollutants themselves but their biological effects by evaluating gene expression patterns in bream samples from the Rhine and comparing them to those from the relatively unpolluted Lake Belau.
Liver samples from bream collected between 1997 and 2023 at sites in Koblenz (Rhine) and Lake Belau were analyzed. Total RNA was extracted, assessed for quality, and sequenced using the Illumina NovaSeq 6000 system. Gene expression was mapped to the bream genome using StringTie and STAR. Differential expression between the Rhine and Lake Belau was calculated for each year, and overrepresentation analyses (ORA) were performed to identify biological functions affected by pollution.
RNA from archived samples had sufficient quality for sequencing (RIN > 7), and successful mapping to the bream genome revealed differentially expressed genes across years. Enriched biological processes such as organic acid metabolism, oxoacid metabolism, and sugar metabolism were identified across all years. Some processes, like fat metabolism, were enriched in specific years.
This study demonstrated the feasibility of using archived ESB samples for retrospective toxicogenomic analyses. Gene expression differences between the Rhine and Lake Belau were identified, validating the technical approach. However, attributing these differences solely to chemical pollutants is challenging, as other factors like water temperature, structure, and food supply may also influence gene expression. Overall, the study highlights the potential of long-term stored samples for environmental monitoring while acknowledging the complexities of method validation.

2.10.P-We141 Chemical Pollution & Biodiversity Loss: How to identify those chemicals that require our immediate attention?

***Oliver Machate**[1], Reza Aalizadeh[2], Nikiforos Alygizakis[3], Henrik Barmentlo[4], Guy Duke[5], Peter Fantke[6], Georgios Gkotsis[2], Romana Hornek-Gausterer[7], Marissa B Kosnik[8], Paola Movalli[9], Dominik Nerlich[1], Tom M. Nolte[9], Susan Oginah[10], Peter Von der Ohe[1], Peter Oswald[11], Jaroslav Slobodnik[11], Nikolaos S. Thomaidis[2], Gabriele Treu[1] and Laura Scherer[4], (1)German Environment Agency (UBA), Germany, (2)University of Athens, Greece, (3)Environmental Institute, Greece, (4)Leiden University, Netherlands, (5)Environmental Insitute, United Kingdom, (6)Environmental Institute, Denmark, (7)Umweltbundesamt osterreich, Germany, (8)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (9)Naturalis Biodiversity Center, Netherlands, (10)Denmark Technical University, Denmark, (11)Environmental Institute, Slovakia*

Biodiversity loss poses a serious threat to the health and functioning of our planet. Gaining control over this crisis is one of the most urgent tasks for mankind, as it could result in an irreversible ecological collapse and thus, destroy planet Earth as our home. It is well known that there is a link between the exposure of our environment to anthropogenic chemicals and the loss of biodiversity. However, the extent to which chemical pollution contributes to biodiversity loss and the specific chemicals driving this loss are currently unknown. This, hence, hampers the implementation of appropriate risk management measures. Therefore, it is highly important to identify those chemicals that have the highest potential to drive biodiversity loss. Only then it will be possible to take action to reduce their emissions and the damage they cause. This poster presents a prioritization scheme that combines chemical biomonitoring data with different lines of evidence (LoEs) on respective ecotoxicity hazards and ecosystem damage. The proposed LoEs thereby bridge different levels of ecological complexity and consider various approaches on how to assess the environmental hazard of the detected chemicals. This novel approach should allow for a relatively robust identification of chemicals that might pose the largest impact on biodiversity and thus should be prioritized for follow-up monitoring and actions. Join me at my poster to learn more about the chosen approach and discuss the proposed prioritization scheme.

Disclaimer/Disclosure: This project received funding from the European Union's Horizon Europe program through the TerraChem project: From soils to apex species: chemical pathways, effects and impacts on terrestrial biodiversity and ecosystem services and applications for better chemicals management (No. 101135483).

2.10.P-We142 Fishing for Pollutants: Eye Lenses Open New Avenues for Reconstructing Lifetime Chemical Exposure Histories

***Rebekah Boreham**[1], Sara Leston[2], Andreia Freitas[3], Philip White[4], Boyd McKew[1], Michael Williamson[5], Adam Piper[5], Rosie Williams[5], Jonathan Barber[6] and Anna Sturrock[1], (1)University of Essex, United Kingdom, (2)University of Coimbra, Coimbra, Portugal, (3)Instituto Nacional de InvestigaC o Agraria e Veterinaria, Portugal, (4)Marine and Freshwater Research Centre at the Atlantic Technological University, Galway, Ireland, Ireland, (5)Institute of Zoology, Zoological Society of London, United Kingdom, (6)Centre for Environment, Fisheries and Aquaculture Science (Cefas), United Kingdom*

To target pollution remediation efforts and predict the impacts of pollutants on fisheries productivity and food security, we need new tools that allow us to reconstruct lifetime exposure histories. This will allow us to understand the legacy effects of contaminant exposure on fish growth and fecundity, and the phenology, intensity and location of exposure events. However, current methods used to quantify chemical burden in fish typically use soft tissues which do not provide temporal information and can miss pulse exposures.

Eye lenses are proteinaceous structures formed of crystallin fiber cells laid down in concentric growth layers. Importantly for pollution reconstruction applications, the lens is not vascularised and the growth layers are metabolically inert creating a permanent record of the fish s life at the point of deposition. For this reason, fish eye lenses are an increasingly popular target for stable isotope analysis to track their habitat use and diet. More recently, lenses have also been used to infer mercury exposure histories, but as of yet, organic pollutants such as pharmaceuticals and PAHs have not been quantified in this tissue. Here, we developed semi-quantitative analytical methods to screen eye lens growth layers (laminae) for multiple classes of contaminants. Lens and liver samples were taken from adult demersal flatfish (dab; Limanda limanda) sampled all around the UK, and from European eel (Anguilla anguilla) sampled in rivers in northern England. Subsamples were analysed using GC-MS/MS and UHPLC-TOF-MS to compare the efficacy and contaminant types detected by the two instruments. The chemical burden observed in eye lenses was compared to that in the livers of the same individuals, which served as a benchmark for exposure assessment due to its role in metabolism and detoxification.

Successive eye laminae recorded a chronology of bioavailable contaminants from the surrounding environment, providing an exciting tool to understand patterns in pollution exposure (chronic or acute) and at what life stage(s) they were exposed. Combining lens data with location and temperature estimates derived from the otoliths (earstones) of the same animal could provide new opportunities to inform pollution mitigation and conservation efforts and to understand carryover effects of chemical exposure events.

2.10.P-We143 Heavy Metals and Microplastics in Northern Lapwing (*Vanellus vanellus*) Nesting Material: A Case Study from Lalinačka saltmarsh, Serbia

***Ana Vladan Samardžić**[1], Dimitrija Savic-Zdravkovic[1], Milica Nikolic[1], Milan Ilic[2], Jelena Slavisa Stojanovic[1] and Marko Nikolic[1], (1)University of Nis, Faculty of Sciences and Mathematics, Serbia, (2)Biological Society Dr. Sava Petrovic, Serbia*

The Northern Lapwing (*Vanellus vanellus*), a ground-nesting wader, has experienced severe population declines across Europe due to habitat degradation, agricultural intensification, and environmental pollution. Despite substantial research on anthropogenic stressors in conventional habitats, their impacts in extreme ecosystems like saltmarshes remain poorly understood. This study represents the first ecotoxicological assessment of the relict Lalinačka saltmarsh in Serbia, focusing on the influence of heavy metals, pesticides, and microplastics on Lapwing breeding success. Fieldwork conducted during the breeding season included detailed monitoring of nesting success and the collection of environmental and biological samples - soil, vegetation, nesting material, eggshells, and feathers. The analysis identified elevated concentrations of heavy metals, including cobalt, nickel, and vanadium, in nesting material and surrounding soil, with samples exceeding established regulatory limits. Additionally, microplastic particles were detected in both the nesting material and soil, highlighting an emerging threat to avian reproductive success. Using advanced analytical techniques, including XRF, ICP-OES, and GC-MS, our work's combination of methods to analyze multiple contamination sources is both novel and interdisciplinary, providing comprehensive insights into contamination pathways. Importantly, this study fills a critical research gap as no previous studies have assessed the impacts of heavy metals and microplastics on the nesting success of *V. vanellus*. The findings illuminate the role of environmental toxins in shaping avian reproductive health in extreme environments, emphasizing the vulnerability of ground-nesting species. By integrating local case studies with global ecotoxicological concerns, this research highlights critical data for the sustainable management of sensitive ecosystems and advances the broader understanding of biodiversity conservation under intensifying anthropogenic pressures.

Disclaimer/Disclosure: This research is part of the project "Ecotoxicological Assessment of Northern Lapwing (*Vanellus vanellus*) Breeding Sites: Unraveling Contaminant Impact in Lalinačka Saltmarsh Area, Serbia," supported by the Waterbird Society Research Grant 2024. The results presented are part of the broader study conducted under this grant, led by Marko Nikolić as the principal investigator. The findings, interpretations, and conclusions expressed are those of the author(s) and do not necessarily reflect the views of the funding organization.

2.11.P Vanishing Scales and Slimy Trails: Interdisciplinary Perspectives on Amphibian and Reptile Conservation

2.11.P-We144 Fish and Amphibian Species Sensitivity Distributions (SSDs) for Insecticides and Fungicides

Lennart Weltje[1], *Dhruv Savaliya*[2] *and Lea Weinisch*[1], *(1)BASF SE, Agricultural Solutions - Ecotoxicology, Germany, (2)Georg-August-University, Division of Plant Pathology and Plant Protection, Germany*

Acute fish testing is a standard data requirement for pesticide registration. The fish acute test yields a 96-h LC50, which is divided by an assessment factor of 100 in the tier 1 EU aquatic risk assessment. A common refinement option for the acute risk assessment is the species sensitivity distribution (SSD), a cumulative distribution fitted to LC50 values from at least five fish species. Then, the hazardous concentration for 5% of species (HC5) is derived from the SSD and divided in the risk assessment by an assessment factor of 9.

There is no requirement to test aquatic life stages of amphibians, but there is a requirement to assess available data (e.g., from public literature). The common approach is to assume that fish cover the sensitivity of the aquatic life stages of amphibians, which has been confirmed by several data reviews. However, it has also been suggested to increase the assessment factor further to include all retrieved amphibian data points from the public literature. Additionally, the EFSA scientific opinion on risk assessment for amphibians and reptiles urges to perform toxicity tests with aquatic amphibian life stages. However, this suggestion clearly contradicts the wish to reduce animal testing as per regulation EU 1107/2009. Finally, the EFSA Aquatic Guidance Document states that it should be checked whether a refined fish risk assessment (e.g., with an SSD) still covers the aquatic amphibian life stages.

Therefore, we fitted SSDs for fish and amphibians for 19 data-rich insecticides and fungicides, using active substance and formulation LC50 values obtained from the U.S. EPA ECOTOX Knowledgebase, supplemented with scientific and regulatory literature. Herbicides were not included due to their generally low acute toxicity and occurrence of formulation effects. SSDs were calculated for fish and amphibians separately and for the combined dataset to investigate: (1) sensitivity differences, and (2) if fish and amphibians are part of a single aquatic vertebrate SSD.

Our analyses show that for 17 out of 19 substances fish are more sensitive than amphibians, while for two substances amphibians were slightly more sensitive (within a factor of 1.5). Also, fish and amphibian data can be combined in a single aquatic vertebrate SSD. This work shows that fish are appropriate and sensitive surrogates for aquatic life stages of amphibians and as such may help in avoiding unnecessary amphibian (i.e., vertebrate animal) testing.

2.11.P-We145 Chronic Effects of Pesticide Mixtures on the Survival, Development, and Metamorphosis of the Iberian Painted Frog

***Samuel Gonzalez Lopez**, Pedro Peiro and Manuel Ortiz Santaliestra, Institute for Game and Wildlife Research, IREC (CSIC-UCLM-JCCM), Spain*

Amphibians are often excluded from pesticide risk assessments, leaving uncertainties about their protection from chemicals. Many species, such as the Iberian painted frog (Discoglossus galganoi), rely on rapid development to leave temporary ponds, making them particularly vulnerable to environmental disruptions. In this study, we investigated the chronic effects of the herbicide 2,4-D and the insecticide flupyradifurone on D. galganoi. To do so, egg clutches of this species were collected from the wild and reared in the laboratory before being assigned to 12 treatment groups, including five 2,4-D concentrations (0.03 100 ppm), two flupyradifurone concentrations (10 or 100 ppm), four combinations of the two pesticides, and a control group. Tadpoles were exposed from early development stages to metamorphic climax, with survival and growth closely monitored. Metamorphosing animals were individually housed until tail resorption for final measurements and pesticide residue analyses. High concentrations of 2,4-D caused severe mortality during aquatic stages, with complete mortality at 100 ppm within the first day of exposure. Combined treatments with flupyradifurone resulted in faster mortality compared to single-substance exposures, indicating additive effects. Average body condition during aquatic development was significantly higher in the control group than in the 30 ppm 2,4-D and combined treatment groups. Animals treated with 0.3 ppm of 2,4-D alone showed slightly better outcomes than those in flupyradifurone combinations, though high variability likely masked statistical significance. Development times were significantly extended for some of the treatments, particularly at 30 ppm of 2,4-D, delaying metamorphosis climax by more than 15 days compared to controls. Among individuals reaching metamorphosis climax, all treatment groups except the control caused mortality before completing metamorphosis, and malformations were prevalent, with the highest rates observed in the 3 ppm 2,4-D group and frequently occurring in combined treatments. These findings underscore the heightened vulnerability of amphibians to pesticides during critical developmental stages and highlight the need for comprehensive risk assessments and research that address their unique ecological challenges.

2.11.P-We146 Assessment of Methylmercury and its Independent and Synergistic Effects on Adult Survival Across Multiple Populations of Amphibians

***Blake R Hossack**, Brian J Tornabene, Collin Eagles-Smith and Kelly L. Smalling, US Geological Survey, United States*

Amphibians face unprecedented global declines from many threats, including contaminants such as mercury and their interaction with other stressors. While the biphasic life history of many amphibians increases the risk of methylmercury (MeHg) exposure in aquatic habitats, the broad-scale distribution of MeHg exposure in amphibians and its effects on animal health remains largely unknown, whether considering MeHg alone or in combination with other stressors like disease. We used nonlethal sampling to assess MeHg bioaccumulation in juvenile and adult amphibians from 26 populations (14 species) in the USA during 2017-2021, including several imperiled species that could not have been sampled by traditional lethal methods. For 10 of these same populations (7 species), we conducted multi-year capture-mark-recapture studies and used hierarchical models to estimate how MeHg affected survival of individual amphibians directly and in combination with Batrachochytrium dendrobatidis (Bd), the fungus that causes the lethal disease amphibian chytridiomycosis. We found a 33-fold difference in tissue concentrations of MeHg from amphibians across study sites. Much of the variation in bioaccumulation was linked with life history characteristics of sampled species such as size and trophic position. Our capture-mark-recapture study revealed MeHg can directly reduce survival of individuals and act synergistically with Bd to further reduce survival. Although effects varied among species and sites, our results provide the first evidence of mercury (Hg or MeHg) reducing survival of wild, adult amphibians. Our results also help clarify the potential for direct and synergistic effects of MeHg and disease and emphasize the complexity of identifying and quantifying interactions among stressors under field conditions.

2.11.P-We147 A Dynamic Model to Assess the Combined Effects of Batrachochytrium Dendrobatidis Infection and Pesticides in Amphibians

***Simon Ewald Hansul**[1], Samuel Gonzalez Lopez[2], Manuel Ortiz Santaliestra[2], An Martel[3], Frank Pasmans[3] and Andreas Focks[1], (1)University of Osnabruck, Germany, (2)University of Castilla-La Mancha, Spain, (3)Ghent University, Belgium*

The global amphibian decline is likely multi-causal. Among other contributing factors, combined effects of chemical toxicity and infectious diseases are likely contributing to population and biodiversity decline. Dynamic models can help to improve mechanistic understanding of such multi-stressor effects and assess possible interactions in a wide range of scenarios.

To model the combined effects of pesticides and Batrachochytrium dendrobatidis (Bd) infection on the life-history of amphibians, we developed a dynamic model consisting of three components: A model of the life-history of amphibians, based on Dynamic Energy Budget (DEB) theory, a model of Bd growth, infection and effects, and a Toxicokinetic-Toxicodynamic (TKTD) model to account for effects of pesticides. The Bd life cycle was modelled based on a previously developed model which accounts for density-dependent growth of sporangia, and was extended to account for variability in Bd infection susceptibility among amphibian individuals.
We estimated DEB parameters for the anuran Discoglossus galganoi from larval and metamorph growth and developmental data.
Parameters accounting for Bd growth and infection dynamics were estimated from the distribution of measured Bd loads across D. galganoi individuals. The parameters describing effects of Bd loads were inferred from effects on the 10-day growth rate of juveniles, commencing 10 days after exposure to Bd. All parameter estimations were done using a likelihood-free Bayesian approach. The full set of parameters was not identifiable from the data, highlighting the need for approaches which account for parameter uncertainty (e.g., Bayesian inference) and reduce uncertainty (e.g., pooling data from multiple sources). Overall, the developed model implementation is highly flexible and allows to extrapolate effects across a wide range of scenarios. Emerging challenges in the calibration of this model lie in the number of parameters, as well as the stochastic nature of Bd infection dynamics. The presented model can help to illuminate possible interactions between Bd infection and chemicals, e.g., by assessing the effect of a chemical s mode of action on the probability of an interactive effect between the chemical and Bd infection on apical endpoints. In combination with further experimental data on the effects of chemicals, this can in turn support the risk assessment of pesticides for amphibians.

Disclaimer/Disclosure: This work is part of AmphiDEB, a project funded by the European Food Safety Authority.

2.11.P-We148 Can Abiotic Factors Related to Climate Change Affect Larval Stages of *Pelophylax perezi*?

*Ana Matos[1], Fernando J M Goncalves[2] and **Sergio Marques**[2], (1)Department of Biology, University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal*

Climate change is a growing concern for the scientific community. It is predicted that climate change-driven alterations will be more profound for the Iberian Peninsula, namely in high-altitude regions. The predictable alterations will have profound implications on biota, with amphibians being suggested as one of the most vulnerable classes due to their unique characteristics and high susceptibility to environmental factors. Additionally, the sensitivity to environmental alterations may vary depending on the background of the populations. This background information is relevant not only to predict the effects of environmental alteration in different regions but also for those conducting ecotoxicological studies resorting to animals from populations with different backgrounds. With this in mind, our study aimed to assess the effects of climate change related abiotic factors (pH and temperature) in amphibian larvae with two distinct altitude background (below 50 m and above 900 m). To achieve this, a full factorial experimental design was performed, with 3 different pH levels (5.5, 6.5 and 7.5) and 3 different temperatures (16, 20, 24 °C) using larvae from both altitudes. Furthermore, to assess the effect of water volume reduction a second assay was carried out, consisting in assessing the effect of several exposure volumes/water column heights in tadpoles from high altitude which will be more prone to be affected to desiccation effect. The endpoints measured for both approaches were both morphological (size) and physiological (activity of antioxidant defence system enzymes and peroxidative damage). From our approach the main results showed that temperature has higher influence than pH in the development time and also in the size in tadpoles, being the effects dependent on the origin (low or high altitude) of the animals. Also, the physiological parameters suggest that animals from high-altitude present higher stress to high temperatures. Furthermore, the scenario of the lowest volume/water column height (desiccation) also revealed high animal stress. Overall, the most relevant results of the present study, indicate that the alteration in abiotic factors, mainly temperature has influence on the development of *P. perezi* and that high-altitude populations may be more severely affected in a scenario of climate change where temperature increases, and desiccation occurs.

2.11.P-We149 From Indicators to Allies: Lizards' Ecological Role and Toxicological Insight in Agriculture Environments

***Giulia Simbula**, BIOPOLIS-CIBIO-InBIO, Portugal*

The application of agrochemicals has become an important tool to maximize harvesting, although their intense use can pose direct and indirect ecotoxicological risks to non-target organisms, such as reptiles. Lacertid lizards are pervasive in agricultural landscapes where they play a key functional role, yet the extent of their exposure to pesticides and their mechanisms for coping with these chemicals remain poorly understood. This study aims to determine whether and how agricultural practices can influence and interfere with lizard fitness (lizards health status) and their trophic networks (diet composition), ultimately affecting the quality of their ecosystem services. Lizards were sampled from seven vineyards sites undergoing different pesticides applications in northern Portugal. Morphometric traits, blood smears (parasite quantification), fecal pellets and tail tips for diet analysis (metabarcoding and isotopes) were collected. Moreover, microhabitat quality was assessed along transects through data loggers, thermos-pictures and pictures to record habitat structure and vegetation. The results revealed slightly variations among pesticides applications in body condition, parasitisation and in dietary patterns. Although some associations remain still unclear due to the complexity of natural systems, yet the observed trends provide valuable insights and warrant further investigation for the conservation of reptiles in agricultural environments. Furthermore, the outcomes of this study are expected to contribute significantly to both functional ecology and agricultural management by providing quantitative evidence to inform decision-making. An integrated functional ecology and ecosystem services framework may be an effective approach to advancing sustainable agriculture and improving conservation practices.

2.11.P-We150 A Comprehensive Dataset of Amphibian Physiological and Biochemical Parameters for Toxicokinetic Modeling and Comparative Analysis

***Luisa Reger**[1], Annegret Annegret Grimm-Seyfarth[2] and Jo Nyffeler[1], (1)Research Unit Chemicals in the Environment, Helmholtz Centre for Environmental Research UFZ, Germany, (2)Research Unit Ecosystems of the Future, Helmholtz Centre for Environmental Research UFZ, Germany*

Amphibians are one of the most diverse vertebrate groups on Earth, playing an important role in terrestrial and freshwater ecosystems. However, they are experiencing the fastest rate of decline among all vertebrates, with populations facing multiple threats worldwide. To navigate their protection from environmental chemicals, read-across from other classes (e.g., mammals) is used. This however could potentially be improved by habitat specific toxicokinetic modeling for which a deeper understanding of their physiology is essential. This study addresses this need by presenting a comprehensive dataset on various relevant physiological and biochemical parameters.,

We conducted a literature review using broad queries combining "amphibia" with specific traits related to physiology (e.g., "skin permeability", "organ weight", "blood plasma"). Over 700 abstracts were retrieved from Web of Science; for 150 entries the full text was retrieved to extract the measurements. Data sources included information extracted from tables and graphs, calculations derived from supplementary information, and details obtained through direct contact with the authors. We differentiated data by species, sex, age, in situ / ex situ, along with trait-specific distinctions.

Preliminary work identified, data for organ weights, expressed as a percentage of body weight, for 27 amphibian species. Lipid content for the whole body and individual organs has been gathered for 30 species across twelve different families. The dataset also includes detailed tissue specific and whole-body composition data, such as moisture, lipid (composition), protein, lean mass, and glycogen percentages. These parameters were best reported for Lithobates catesbeianus, which is farmed on an industrial scale, and for the model organism *Xenopus laevis*, but data for various species within the family Hylidae and Salamandridae were also retrieved. For the liver, which plays a key role in the degradation of chemicals, different characteristics were documented for 38 species.

Ongoing work aims to expand the dataset. This dataset supports the comparative analysis of species-specific biochemical profiles, providing insights into physiological variation within and across taxonomic groups, sexes, habitat and study conditions. Additionally, it is the basis for future physically based toxicokinetic modelling for amphibians which could improve their risk assessment, leading to better protection.

2.11.P-We151 From Soil to Skin: Predicting Pesticide Uptake in Caudates

***Valentin Mingo**[1], James Robert Wheeler[2] and Manousos Foudoulakis[3], (1)Corteva Agriscience, Germany, (2)Corteva Agriscience, Netherlands, (3)RAS, Corteva Agriscience, Peristeri, Greece*

Dermal uptake is considered one of the key drivers for amphibian exposure to pesticides. Indeed, multiple

studies have confirmed the relevance of this uptake pathway, which is generally considered to be the result of their highly permeable skin. We recently, described a modelling approach that aims at deriving body burdens resulting from exposure via contaminated soil. However, these efforts have been mainly focused on anurans, as exposure data in caudates is scarce.
Here we present an updated one-compartment Toxicokinetic (TK) model that aims at deriving realistic body burdens resulting from exposure via contaminated soil in caudates. The TK model was adapted to describe uptake mechanisms (passive, active, rehydration) in caudata, and was validated for 5 pesticides. Parameters used in the model included tested species, body weight, soil concentration, body burdens, skin surface area, skin thickness, Koc, permeability coefficient of the pesticide and water uptake rate of the animals. Poly-parameter Linear Free Energy Relationships modelling was used to describe the distribution of the corresponding pesticide between water and amphibian tissue and integrated into the equation. Modelled body burdens were subsequently compared to actual, measured body burdens for a total of 25 individuals exposed to 5 different pesticides. In order to compare the overall predictibility of the model for a given pesticide, predictions and measured concentrations were averaged over all individuals for a given pesticide. Overall, a good concordance between modelled and measured body burdens was observed, comparable with the previously described anuran model. Results were subsequently plotted on a log-log plot and a regression analysis performed, resulting in an R2 of 0.62 and a correlation coefficient of 0.67, suggesting adequate predictivity of the model.
Based on these results, it is possible to derive realistic body burdens using TK modelling in caudates, although more data would be desirable to confirm applicability to a wider range of pesticides. We suggest that similar to anurans, TK models could be used to characterize dermal exposure in caudates, to screen for pesticides of concern, reducing the overall need for animal testing.

2.11.P-We152 From Fish to Frogs: Leveraging Fish Toxicity Data to Predict Chronic Pesticide Effects on Aquatic Amphibian Life Stages
*Elena Adams[1], **Lennart Weltje**[2], Eric Bruns[1] and Dominic Englert[1], (1)Bayer AG, Crop Science Division, Germany, (2)BASF SE, Agricultural Solutions - Ecotoxicology, Germany*
Existing data indicate that fish toxicity is predictive for pesticide toxicity on aquatic life stages of amphibians. While many studies have confirmed this for acute toxicity, predicting chronic toxicity is more challenging. Since 2018, the European Food Safety Authority has mandated the submission of amphibian studies for pesticides as part of its Guidance for identifying endocrine disruptors. This requirement has significantly increased the availability of Amphibian Metamorphosis Assay (AMA) data, allowing for an update of former correlations between fish Early Life Stage (ELS) and AMA data. This project aims to evaluate the relative sensitivity of amphibians compared to fish using existing AMA-ELS data. We extracted data on apical endpoints survival, body weight, and length from ELS and AMA study reports used for plant protection product registrations, as well as publicly available sources. In our analysis, we focused on No Observed Effect Concentrations (NOECs), which are routinely used in environmental risk assessments (ERA). We assessed the statistical correlation between fish and amphibian NOEC values using Spearman s rank correlation. Ultimately, we aim to develop an interspecies correlation estimation (ICE) model to predict chronic aquatic amphibian sensitivity based on fish ELS endpoints. Preliminary data for 65 pesticides show that aquatic-phase amphibians and fish exhibit similar chronic sensitivities to pesticides, showing a significant correlation. Fish were found to be more sensitive to a greater number of pesticides. For only <10% of assessed pesticides frogs were 10-fold more sensitive than fish regarding body weight and length. Considering survival, a 100-fold higher sensitivity was found for a single pesticide only. It is important to note that the limited number of test concentrations in the AMA may result in low NOECs, which introduces some bias into the analysis. Furthermore, the endpoints derived from the AMA are specifically designed for endocrine screening and are not intended for use in ERA. Future work will focus on expanding the database, refining endpoint calibration, evaluating the impact of unbound NOECs on the analysis, and examining variations between pesticide classes. The ultimate goal is to enhance amphibian protection in the ERA of plant protection products while minimizing the need for additional vertebrate studies. To this end, we will derive an ICE model to predict amphibian sensitivity based on ELS endpoints.

2.11.P-We153 Evaluating the Direct and Indirect Effects of Chemical Contamination on Amphibians in the Interface Between Water and Land in Agricultural Landscapes
***Ana Maria Lemos-Marques**, Araceli Gort-Esteve and Manuel Ortiz Santaliestra, Instituto de Investigacion en Recursos Cinegeticos (IREC CSIC, UCLM, JCCM), Spain*
Chemical contamination is widely recognised as one of the main drivers of biodiversity loss, which is especially concerning for amphibians, currently the most threatened vertebrate group. Due to their unique physiological and biological characteristics, amphibians are particularly vulnerable to the threat posed by

chemical contaminants. A case of especial concern pertains to pesticide use and application on agricultural land, which can severely impact the species living in or around cultivated fields. Although there are regulations in place to protect the environment from such threats, these regulations are mainly based on Environmental Risk Assessments (ERAs) that are both limited and fragmented. Furthermore, amphibians are often neglected in the ERA and subsequently not adequately protected. The current framework contemplates separated ERAs for aquatic and terrestrial environments, as well as for different chemicals. However, this framework does not represent the real-life scenario of amphibian exposure to pesticides in agricultural fields, as it oversights the possibility of multiple exposure routes and the potential of occupancy of both aquatic and terrestrial compartments during the course of their life cycles and foraging periods. As such, the present work aims to understand the flow of pesticides from agricultural fields to the nearby ponds in central Spain; record their risks for the amphibian populations developing in these ponds; and study how the effects on these populations mediate the return of contaminants, along with their nefarious consequences, to the terrestrial habitat. The ultimate goal is to generate data to provide a reference scenario for an ERA scheme combining aquatic and terrestrial environments in a more holistic approach. To do so, the present study proposes to focus on assessing food availability, diet composition, susceptibility to diseases, body condition, species richness and diversity, demographic structure and reproductive output of field populations of amphibians whose aquatic development is completed in ponds generated by the runoff water of the neighbouring cultivated fields, paralleled with the experimental evaluation of long-term effects of early aquatic exposure manifested in terrestrial adults. A gradient of detrimental effects positively associated with the degree of contamination is expected to be observed.

Disclaimer/Disclosure: Funded by the Horizon Europe project SYBERAC (ref 101135213).

2.11.P-We154 The Impact of Agricultural Contaminants on Populations of the European Common Toad

***Sarah Devliegere**[1], Siegrid De Baere[1], Andrea Barbi[2], Ellen Blomme[2], Pieter Vantieghem[3], An Martel[2], Dries Bonte[3], Frank Pasmans[2] and Siska Croubels[1], (1)Ghent University, Department of Pathobiology, Pharmacology and Zoological Medicine, Laboratory of Pharmacology and Toxicology, Faculty of Veterinary Medicine, Belgium, (2)Ghent University, Department of Pathobiology, Pharmacology and Zoological Medicine, Wildlife Health Ghent, Faculty of Veterinary Medicine, Belgium, (3)Ghent University, Department of Biology, Terrestrial Ecology Unit, Belgium*

Amphibians are the most threatened class of vertebrates worldwide, according to the IUCN Red List. Habitat loss and degradation are considered to be major threats causing population declines. Even common and widespread species, such as the European Common toad (Bufo bufo), are facing gradual population declines. Even a minor decline of a common species results in a significant decrease in biomass, which is expected to have major effects on ecosystem functions and services. Therefore, it is crucial to understand the causes of toad population decline in order to formulate effective conservation strategies.

Agricultural contaminants were analysed in water samples from ten ponds with declining toad populations and compared to ten ponds with stable populations, selected throughout different ecoregions in Flanders (Belgium) and sampled monthly over a period of 3 months. Pesticides ($n = 112$), mycotoxins ($n = 20$), and antiparasitic drugs ($n = 15$) were analyzed by targeted ultra-high performance liquid chromatography-tandem mass spectrometry methods (UHPLC-MS/MS). Furthermore, 46 antimicrobial drug residues were detected using UHPLC combined with high resolution MS (UHPLC-Orbitrap-HRMS). For the analysis of 11 heavy metals, both inductively coupled plasma - optical emission spectrometry (ICP-OES) and ICP-MS were used. In addition, nutrient ($n = 5$) levels were measured using ion-exchange chromatography (IC), and total nitrogen content was determined using a Kjeldahl digestion combined with a distillation-titration method.

An exploratory data analysis of a subset of samples indicates that declining populations are linked to slightly higher total concentrations of nutrients and pesticides, but heavy metals and total nitrogen content do not appear to be related to population status. Other analyses are currently in process. A Principal Component Analysis (PCA) will be carried out to explore the relationships between the measured concentrations of contaminants and population status, and potential interactions between contaminants. By linking toad population decline to the presence of certain contaminants, we can provide effective conservation strategies to mitigate threats to an ecologically valuable species. Future research will focus on contaminants that were identified as possible drivers of population decline, in order to fully understand how these contaminants affect toad health.

Disclaimer/Disclosure: This project (Ossobufo) is supported by the Special Research Fund of Ghent University grant number BOF23/GOA/008.

2.11.P-We155 Interaction Between *Pelophylax perezi* and the Amphibian Pathogen *Saprolegnia australis* under Salinisation Scenarios - What Doesn't Kill You Makes You Stronger?

*Sara Costa and **Isabel Lopes**, Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal*

Oomycetes from the genus Saprolegnia constitute one of the groups of pathogens contributing to the global amphibian s decline. Considering that amphibians increasingly live in areas altered by anthropogenic activities, the interplay between host-pathogens-environment has emerged as a critical aspect for understanding the spread and severity of saprolegniosis under environmental perturbations. This study intends to contribute for a better understanding of the effects of rising salinity levels - driven by climate change-sea level rise, and subsequent seawater intrusion in coastal areas - on the interaction amphibian-Saprolegnia. It is hypothesised that tadpoles sensitivity to salinisation is influenced by the pathogen Saprolegnia. For this, a full-cross factor experimental design was performed by exposing tadpoles of the Perez s frog *Pelophylax perezi* to two salinity levels (obtained by dilution of natural seawater) in the presence or absence of the pathogen *Saprolegnia australis* and to a control (without seawater and *S. australis*), for 14 days. Tadpoles were exposed to *S. australis* using two methodologies: (1) full contact, where seeds inoculated with mycelium were deposited on the bottom of the test vial; (2) and partial contact, where seeds inoculated with mycelium were introduced inside a net of 50 µm pore to allow exposure only to the spores. In both cases, a protocol of sporulation induction was performed. Mortality, weight, growth, developmental stage and macroscopic signs of infections were the endpoints observed during the experiment. The obtained results revelated that the presence of *S. australis* influenced the sensitivity of tadpoles to salinity. Overall, the presence of *S. australis* in full contact with tadpoles caused more mortality compared to the salinity treatments in the absence of the pathogen or when tadpoles were in partial contact with it (only for the lowest salinity level). Furthermore, *S. australis* in full contact with tadpoles induced their faster development and an increase in their biomass and growth.
This hypothesis was further tested with tadpoles originated from natural populations with different historical background of exposure to anthropogenic stressors to identify if this pattern of responses persists.

2.11.P-We156 Different Faces, Same Dangers? Comparative Hazard Assessment Of Bisphenol A And Its Analogue Bisphenol S-MAE With In Vivo And In Vitro Amphibian Models

*Fábio Miguel Ribeiro Gomes[1], **Isabel Lopes**[1], Miguel Oliveira[1] and Lluis Tort[2], (1)Centre of Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, Portugal, (2)Department of Cellular Biology, Physiology and Immunology, Spain*

With the growing demand for plastic products, the environmental release of plasticizers is expected to increase. Bisphenol A (BPA), one of the highest-volume industrial chemicals, is widely detected as a contaminant in aquatic ecosystems worldwide. Due to its estrogenic, neurotoxic, and genotoxic properties, as well as its potential for bioaccumulation and biomagnification, BPA is classified as a substance of very high concern. In response to its hazards to human and environmental health, the European Union has prioritized finding safer alternatives. Bisphenol analogues, such as bisphenol S-MAE (BPS-MAE), have been proposed as possible replacements; however, their similar physicochemical properties suggest they may also pose similar toxicity hazards. Due to their recent production and usage, limited information is available on organisms susceptibility to these xenobiotics, particularly for vulnerable groups like amphibians. This study aimed to make a comparative assessment of the toxicity of BPA and BPS-MAE using *Xenopus laevis* in vivo and in vitro models. It also aimed to evaluate the suitability of in vitro assays as non-animal alternatives for first-tier risk assessment of amphibian aquatic stages. Tadpoles were exposed to various concentrations of BPA and BPS-MAE for 96-h, while A6 and XTC-2 cell lines were exposed to equivalent concentrations for 72-h. This work provides the first evidence of BPS-MAE toxicity on amphibians. In tadpoles, BPA had a significant effect on survival, malformations and body growth, with 96-h LC50, EC50, and LOEC values of 11.4, 10.0, and 5.3 mg/L, respectively. BPS-MAE affected these endpoints but also heartbeat, at slightly higher values of 18.1, 18.0, and 15.5 mg/L. Considering cytotoxicity, for A6 cells the 72-h LC50 values of BPA and BPS-MAE were 18.2 and 21.7 mg/L, respectively, while for XTC-2 cells were 26.4 mg/L for BPA and 22.9 mg/L for BPS-MAE. Overall, XTC-2 cells were more resistant than A6 cells to both bisphenols, and tadpoles were more sensitive than either cell line. The overlapping confidence intervals of the computed toxicity parameters between in vivo and in vitro models support the viability of in vitro assays as reliable alternatives for initial risk assessments in amphibians. Additionally, although BPA demonstrated higher toxicity, the similarity of LC50, EC50, and LOEC values between BPA and BPS-MAE highlights the unsuitability of the latter BPS-MAE as a safe environmental alternative to the former.

2.11.P-We157 Toxicity and Behavioral Effects of Wildfire Ash on *Xenopus laevis*: The Role of Portuguese Native and Exotic Vegetation

*Diogo Gabriel Coutinho Santos[1], Nelson Abrantes[1], Isabel Campos[2] and **Isabel Lopes**[1], (1)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (2)Department of Environment and Planning, University of Aveiro | CESAM, University of Aveiro, Portugal*

Recent wildfire seasons in Europe have been increasingly destructive, severely impacting ecosystems and biodiversity. In Portugal, wildfires devastated forests, including of both native and exotic species. These wildfires introduce ash with toxic compounds, such as polycyclic aromatic hydrocarbons and metals, into aquatic ecosystems. Vegetation cover can affect ash composition and subsequently its toxicity to aquatic organisms, yet its specific effects on amphibians, which are important indicators of the ecosystem s health, remain underexplored. This study assessed the influence of wildfire ash elutriates, originated from Portuguese native Arbutus unedo (strawberry tree) and from exotic Eucalyptus globulus, on the behaviour and other fitness related parameters of *Xenopus laevis* tadpoles. To achieve this goal, two experimental setups were performed: (1) a 96-hour acute toxicity assay was performed by exposing tadpoles to a range of concentrations of aqueous ash extracts (AAE) from each vegetation cover (0.625 10.0 g L-1). At the end of the assay the following endpoints were measured: mortality, body lengths (tail, snout-to-vent, and interorbital), and body weight. (2) a 12-h avoidance assay in the HeMHAs system, where tadpoles of *X. laevis*, previously fed or non-fed, were exposed to a gradient (0.625 10.0 g L-1) of AAE from both vegetation covers. At the end of this assay, the avoidance from AAE contaminated compartments was quantified.

In the 96-hour assay, no significant mortality was observed, but significant decreases in body length and weight (LOEC = 6.25 g L-1) occurred across all concentrations, with the most severe effects at the highest concentrations of E. globus AAE. In the avoidance assay, neither E. globulus nor A. unedo affected the relative distribution of *X. laevis* tadpoles across the compartments of the HeMHAs system. However, both AAE led to avoidance behaviour in previously fed tadpoles, with E. globulus (LOEC = 6.25 g L-1) inducing a greater avoidance response than A. unedo (LOEC = 12.5 g L-1). These results suggest that Eucalyptus ashes have a stronger adverse effect on tadpoles compared to A. unedo AAE.

These findings indicate that the vegetation type burned significantly influences ash toxicity. The avoidance and toxicity assays highlight E. globus as more harmful to *X. laevis* tadpoles, potentially affecting their growth and survival. Further research is needed to understand how these impacts might affect their development.

2.12 Ecotoxicology and Environmental Chemistry in Mountain and Remote Areas: Challenges, Impacts, and Future Directions

2.12.T-01 Polycyclic Aromatic Hydrocarbon (PAHs) Contents in Soil Organic Matter Fractions Along an Elevation Gradient in the French Alps

***Lise Marchal**[1], Noelia Garcia-Franco[2], David Gateuille[1], Luis Carlos Colocho Hurtarte[3], Christopher Just[2], Emmanuel Naffrechoux[1], Martin Wiesmeier[4] and Jer me Poulenard[1], (1)University Savoie Mont-Blanc, France, (2)Chair of Soil Science, TUM School of Life Sciences Weihenstephan, Technical University of Munich, Germany, (3)Diamond Light Source Ltd, United Kingdom, (4)Bavarian State Research Center for Agriculture, Institute for Organic Farming and Agroecology, Germany*

Polycyclic aromatic hydrocarbons (PAHs) are toxic, ubiquitous and persistent organic pollutants in the environment, mainly produced by road traffic and domestic heating. These pollutants are semi-volatile compounds which, once released into the atmosphere, can be transported over long distances and reach remote areas such as mountainous regions.

PAHs have a high affinity for soil organic matter (SOM) and therefore tend to accumulate in soils after deposition. Thus, PAH and SOM dynamics cannot be dissociated. We used a common approach of SOM studies (density fractionation) to better understand the PAH dynamic in mountain soils, along an elevation gradient (Lautaret, France). This approach consisted to study 3 different SOM fractions: the free particulate organic matter (fPOM), the occluded particulate organic matter (oPOM) and the mineral-associated organic matter (MaOM) and to measure PAH and organic carbon (OC) contents in bulk soils and SOM fractions. SOM quality were analysed by nuclear magnetic resonance (NMR) spectroscopy for fPOM and oPOM fractions, and by attenuated total reflectance (ATR) for MaOM fraction.

The results showed that total PAH contents in bulk soils ranged from 55 to 239 ng·g-1, corresponding to typical regional background values for PAH contamination in mountainous areas. In the fractions, the highest PAH contents were found in the oPOM fraction, followed by the fPOM fraction then the MaOM fraction. The results revealed that the distribution of PAHs in the soil is partly determined by the amount of OC in each fraction. The NMR results showed that PAH contents were strongly correlated with the increase degree of decomposition of SOM. This suggests that the distribution of PAHs may be linked to the transformation of fractions (from fPOM to oPOM), also associated with the formation of aggregates (providing physical protection for PAHs). With regard to the MaOM fraction, the lower PAH contents can be simply explained by the nature of this fraction, which consists of microbial- and plant-derived SOM. The results of this research indicated a preferential distribution of PAHs within soils (oPOM > fPOM > MaOM), driven by the OC contents and probably link to the formation of aggregates in soils. As a such distribution may have an impact on the dynamic of pollutants in soils, it can be taken into consideration in future research.

2.12.T-02 Airborne Benzothiazoles and Organophosphate Flame Retardants at a High-altitude Background Site in the Eastern Italian Alps: Occurrence, Sources and Temporal Trends

Eleonora Favaro[1]*, Giovanna Mazzi*[1]*, Elena Barbaro*[2]*, Andrea Gambaro*[1] *and Matteo Feltracco*[1]*, (1)Department of Environmental Sciences, Informatics and Statistics (DAIS), Ca Foscari University of Venice, Italy, (2)Insitute of Polar Sciences, National Research Council (CNR-ISP), Italy*

In the last decades, rapid urbanization and industrial and economic growth have led to the acceleration of the anthropogenic impact on the planet and even remote areas are no longer pristine. The emission in the environment of Chemicals of Emerging Concern (CECs) is consistently increasing, hence their monitoring is of growing interest for the scientific community and policy makers. Among other environmental compartments, the atmosphere is one of the most affected by the growing number of CECs, as they are still poorly regulated and not extensively monitored.

Both benzothiazoles (BTHs) and organophosphate flame retardants (OPFRs) are listed as high volume production chemicals due to their extensive use in a wide range of industrial and consumer products, and their increasing release in the environment poses risks for the ecosystems and human health, as different studies have demonstrated their potential toxic effects.

This study aimed to investigate the occurrence of eight BTHs and six OPFRs in PM10 samples collected at a high-altitude background site located in the Eastern Italian Alps, to observe temporal trends and to assess their sources and transport processes.

Aerosol sampling was carried out from April to October 2023 at Col Margherita Observatory (2543 m a.s.l.) using a PM10 low volume sampler. Analytical determination was performed via UHPLC-MS/MS. NOAA ARL s HYSPLIT model was used to determine the origin of air masses reaching the study area. The effect of typical alpine phenomena, such as the valley breeze, on atmospheric transport of the target compounds was evaluated by calculating the daily average temperature lapse rate considering the main valleys that influence the air fluxes to the study site.
