Results confirmed the presence of both BTHs and OPFRs in alpine aerosol, with concentrations ranging from pg to ng m-3. Both classes of contaminants exhibit a seasonal trend, with higher concentrations in spring, probably due to a combination of atmopsheric processes such as thermal convection, mountain-valley breeze regimes and upward motion due to mixed-layer expansion.

The present study provides for the first time information on background concentration levels of BTHs and OPFRs in the atmosphere of an high mountain remote area, offering insights into their sources and transport mechanisms that will help for future investigations on the pathways and environmental fate of these classes of chemicals.

2.12.T-03 High-Mountain Lakes as Indicators of Microplastic Pollution: Insights From the Alps

Alice Gabetti[1]*, Serena Anselmi*[2]*, Monia Renzi*[3]*, Francesca Provenza*[2]*, Giuseppe Esposito*[1]*, Elisabetta Pizzul*[3]*, Antonia Concetta Elia*[4]*, Damia Barcelo*[5]*, Marino Prearo*[1] *and Paolo Pastorino*[1]*, (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy, (2)Bioscience Research Center srl, Italy, (3)Department of Life Sciences, University of Trieste, Italy, (4)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (5)Chemistry and Physics Department, University of Almeria, Spain*

Microplastics can reach remote areas, such as alpine lakes, through atmospheric transport and deposition. These ecosystems are sentinel systems that can provide information on the effects of climate change and anthropogenic pressures. This study aimed to investigate the presence of microplastics (MPs) in abiotic matrices (water and sediments) and aquatic organisms (zooplankton, tadpoles (Rana temporaria), fish (Salvelinus fontinalis)) in two high mountain lakes (Upper Lake Balma and Lower Lake Balma) in the Cottian Alps (northwest Italy). Biotic and abiotic samples were processed in the laboratory and MPs were detected by Fourier transform infrared spectroscopy.

The MPs found in the biotic samples were compatible in shape (fibers and fragments), colour (black, blue, white) and chemical type (polypropylene and polyethylene) with those found in the abiotic samples. No MPs were detected in the water samples. The average MPs in the sediment samples were 1.33 ± 0.67 items/m3 and 1.75 ± 0.62 items/m3 in the Lower and Upper Lake Balma, respectively. No MPs were found in zooplankton: this could be due to the absence of MPs in the water and the ability of copepods to shed microplastics while foraging. The mean number of MPs in tadpoles was 0.33 ± 0.58 items/individual and 0.66 ± 0.58 items/individual in Lower and Upper Lake Balma, respectively. Further studies are needed to investigate the effects of MPs on tadpole development and growth. The mean number of MPs elements found in the gastrointestinal tract (GIT) of fish was significantly higher in samples from the Lower Lake (0.45 elements/g GIT) than in those from the Upper Lake (0.20 elements/g GIT). A negative relationship was found between fish size and MPs abundance in GIT, indicating that juvenile fish accumulate more MPs, probably due to the high prey ingestion rate compared to adults. This study represents a comprehensive assessment of the presence of MPs in the biotic and abiotic compartments of a high mountain lake. Although the number of items in the samples was low, our findings suggest long-range transport contamination. Salvelinus fontinalis could be considered as a good bioindicator of MPs pollution in alpine lakes, and as most of these environments were originally fishless, fish could be removed for MPs monitoring in high mountain environments. Further studies are desirable to better understand the source and dynamics of MPs in high mountain lakes.

Disclaimer/Disclosure: This study was funded by ALPA III Project (23D02).

2.12.T-04 Using Dragonflies as Bioindicators of Per-and Polyfluoroalkyl Substances (PFAS) Exposure in United States Protected Areas

Kelly L. Smalling[1]*, Brian J. Tornabene*[1]*, Andrea Tokranov*[1]*, Zachary Hopkins*[1]*, Collin Eagles-Smith*[1]*, Colleen Emery*[1] *and Colleen Flanagan Pritz*[2]*, (1)US Geological Survey, United States, (2)US National Park Service, United States*

Per- and polyfluoroalkyl substances (PFAS) are ubiquitous in the environment and are of significant global concern to human health, wildlife, and ecosystems because of their prevalence, persistence, and toxicity. Because of their wide variety of uses, PFAS are found in many environments and organisms, including in atmospheric particulate matter and wet deposition. Organizations worldwide have emphasized a critical need for understanding the occurrence, fate, transport, and effects of PFAS in the environment and to the public. Currently, there is an incomplete understanding of PFAS exposure within ecosystems and food webs, especially on protected lands including remote and mountainous areas, limiting our understanding of whether sensitive natural resources are at-risk. Dragonfly larvae are considered an ideal biosentinel for bioaccumulative contaminants due to their predatory nature, prevalence in a variety of water bodies, and widespread geographic distribution across six continents. They are also easy to sample making them an ideal species for large network designs including those incorporating aspects of participatory science. The current study was designed to address the prevalence of PFAS on protected lands, determine the ecologically relevant PFAS mixtures occurring in biota, and quantify the utility of dragonfly larvae as biosentinels for PFAS to address potential risks to fish and humans. To accomplish these objectives, we utilized an existing citizen-science network to collect dragonfly larvae from over 90 national parks and wildlife refuges across the United States (US) from 2021 2023. After collection, samples were dried, composited (N = 160 composites) and analyzed for 28 individual PFAS. Based on preliminary data from about half the samples, at least one PFAS was observed in each composite dragonfly larvae collected and PFBA, PFOS and PFTrDA were observed most frequently at concentrations ranging from <1 480 ng/g dry weight (median: 2.5 ng/g dry weight). Results from this initial broad scale assessment of PFAS on protected lands will provide parks and refuges with information needed to proactively manage their resources, particularly in areas where PFAS contamination is an issue. Information from this study will also identify localized contamination hotspots, prioritize future monitoring and modeling efforts, and establish future management strategies with the goal of minimizing or reducing PFAS contamination across US protected areas.

2.12.T-05 No Longer Pristine! Occurrence of Perfluoroalkyl Chemicals (PFAS) and an Herbicide in Water Bodies in the Tropical Rainforest of Madagascar

Walter Cristiano[1]*, Anna Maria Ingelido*[2]*, Melis Muz Massei*[3]*, Annalisa Abballe*[2]*, Mario Carere*[1]*, Ines Lacchetti*[1] *and Laura Mancini*[1]*, (1)Unit of Ecosystems and Health, Department of Environment and Health, Italian National Institute of Health (ISS), Italy, (2)Unit of Human Exposure to Environmental Contaminants, Department of Environment and Health, Italian National Institute of Health (ISS), Italy, (3)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany*

The increasing presence of chemical pollutants in even the most remote regions raises concerns for both human health and ecosystem integrity. This is especially important in biodiversity hotspot areas, where pollutants can disturb threatened species and habitats. This study aimed to assess the occurrence of chemical contaminants, including perfluoroalkyl substances (PFAS), herbicides, biocides, and other micropollutants, in the tropical mountain rainforests of Eastern Madagascar an area traditionally considered to be minimally affected by chemical pollution. Water samples were collected from five sites with varying levels of anthropogenic disturbance and forest fragmentation: Maromizaha (MZ), Mitsinjo (MJ), Mahatsara (MH), Andasibe (AD), and Anevoka (AK). We performed a target analysis on 747 micropollutants that are known to be widespread globally and a separate analysis on 13 PFAS compounds. Our findings revealed the presence of eight PFAS compounds, with five (PFPeA, PFHxA, PFHpA, PFOA, and PFDA) detected in more than half of the samples, at concentrations ranging from 0.56 ng/L to 2.13 ng/L. We also detected several other pollutants, including the herbicide Dinoterb, which exceeded its Predicted No Effect Concentration (PNEC) in some sites, particularly in the village of Andasibe, where agricultural activities are constantly carried out. It is worth noting that we found low concentrations of different chemical pollutants even inside the protected area of Maromizaha, which was supposed to be pristine. Overall, while most pollutants were found at levels below their respective PNEC values, these results underscore the growing threat of chemical pollution in tropical areas that already facing habitat fragmentation and climate change. Chemical pollution in the area suggests potential underestimated risks to both human health and the biodiversity of Eastern Madagascar s rainforests. These findings call for continued monitoring and protective measures to safeguard these vulnerable ecosystems.

2.12.P Ecotoxicology and Environmental Chemistry in Mountain and Remote Areas: Challenges, Impacts, and Future Directions

2.12.P-We158 Understanding Drivers of PFAS Contamination in Seabirds: Insights from Biologging Devices

Prescillia Lemesle[1]*, David Rozen-Rechels*[2]*, William Jouanneau*[3]*, Helene Budzinski*[4]*, Pierre Labadie*[4]*, Manrico Sebastiano*[5]*, Paco Bustamante*[6] *and Olivier Chastel*[3]*, (1)Littoral Environnement et Societes (LIENSs), UMR 7266 CNRS, La Rochelle Universite; Centre d Etudes Biologiques de Chize (CEBC), UMR 7372 CNRS, La Rochelle Universite, France, (2)Sorbonne Universite, CNRS, IRD, INRAE, Universite Paris Est Creteil, Institut d ecologie et des Sciences de l environnement de Paris (iEES-Paris), France, (3)Centre d Etudes Biologiques de Chize (CEBC), UMR 7372 CNRS - La Rochelle Universite, France, (4)Environnements et Paleoenvironnements Oceaniques et Continentaux (EPOC), UMR 5805 CNRS - Universite de Bordeaux, France, (5)Unite Physiologie Moleculaire et Adaptation, Museum National d'Histoire Naturelle, CNRS; Behavioural Ecology & Ecophysiology Group, Department of Biology, University of Antwerp, Belgium, (6)Littoral Environnement et Societes (LIENSs), UMR 7266 CNRS, La Rochelle Universite, France*

Per- and poly-fluoroalkyl substances (PFAS) are synthetic, persistent and ubiquitous compounds. Although PFAS occur widely in wildlife tissues, few studies have investigated the link between PFAS exposure and habitat use during reproduction and migration. Deployment of tracking devices (bio-logging) could provide invaluable insights into the identification of spatial origins of contamination. Seabirds are commonly used as bioindicators of marine pollution, especially gull species (Larus sp.) which use a variety of coastal, pelagic, urban and terrestrial habitats, potentially providing crucial information on the geography of PFAS contamination. Here, we combined blood analyses of 11 PFAS and stable isotope ratios with GPS tracking in three gull species (lesser black-backed gull - Larus fuscus, great black-backed gulls - *Larus marinus* and European herring gull Larus argenteus) breeding in South-West France. Long-chain perfluoroalkyl carboxylates (PFCAs) were positively correlated to marine ($\delta^{13}C$ and $\delta^{34}S$) and high trophic level resources ($\delta^{15}N$) in herring gulls. This was confirmed by GPS tracking, with positive associations between PFAS concentrations and the proportion of the foraging sites located in the marine environment. In contrast, PFAS concentrations and stable isotope values were weakly and negatively associated in lesser black-backed gulls, with no link with the proportion of marine foraging sites, suggesting that other drivers were involved. For great black-backed gulls, only stable isotope ratios were quantified and were not associated with PFAS concentrations. These species-specific associations between PFAS and trophic ecology (isotopic markers and GPS) might stem from a contrasted use of the marine environment depending on the species, with terrestrial-coastal foraging habitats for herring gulls, terrestrial-coastal-pelagic foraging habitats for lesser black-backed gulls and only coastal for great black-backed gulls. Overall, the results suggest that the use of marine foraging habitats can increase exposure to PFCAs, particularly for species relying mostly on coastal areas. Mixed use of the marine environment (coastal/pelagic) and the potential pelagic dilution of PFAS may complicate our understanding of PFAS contamination, calling for further research. Combination of biologging with ecotoxicological study demonstrates that multidisciplinary approaches are essential to a comprehensive understanding of spatial exposure of wildlife to PFAS.

2.12.P-We159 Multispecies Contamination with Per- and Polyfluoroalkyl Substances: A Large-Scale Study in Metropolitan France and Sub-Antarctic and Antarctic Territories

Prescillia Lemesle[1], *Alice Carravieri*[2], *Gauthier Poiriez*[3], *Frederic Angelier*[2], *Christophe Barbraud*[2], *Romain Batard*[4], *Coraline Bichet*[2], *Aurelie Blanck*[5], *Helene Budzinski*[6], *Karine Delord*[2], *Armel Deniau*[4], *Gilles Faggio*[7], *Jerome Fort*[3], *Fabrice Gallien*[8], *William Jouanneau*[2], *Pierre Labadie*[6], *Carole Leray*[9], *Ignacio Martinez-Alvarez*[6], *Karen D. McCoy*[10], *Samuel Peroteau*[2], *Pascal Provost*[4], *Bernard Recorbet*[11], *Marie-Catherine Santoni*[7], *Manrico Sebastiano*[12], *Olivier Scher*[13], *Alain Ward*[14], *Olivier Chastel*[2] *and Paco Bustamante*[3], *(1)Littoral Environnement et Societes; Centre d Etudes Biologiques de Chize, France, (2)Centre d Etudes Biologiques de Chize, France, (3)Littoral Environnement et Societes, France, (4)Ligue pour la Protection des Oiseaux, France, (5)Office FranCais de la Biodiversite, OFB, France, (6)Environnements et Paleoenvironnements Oceaniques et Continentaux, France, (7)Office de l'Environnement de la Corse (OEC), France, (8)Groupe Ornithologique Normand, France, (9)Tour du Valat, Research Institute for the Conservation of Mediterranean Wetlands, France, (10)Maladies Infectieuses et Vecteurs: Ecologie, Genetique, Evolution et Contr le, France, (11)Direction Regionale de l Environnement, de l Amenagement et du Logement de Corse, France, (12)Behavioural Ecology & Ecophysiology Group, University of Antwerp, Belgium, (13)Conservatoire Espaces Naturels Occitanie, France, (14)Groupe ornithologique et naturaliste, France*

Per- and polyfluoroalkyl substances (PFAS) are persistent and ubiquitous chemicals whose effects on wildlife are of growing concern, requiring urgent large-scale monitoring. Seabirds are apex predators commonly used as bioindicators of marine pollution. The extent of PFAS contamination in seabirds is however still poorly known in many areas. Here we aimed at filling this gap by studying nine species from metropolitan France (M-Fr) and 15 species from French Southern and Antarctic Territories (TAAF), thereby providing insights into PFAS contamination in seabirds from temperate (M-Fr), subantarctic and Antarctic ecosystems. 11 PFAS were analysed in the plasma of chicks from M-Fr (n = 340) and the TAAF (n = 167). PFOS was the dominant PFAS, being detected in almost all chicks from both M-Fr (100%) and the TAAF (91%). In M-Fr, mean linear-PFOS concentrations ranged from 15.8 ± 6.6 ng g-1 wet weight (ww) in Audouin s gulls to 77.4 ± 21.8 ng g-1 ww in Scopoli's shearwaters. In the TAAF, linear-PFOS concentrations ranged from 0.7 ± 0.5 ng g-1 ww in macaroni penguins (the least contaminated species) to 14.9 ± 4.6 ng g-1 ww in giant petrels, with kelp gulls and Adélie penguins showing nonquantifiable concentrations (<0.2 ng g-1 ww). PFNA, PFDA, PFUnDA, PFDoDA and PFHxS were also quantified in more than 70% of chicks in M-Fr, while these PFAS were only quantified in predatory and scavenging species in the TAAF (albatrosses, giant petrels and skuas). PFUnDA was the second most dominant PFAS, in both M-Fr (from 1.2 ± 0.6 in yellow-legged gulls to 9.4 ± 2.1 ng g-1 ww in Scopoli s shearwaters) and the TAAF (from 0.7 ± 0.2 in snow petrels to 1.6 ± 1.3 ng g-1 ww in brown skuas). Trophic ecology (foraging habitat and trophic position) studied via the stable isotope technique seemed to be a significant driver of carboxylic perfluoroalkyl acid concentrations at both the intra- and inter-specific levels in M-Fr. Overall, concentrations in the TAAF were low when compared to M-Fr, confirming a lower exposure in oceanic habitats of the Southern Hemisphere, far from direct emission sources. In M-Fr, 88% of chicks were above PFOS toxicity thresholds reported for avian model species, calling for further research into potential toxic effects of multi-PFAS contamination in early life stages.

2.12.P-We160 Organophosphate Esters in a Firn Core from Holtedahlfonna, Svalbard

Mark H. Hermanson[1], *Elisabeth Isaksson*[2] *and Geir Wing Gabrielsen*[3], *(1)Hermanson & Associates LLC, United States, (2)Norwegian Polar Institute, Norway, (3)Norwegian Polar Institute, Norway*

In spring 2018, we drilled an 11.6 meter-deep firn core from Holtedahlfonna, a large glacier on western Svalbard. The drill site is at 1150 m a.s.l. and the age at bottom of the core was 14.35 years. The core was cut into 9 sections to for minimum 500 mL sample size. The OPE analytes include 17 different compounds analyzed by LC-MS/MS. The OPEs detected in all samples included triethyl phosphate (TEP), tris(2-chloroethyl phosphate (TCEP), tris(2-chloroisopropyl) phosphate (TCIPP), triphenyl phosphate (TPP), tributyl phosphate (TnBP), tris(2-butoxyethyl phosphate (TBEP), 2-ethylhexyl-diphenyl phosphate (EHDPP). Tris(1,3-dichloro 2-propyl) phosphate (TDCPP) was detected only in the surface sample. The highest concentration in 7 of 9 samples was TCIPP ranging from 13.2 ng L-1 to 143 ng L-1 at the surface, with the other 2 highest being TBEP which throughout the core ranged from 9.34 ng L-1 to 56.5 ng L-1 again highest at the surface. The total OPE amounts detected ranged from 48.9 ng L-1 at year 1995 to 265 ng L-1 in the surface sample representing winter 2017-2018 accumulation, a factor of 5.4 increase. The percent chlorinated is 56.7 at the surface which is the only sample where the chlorinated fraction is greater than non-chlorinated in part because of the comparatively high amounts of TBEP throughout the core, except at the surface. This is unlike air data collected at Ny-Ålesund, Svalbard, (37 km southwest from Holtedahlfonna) in 2021 where chlorinated OPEs comprised 81 percent of all detected OPEs. In the Austfonna 2015 firn core drilled 230 km east from Holtedahlfonna at 700 m a.s.l., the percent chlorinated ranged from 51 to 70 percent in six of 15 samples, suggesting that chlorinated compounds are deposited to glacier surfaces on Svalbard only with high atmospheric concentrations. TCIPP and TnBP at Holtedahlfonna are highly correlated with r = 0.913, significance <<0. 05 suggesting that they were mixed when used at the source, similar to results for the Austfonna 2015 firn core.

Disclaimer/Disclosure: Funding for this project came in part from the Arctic Monitoring & Assessment Program, The Ministry of Climate and Environment (KLD) and the Svalbard Environmental Protection Fund.

2.12.P-We161 Leveraging Mountain Pine Needles as Bioindicators of Potentially Toxic element Contamination in High-Elevation Ecosystems

Michaela Zeiner[1]*, Wolfgang Kandler*[2]*, Katerina Prohaska*[3] *and Rudolf Krska*[2]*, (1)Man-Technology-Environment Research Centre, School of Science and Technology, Örebro University, Sweden, (2)University of Natural Resources and Life Sciences, Department of Agrobiotechnology, Austria, (3)Biotech Campus Tulln, University of Applied Sciences, Austria*

Pine needles from various species have long been utilized as bioindicators of air pollution. The accumulation of major and trace elements in these needles results from both dry and wet deposition of airborne pollutants, as well as the uptake of substances through plant roots. Environmental pollutants can be transported over long distances and reach remote areas. To investigate this, a mountainous region at the confluence of the Lower Inn Valley and Achental in Tyrol, Austria, was selected for sampling. Needles from mountain pines (Pinus mugo) were collected at three different sites at altitudes from 1400 meters to 2000 meters. Sampling covered needles of varying ages young, one-year-old, two-year-old, and older from five to ten trees at each site, pooling needles of the same age. Sampling was conducted annually every July from 2018 to 2024. For elemental analysis, dried samples underwent acidic digestion (either microwave assisted or by high pressure asher) followed by quadrupole and high-resolution inductively coupled plasma mass spectrometry (ICP-MS) measurements. The metabolic state of the plant material was monitored in a fast and non-destructive way by Raman spectroscopy providing additional information on the growing conditions of the mountain pines. The highly sensitive differentiation in fingerprint region of the spectra allows the classification of differently grown pine needles. Rigorous quality assurance protocols were implemented to ensure the reliability of the analytical results and their comparability with previously published data. The findings revealed that altitude had a greater effect on the concentrations of macroelements than on potentially toxic elements. Like other pine species, age-related accumulation of certain elements was observed in the needles.

2.12.P-We162 Chemical Contaminants in Alpine High-Mountain Lakes: Sources, Transport Mechanisms, and Ecological Implications

Paolo Pastorino[1]*, Marino Prearo*[1] *and Damia Barcelo*[2]*, (1)The Veterinary Medical Research Institute for Piedmont, Italy, (2)Chemistry and Physics Department, University of Almeria, Spain*

High-mountain lakes in the Alps, despite their remote locations, are highly susceptible to chemical pollution. This review highlights their role as reservoirs for Persistent Organic Pollutants (POPs) and Contaminants of Emerging Concern (CECs), examining their origins and the resulting environmental and human health implications. Regarding POPs, 14 studies have documented the occurrence of polychlorinated biphenyls, dichlorodiphenyltrichloroethane (DDT) and its metabolites, polybrominated diphenyl ethers, and polycyclic aromatic hydrocarbons in high-altitude Alpine lakes. Most of this research has focused on the Italian Alps (63%), followed by Switzerland (22%), Austria (12%), and France (3%). Sediments are the most frequently studied compartment (65%), with fish (33%) and water (2%) receiving less attention. Similarly, six studies have investigated the presence of CECs in these environments, including musks, perfluorinated compounds, and microplastics. Research on CECs is primarily concentrated in Switzerland (42%), France (33%), and Italy (25%), with fish tissues (muscle and liver) being the predominant focus (46%), followed by sediment (17%) and water (17%). Other compartments, such as zooplankton, amphibians (frogs and tadpoles), and snow, remain underexplored. The review also addresses the key pathways by which pollutants reach these remote ecosystems, including atmospheric deposition, glacial meltwater, and human activities. Safeguarding these fragile environments necessitates sustained research, comprehensive monitoring, and targeted conservation strategies.

2.12.P-We163 Toward a Sociological Approach of Emerging Pollutants (Microplastics, PFASs) Presences in the Alps

Stephane Marpot *and Clemence Perrin-Malterre, EDYTEM Laboratory, France*

Each year, recreational activities such as hiking, ski-touring or mountaineering bring more and more

people in contact with alpine ecosystem. Recently, sociology showed how these practices seem to be driven by practioners dispositions to feel attach and to perceive alpine abiotic elements, fauna or plants. However, in one hand, hikers tend to leave offscreen of consciousness what remind them of touristical harnessing and the component of their practices which contribute to mountain pollution (waste, uses of high-tech textiles, road traffic). In another hand, alpine park managers confront overtourism and question how they can increase public awareness about mountain ecosystem vulnerability. The threat. The presence of emerging pollutants in these remote areas, bring by practioners and their equipment, represents a challenge for both social sciences and environmental sciences
This study questions the historical and social constitution of emerging pollutants (microplastics, PFASs) as objects of scientific research in the Alps, i.e., how they have been put on the agenda of environmental sciences, or not, and how in return research contribute to specifying their presences. At the crossroads of sociology of science and sociology of the environment, this research focuses on the circulations and presence modes of these pollutants within mountainous areas. It aims to identify the knowledge produced and the scientific practices used to study these pollutants described as persistent in the context of climate transition.
Based on a survey combining bibliographic research, sociological interviews and ethnographic fieldwork, the objective of this study is (1) to reconstruct the sociohistorical context of the scientific management of persistent pollutants, particularly in the Alpine region, and (2) to question in situ how environmental science researchers respond to the environmental and health issues represented by PFAS and microplastics.

Disclaimer/Disclosure: This study is allowed and funded by Labex ITTEM (Innovations and Territorial Transitions in Mountain Regions)

2.12.P-We164 Two-Year Study of Microplastic Contamination and Ecological Risks in Fish Species of an Alpine Lake (Cesana Torinese, Northwest Italy)
***Camilla Mossotto**[1], Alice Gabetti[2], Alessandra Maganza[1], Giuseppe Esposito[2], Serena Anselmi[3], Tecla Bentivoglio[3], Monia Renzi[4], Marino Prearo[2] and Paolo Pastorino[2], (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua); Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (2)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy, (3)Bioscience Research Center srl, Italy, (4)Department of Life Sciences, University of Trieste, Italy*
Despite their remote location, alpine lakes are highly vulnerable to environmental changes and pollution. These lakes are increasingly affected by various anthropogenic stressors, and contaminants such as microplastics (MPs) that can be transported through atmospheric deposition, runoff, and human activities. Alpine lakes are typically fishless due to their isolated locations and extreme conditions, though fish have occasionally been introduced for recreational fishing. Using Lake Nero in Cesana Torinese, Italy, as a case study, a two-year research project aimed to assess the prevalence, distribution, and potential ecological risks of MP contamination in fish species. This study explores the impacts of anthropogenic pollutants like MPs, even in remote alpine lakes with minimal human presence, but where activities such as recreational fishing occur.
Fish were sampled in the summers of 2023 and 2024 to assess MP contamination in their gastrointestinal tracts. MPs were analyzed for size, color, frequency, and polymer type using Fourier-transform infrared (FT-IR) spectroscopy, and comparisons were made between the two years. In 2023, MPs were predominantly found in Salmo trutta. Polymers such as polypropylene (PP), polyethylene terephthalate (PET), and polyethylene (PE) were identified, suggesting an origin from common consumer goods or degraded plastics in the environment. In 2024, sampling expanded to include Salvelinus fontinalis, which was absent in 2023, providing a broader assessment of MP variability in the lake.
The results suggest that MP contamination could pose ecological risks, including bioaccumulation in the food web and potential physical or chemical effects on aquatic species. A risk assessment conducted as part of the study emphasized the importance of monitoring MPs as emerging contaminants, even in remote ecosystems. This research highlights the need for conservation and mitigation strategies to protect alpine lakes and their fragile ecosystems.

2.12.P-We165 Ecotoxicological Effects of Potassium Chloride on *Daphnia middendorffiana* From Alpine Lake Under Warming Scenarios
***Camilla Mossotto**[1], Serena Anselmi[2], Monia Renzi[3], Francesca Provenza[2], Elisabetta Pizzul[3], Antonia Concetta Elia[4], Damia Barcelo[5], Elena Bozzetta[6], Marino Prearo[7] and Paolo Pastorino[7], (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of*

Aquatic environments (BioAqua); Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (2)Bioscience Research Center srl, Italy, (3)Department of Life Sciences, University of Trieste, Italy, (4)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (5)Chemistry and Physics Department, University of Almeria, Spain, (6)The Veterinary Medical Research Institute for Piedmont, Italy, (7)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy
Climate change directly affects aquatic ecosystems by increasing water temperatures, which can lead to shifts in the distribution and range of aquatic species. Impacts will affect all biomes, with alpine environments being particularly vulnerable. This study investigates the combined effects of temperature increase and potassium chloride (KCl) exposure on *Daphnia middendorffiana*, an endemic species from high-mountain lakes, compared to *Daphnia magna* as a model organism.
Zooplancton sampling was carried out in the Upper Balma Lake (Northern Italy) for the research of *D. middendorffiana* while *D. magna* was obtained from MicroBioTest Inc. Specimens were exposed to varying concentrations of KCl for 24 and 48 hours at two temperatures: 15°C (lake temperature) and 20°C (simulating a warming scenario). Immobilization was measured as the endpoint to assess the ecotoxicological effects of KCl under different thermal conditions.
The results showed that both species showed a significant negative response to KCl exposure, with complete immobilization observed at higher concentrations. The synergistic effect of temperature on toxicity was evident in *D. middendorffiana*, as the EC values (effective concentrations) were consistently lower at 20°C, suggesting that warmer temperatures reduce the tolerance to KCl. These results are consistent with the hypothesis that temperature increases can exacerbate the toxic effects of pollutants, potentially disrupting the trophic dynamics of high-altitude lakes. Both daphnid species showed an enhanced effect with the co-exposure to a non-optimal water temperature (20 °C for *D. middendorffiana* and 15 °C for *D. magna*).
The study highlights the importance of considering both climate change and chemical pollution when assessing the risk of alpine ecosystems.

2.12.P-We166 Effects of Water Chemistry and Contaminants on Antioxidant Responses in *Cottus gobio* from a High-Mountain Lake
Alessandra Maganza[1]*, Marco Bertoli*[2]*, Barbara Caldaroni*[3]*, Roberta Giugliano*[4]*, Maria Cesarina Abete*[4]*, Monia Renzi*[2]*, Giuseppe Esposito*[5]*, Elisabetta Pizzul*[2]*, Damia Barcelo*[6]*, Antonia Concetta Elia*[3]*, Marino Prearo*[5] *and Paolo Pastorino*[5]*, (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua); Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (2)Department of Life Sciences, University of Trieste, Italy, (3)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (4)The Veterinary Medical Research Institute for Piedmont, Italy, (5)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy, (6)Chemistry and Physics Department, University of Almeria, Spain*
Oxidative stress is a critical factor in fish ecology, influenced by both internal and external factors like metabolic processes, pollutants, and fluctuations in water conditions. High-altitude lakes, with their unique environmental conditions, can increase oxidative stress in fish due to low temperatures, high UV radiation, and nutrient scarcity. Monitoring oxidative stress markers in fish from these lakes provides valuable insights into their health and adaptation to extreme environments.
Dimon Lake, located at 1,857 meters in the Carnic Alps of northeastern Italy, is a glacial lake that hosts *Cottus gobio* as the only fish species. In 2021, thirty fish were sampled in both summer and autumn. Water quality was assessed, measuring temperature, dissolved oxygen, conductivity, pH, and concentrations of ammonia, nitrate, and phosphate. Additionally, fish muscle tissue was analysed for trace elements (As, Cd, Pb, Zn), PAHs, non-dioxin-like PCBs (NDL-PCBs), and pesticides. Microplastics were also examined in the fish gastrointestinal tracts. Oxidative stress biomarkers, including superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione S-transferase (GST), glutathione reductase (GR), and metallothioneins (MTs), were evaluated in liver, gill, and muscle tissues. Significant seasonal variations were observed in water parameters. In summer, oxygen, pH, conductivity, and phosphate levels were lower compared to autumn, while temperature, ammonium, and nitrate concentrations were higher in the warmer months. In fish muscle, metal concentrations were notably higher in autumn. PAHs, NDL-PCBs, and pesticides were below detection limits, and no microplastics were found. Biomarkers of oxidative stress revealed organ-specific and seasonal patterns. The liver exhibited the highest activities of different biomarkers, emphasizing its central role in detoxification. A significant correlation was found between pH and the activities of SOD, CAT, GPx, GR, and MTs, suggesting that water chemistry strongly influences oxidative stress responses. Elevated MT levels in autumn suggested increased exposure to metals or other environmental stressors, such as pH fluctuations.

This study highlights seasonal changes in water quality, contaminants, and oxidative stress in a high-mountain lake. Long-term research is needed to assess the impacts of climate change on these sensitive ecosystems and inform conservation strategies to ensure their resilience.

Disclaimer/Disclosure: This study was funded by ALPA III Project (23D02).

2.12.P-We167 Comparison of Pollution in High Mountain Aquatic Ecosystems - Glacial Tarns and Alpine Stream and Effects of Flash Flood Using Alpine Bullhead as an Indicator
***Martin Janiga**[1], Marian Janiga[1] and **Zuzana Kompisova Ballova**[2], (1)Institute of High Mountain Biology, University of Žilina, Slovakia, (2)Institute of High Mountain Biology, University of Žilina, Slovakia*
The alpine bullhead (Cottus poecilopus) is representative of the ichthyofauna of high mountain stream and lake ecosystems in the Western Carpathians. This study aimed to investigate the spatio-temporal distribution and transport of mercury, zinc, molybdenum, rubidium, and strontium from alpine lake to alpine stream ecosystems and to compare elemental concentrations among populations of alpine bullhead in alpine tarns and mountain stream. Elemental analysis was performed on collected dead fish found in three tarns in the West Tatras (n = 15) and the Javorinka stream (n = 51) from 2017 to 2022. After all manual and instrumental measurements, the alpine bullheads were stored in freezers to preserve the biological material for the future. was used for fast and accurate measurement of element concentrations in fish bodies. Mercury was measured using a DMA-80 direct mercury analyzer (Milestone, Italy) for total mercury in dry weight. Concentrations of mercury and zinc in fish from the lake were found to be 6 and 2.5 times higher, respectively, than in fish from the stream. Rubidium, molybdenum, and strontium concentrations did not differ between lacustrine and fluvial fish, suggesting that their sedimentation patterns are similar in rivers and lakes. In July 2018, a major flood occurred in the area of the Javorinka stream. This year, the mercury content in alpine bullheads in the Javorinka stream increased significantly. Biomagnification of mercury in fish occurred very quickly after the flood and was significant also in the following year, 2019. Subsequently, there was a notable decline in mercury concentrations, reaching a reduction of up to 70% between 2021 and 2022. As this research continues over the next years, changes in other biogenic elements between the tarns and the stream may become apparent due to climate change, and because the tarns are more isolated ecosystems by the mountains. This may make the high mountain tarns even more unsustainable for any life in the future than they are now.

Disclaimer/Disclosure: This research was supported by Institute of High Mountain Biology, University of Žilina.

2.12.P-We168 Seasonal Dynamics and Biota's Role in Elemental Transfer and in the Javorinka Mountain Stream Ecosystem
***Patrik Panik** and Martina Haas, Institute of High Mountain Biology, University of Žilina, Slovakia*
The impacts of climate change are causing significant changes in aquatic biogeochemical processes and, through changes in the distribution and levels of elements, may alter the dynamics and quality of aquatic habitat biodiversity. Seasonal dynamics of elements are influenced by local environmental factors, seasonal influences and short-term events (droughts, floods). Assessing the connectivity and importance of elemental transfer through the food chain with respect to seasonality will allow for a more comprehensive assessment of water quality over time, helping to evaluate both current and potential constraints. Elements enter the cycle from basic natural sources and are taken up and transferred by organisms.
This study summarises the current knowledge on the accumulation of elements in individual food chain components (algae, macrozoobetos, fish) in the Javorinka mountain stream (High Tatras, Western Carpathians) through long-term monitoring (2019-2023) and analysis of elements in tissues using X-ray fluorescence spectroscopy (ED-XRF). In this study, we focused on the transfer of elements (S, Cl, K, Cr, Zn, Fe and Mn) in food chain components in cyanobacteria (Oscillatoriales), insect orders (Ephemeroptera, Plecoptera) and fish (Cottus poecilopus). We found that the highest levels of elements shifted between groups from lower to higher trophic chain levels mainly in the following seasons. The highest values of the elements S, Cl, K were recorded in cyanobacteria in spring, in invertebrate larvae in summer and in fish in winter. The elements Cr and Mn are highest in both cyanobacteria and insect larvae in autumn, and in fish in winter. Fe is highest in Oscillatoriales in autumn, in insect larvae in autumn and winter, and in fish only in spring. Zn is highest in Oscillatoriales in summer, but only in insect larvae and fish in winter. The uptake of elements by biota depends on their availability in the environment. Their excretion and transport is mainly influenced by dietary and metabolic patterns during ontogeny and biomagnification.
Mountain streams also play an important role in transporting sediment and nutrients to lower areas and are

a source of drinking water. Long-term studies of elemental dynamics in stream biota are important not only for understanding the processes occurring in streams, but also for assessing the impacts of climate change, such as flash floods, prolonged droughts or other extreme events that alter elemental cycling and levels.

Disclaimer/Disclosure: No grant funding was used for the research.

2.12.P-We169 Indication of Environmental Pollution by Mercury and Other Elements Using Equivalent Alpine and Subalpine Mammals from the Western Carpathians and the Zhongar Alatau

Lenka Zábojníková, *Zuzana Kompisova Ballova, Martina Haas and Marian Janiga, Institute of High Mountain Biology, University of Žilina, Slovakia*

Heavy metals and other potentially toxic elements accumulate in remote mountain areas through atmospheric transport. Previous studies have identified the Western Carpathians as one of the most heavily polluted mountain ranges. For comparison, we chose the Zhongar-Alatau mountain range in Central Asia, where pollution from the surrounding industrialised countries is also thought to be high. As herbivorous species are considered to be one of the best indicators of heavy metal pollution from the air, we decided to use samples from herbivorous mammals living in the alpine and subalpine areas of the Western Carpathians and the Zhongar Alatau. We collected non-invasive samples of marmot faeces and bones of naturally deceased ungulates. Marmots (Marmota marmota latirostris) and Tatra chamois (Rupicapra rupicapra tatrica) are symbols of Tatra National Park in the Western Carpathians, they are iconic species with high conservation value. For comparison, we chose ecological equivalents of these species from Zhongar Alatau (Marmota baibacina, Asiatic ibex, Marco Polo sheep, other Bovidae and horses). The samples were collected in autumn (September October) 2022. The faecal samples were analysed by X-ray fluorescence for detection of S, Ba, Mn, Mo, Zn, Cu, and Cr. Mercury concentrations in faeces and bones were determined using a DMA-80 analyzer. We found that marmot faeces from the Western Carpathians contained significantly more amount of total mercury ($p < 0.001$; mean = 0.066 μg/g dry weight) than marmot faeces from Zhongar Alatau (mean = 0.034 μg/g dry weight), as well as sulphur and selected heavy metals (Ba, Mn, Mo, Zn, Cu, and Cr). Bones of ungulates found in Zhongar Alatau had significantly lower levels of total mercury ($p < 0.05$; mean = 0.0024 μg/g dry weight) than bones found in the Western Carpathians (mean = 0.0063 μg/g dry weight). The Western Carpathians are relatively more polluted by mercury, sulphur and heavy metals (Ba, Mn, Mo, Zn, Cu, and Cr) from anthropogenic activities than the Zhongar Alatau Mountains. The most likely sources of pollution are the continuing industrialisation of north-western Europe, mining and smelting, and traffic emissions, which can reach remote mountain ranges through long-range atmospheric transport by the westerly winds that prevail in this region.

2.12.P-We170 Impact of Flash Floods on Physicochemical Dynamics in Alpine Streams: Insights from Long-Term Monitoring in the Tatra Mountains

Jaroslav Solar *and Tatiana Pitonakova, Institute of High Mountain Biology University of Žilina, Slovakia*

Physicochemical changes of water in alpine/mountain streams can provide useful information on ongoing natural and anthropogenic processes in their catchments. Periodical monitoring of these changes can determine the extent of seasonal variations or define repeating patterns (cycles) and mutual interactions. Particularly important in the context of ongoing climate change is observing the development of conditions following extreme or accidental events that can significantly affect dynamic trends in these vulnerable aquatic ecosystems.

Over five years of continual (weekly) monitoring of physicochemical conditions in the alpine/mountain stream Javorinka in the Tatra Mountains, we recorded one major flash flood (July 2018), which not only significantly altered the stream morphology but also affected the trajectories of organic and inorganic compounds. For example, we observed a significant decrease in the chemical consumption of oxygen and ammonia after the flood, alongside an increase in oxygen saturation and nitrate concentrations. Streambed erosion caused elevated phosphate levels over the subsequent two years and a marked enrichment of the water with dissolved solids during the following spring seasons.

We hypothesize that, from a long-term perspective, such flash floods are critical in sustaining the oligotrophic profile of alpine and mountain streams. To test this hypothesis, our main objective is to continue monitoring and compare the seasonal trends of key physicochemical parameters in the stream before and after such events. Based on paleohydrological studies, flash floods in the Tatra Mountains are

recurring natural phenomena, typically occurring every 6 9 years, and are expected to increase in frequency and severity due to climate change. Observing future flash floods will reveal whether these events continue to reinforce the regular patterns and interactions that maintain the oligotrophic characteristics of these ecosystems.
The impact of flash floods on the physicochemical dynamics of alpine streams is poorly understood. Understanding these effects is crucial for predicting long-term changes and provides insights into the resilience and dynamics of vulnerable mountain aquatic ecosystems.

Track 3. Environmental Chemistry and Exposure Assessment: Analysis, Monitoring, Fate and Modelling

3.01 Innovative Analytical Methodologies to Support Next-Generation Risk Assessment and Early Warning

3.01.T-01 Innovative Suspect and Non-Targeted Screening Approaches as a Support to Chemical Risk Assessment: From Research Results and Promises to Regulatory Expectations

Jean-Philippe Antignac[1]*, Solene Motteau*[1]*, Tarek Moufawad*[1]*, Bruno Le Bizec*[1] *and Marja Lamoree*[2]*, (1)Oniris, INRAE, LABERCA, France, (2)Vrije Universiteit, Amsterdam Institute for Life & Environment, Netherlands*

Our environment is a vector of exposure to thousands of chemicals, some of which may be harmful for ecosystems and humans. This complexity of real-life chemical exposure is a major challenge for the scientific community and public health authorities. Suspect and non-targeted screening approaches (SS/NTS) have emerged to expand our knowledge on this environmental and human chemical exposure. These approaches have been a matter of various research based proof-of-concepts in the environment, food and human biomonitoring fields, illustrating their potential and generating high expectations for support to policy purposes. This last application area is however associated to a number of challenges requiring to clarify what could be and could not be expected from these approaches. This work aims at presenting a number of applications of SS/NTS to environmental and human sample specimen, based on results originated from research program conducted at EU level. Based on these illustrating examples, a clarification regarding their positioning for risk assessment is given.

In the Human Biomonitoring for Europe initiative (HBM4EU, H2020, 2017-2022), a number of methodological development and harmonisation actions were conducted with regard to SS/NTS approaches applied to human samples. A summary of the elaborated QAQC provisions for data generation and result reporting will be given. The results of a wide multicentric study (SPECIMEn) consisting to analyse 2000 human urine samples collected in 5 different EU countries by 5 different EU laboratories thanks to a SS approach under harmonized conditions will be then presented.

In the Partnership for the Assessment of Risks from Chemicals (PARC, Horizon EU, 2022-2029), the methodological improvement and harmonization objective regarding SS/NTS approaches is pursued in a more integrated perspective across the environment-food safety-human biomonitoring silos. A summary of the established worklines for harmonisation will be given, as well as first results of real sample analyses.

In the project Providing risk assessments of complex real-life mixtures for the protection of Europe s citizens and the environment (PANORAMIX, H2020 Green Deal, 2021-2025), a SS profiling approach was applied to reveal, compare and connect real-life chemical mixtures present within an environmental-food-human continuum. The applied analytical strategy from sample preparation to data analysis, as well as main results obtained will be described.

Disclaimer/Disclosure: The authors thank the co-funding support and coordination teams of the cited EU research projects HBM4EU (Grant nb. 733032, M. Kollossa, UBA, DE), PARC (Grant nb. 101057014, P. Sanders, ANSES, FR) and PANORAMIX (Grant nb. 101036631, AM Vinggaard, DTU, DK).

3.01.T-02 Utilities of Long-Term Chemical Pollution Monitoring Data of Surface Waters in the Netherlands

Thomas Hofman[1]*, Leo Posthuma*[1]*, Matthias Hof*[1]*, Jaap Postma*[2]*, Jaap Slootweg*[1] *and Rineke Keijzers*[2]*, (1)RIVM, Netherlands, (2)Ecofide, Netherlands*

Chemical pollution is considered as one of three planetary crises. Long-term chemical pollution monitoring data for an area provide information to characterize spatial patterns and temporal trends, and to define regulatory measures to prevent and limit the pollution. Such data are however commonly dispersed over various sources and difficult to obtain and use in practice. This research aimed to collate spatio-temporal monitoring data, to support developing or validating novel risk characterisation models and mitigation approaches.

This research collated data on chemical pollutants in Dutch surface waters covering the whole country in a 68-year time period till 2020 measuring 1712 parameters. Data were harmonized to provide a resource for scientific research and practical purposes in characterization, prevention and mitigation of chemical pollution of surface waters.The collated data set contains a total of 42.5 million spatiotemporal measured water quality parameters, representing the most dense water quality set of Europe, available for the evaluation of the water quality goals of the Water Framework Directive in 2027, the development of

exposure models, and developing risk assessment and mitigation approaches.
The harmonization of the data collated by different waterboards, while crucial for spatiotemporal district comparison, highlighted the need for more integrated approach. Differences in units, measurement techniques and the decimals/accuracy reported between waterboards and over, lower the quality of an otherwise very rich dataset. Nevertheless, the dataset allows for the analysis and characterzation of both spatial and temporal trends. The dataset has been use to show mixture toxic pressure has high spatial variability. Moreover, the management efforts that were taken to lower the level of imidacloprid in an area have been effective in lowering the concentration over time, as is shown by the data.
This research shows that collated monitoring results are a rich source to support risk assessment and management of pollutants. The concentration data are useful to develop and improve region-specific exposure models, able to prevent cumulation of risk beyond the no-effect level. Moreover, the dataset may be combined with hazard data, to derive spatial and temporal patterns in impacts of chemical pollution on aquatic life. These approaches together are supportive of next generation risk assessment methods, and could result in an early-warning approach.

3.01.T-03 In Vitro Bioassay Profiling of Endocrine Activities in European Surface Waters: A Large-Scale Pilot Project

***Elise Chatillon**[1], Abd-El-Rahman El-Mais[1], Sebastian Buchinger[2], Meike Hahn[2], Beate Escher[3], Anna Bialk-Bielinska[4], Tina Kosjek[5], Azziz Assoumani[1], Valeria Dulio[6], Nina Huynh[1], Kerstin Putz[7], Gunnar Thorsen[7], Katrin Vorkamp[8], Patrick Balaguer[9] and Selim Ait-Aissa[1], (1)INERIS, France, (2)BfG (German Federal Institute of Hydrology), Germany, (3)UFZ, Germany, (4)UG-PL, Poland, (5)JSI, Slovenia, (6)Ineris, France, (7)Swedish Environmental Research Institute (IVL), Sweden, (8)Department of Environmental Science, Aarhus University, Denmark, (9)INSERM, France*

Endocrine-disrupting compounds (EDCs) are structurally diverse chemicals from various sources that can harm the environment and human health. Monitoring EDCs with chemical methods remains challenging due to the vast number of potential compounds to be assessed at low concentrations in complex environmental matrices. Effect-based monitoring using in vitro bioassays has been proven as a relevant tool to reveal the presence of EDCs in a sample, but without identifying the responsible compounds. Thus, combining bioassays with chemical analysis offers a promising approach for the detection and identification of EDCs, with a view to tracing their sources, and understanding their biological effects. Within the Horizon Europe Partnership for the Assessment of Risks from Chemicals (PARC), monitoring strategies integrating both chemical and effect-based methods have been developed to characterize EDCs in air, soil, surface water, and biota. This presentation will focus on effect-based assessment of EDCs in European surface waters using a comprehensive panel of in vitro bioassays.
Sampling campaigns were conducted in 2024 by collaborative efforts of multiple laboratories, covering different regions in Europe and types of anthropogenic pressures (industrial and agricultural regions, urban run-off, and waters receiving effluents from wastewater treatment plants). A total of 117 water samples were collected and processed following standardized extraction procedures. The organic extracts were then subjected to in vitro receptor-based bioassays targeting 10 human nuclear receptors (AR, ER, GR, MR, PR, AhR, PXR, PPAR, RAR/RXR) and the thyroid hormone binding protein TTR. In addition, for some modes of action with cross-species differences, both human and zebrafish receptors were employed to reveal possible effects specific to aquatic vertebrates. Furthermore, quality assurance and controls were defined and implemented for sampling, sample preparation, and bioassays.
Bioactivity profiles observed in the water samples will be presented and discussed in terms of the type of endocrine receptor activated and site typology. Potential differences between human and zebrafish bioassay responses will be reported and discussed regarding an EDC monitoring strategy. In the future, bioassay results will be compared with target chemical analyses to assess the contribution of prioritized EDCs to the observed bioactivity.

Disclaimer/Disclosure: This work was carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union s Horizon Europe research and innovation programme under Grant Agreement No 101057014. 3.01.T-04 Integration of Dysregulation Measures in Behavior and Exo-Metabolic Profile for Biological Early Warning System Using *Daphnia magna*

***Hyeon-Jeong Bae**[1], Byeong Cheol Kim[2] and Tae-Young Jeong[1], (1)Hankuk University of Foreign Studies, Republic of Korea, (2)Korea Institute for Water Technology Certification, Republic of Korea*

Biological early warning systems (BEWSs) utilize organismal responses to pollutants for continuous water quality monitoring and detection of a wide range of toxic substances. *Daphnia magna* alters its swimming behavior in response to chemical or environmental stress, making it a valuable bioindicator. However, the reliability of Daphnia-based BEWS is often challenged by false alarms due to non-specific behavioral responses. Beyond behavioral monitoring, recent research explores metabolomics to provide a complementary perspective in water quality assessment. This study aims to enhance BEWS by integrating behavioral responses of *D. magna* with exo-metabolome analysis. Using high-throughput video tracking and liquid chromatography quadrupole time-of-flight mass spectrometry (LC-QTOF-MS), a time-course analysis was conducted to examine locomotion and metabolic regulation under various exposure conditions.

Among 1,228 metabolic features, 841 features were significantly increased in the group containing *D. magna* compared to the control group containing only river water (false discovery rate (FDR) adjusted $p < 0.05$). Of these, 487 features displayed significant differences across pre-exposure (Pre), exposure (Exp), and post-exposure (Post) conditions ($p < 0.05$). Metabolic features exhibiting continuous increases or decreases across Pre, Exp, and Post groups were identified as potential markers for chemical exposure. During copper exposure, metabolic features correlated with copper concentration were observed. Among the 487 significant features, 28 showed a decreasing trend, and 3 exhibited an increasing trend ($p < 0.05$). In this study, annotation was not possible due to the lack of an exo-metabolome database and derivatization, and the functions of the detected features could not be confirmed. In behavioral analysis, we expect that the average swimming speed, swimming angle, and dispersion of *D. magna* will alter more rapidly at higher copper concentrations.

This study demonstrates the potential of integrating exo-metabolomic data with traditional behavioral monitoring in *D. magna*-based BEWS. Future research will focus on validating the reproducibility of these findings in diverse river waters with varying physicochemical properties. This integrated approach offers a promising avenue for advancing BEWS, ensuring more accurate and timely detection of water quality changes while reducing false alarms.

Disclaimer/Disclosure: This research was supported by the cooperation project 2024 Precision Drug Induced Liver Injury (DILI) prediction model based on Artificial Intelligence funded by Korea Institute of Toxicology (KIT) and National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) [2021R1C1C1006155] .

3.01.P-Tu197 A New Systems Approach Addressing Chemical Risks to Terrestrial Biodiversity in Europe

Guy Duke[1]*, Nikiforos Alygizakis*[1]*, Paola Movalli*[2]*, Susan Oginah*[3]*, Gabriele Treu*[4]*, Nikolaos S. Thomaidis*[5]*, Marissa B Kosnik*[6]*, Martina G. Vijver*[7]*, Henrik Barmentlo*[7]*, Koos Biesmeijer*[2]*, Peter Fantke*[1]*, Georgios Gkotsis*[5]*, Romana Hornek-Gausterer*[8]*, Olivier Jolliet*[3]*, Oliver Machate*[4]*, Peter Oswald*[1]*, Laura Scherer*[7] *and Jaroslav Slobodnik*[1]*, (1)Environmental Institute, Slovakia, (2)Naturalis Biodiversity Center, Netherlands, (3)Technical University of Denmark, Denmark, (4)German Environment Agency (UBA), Germany, (5)National and Kapodistrian University of Athens, Greece, (6)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (7)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (8)Environment Agency Austria, Austria*

Anthropogenic chemicals (with other novel entities) have passed the safe operating space of the planetary boundary, since annual production and releases outstrip global capacity for risk assessment and environmental monitoring. In Europe, the number of chemicals in use far exceeds capacities of conventional risk assessment and monitoring, chemical registration data is often inadequate and risk assessment does not sufficiently consider damages to biodiversity and ecosystem services, in particular in the terrestrial compartment. To address these challenges, we propose a new systems approach, which can support regulators in accelerating delivery of the European Union s zero pollution ambition in the terrestrial compartment. This approach is being developed and tested by the Horizon Europe project TerraChem. The systems approach integrates four key elements: (1) periodic pan-European monitoring of chemicals exposure and mixture effects in selected apex species food chains across representative terrestrial biomes; (2) modelling of chemical source-to-damage pathways in terrestrial ecosystems; (3) novel tools to prioritise substances for further risk assessment and novel approaches to better address terrestrial biodiversity and ecosystem services in environmental risk assessment and risk management of chemicals; (4) a European data management and early warning system for chemicals in terrestrial biota and soils that integrates the monitoring data, modelling output and prioritisation tools. This TerraChem approach would provide a near real-time picture of which substances among the entire universe of ERACs are turning up in terrestrial biota and soils across Europe, provide early warning of emerging contaminants, prioritise substances for further risk assessment and risk management measures, and enable risk assessment and management to better take account of damages to terrestrial biodiversity and ecosystem services. TerraChem will test this systems approach, deliver a blueprint for a robust, coherent, pan-European monitoring-modelling-prioritisation-risk assessment and management scheme for chemicals in the terrestrial compartment, and identify next steps to put such a scheme in place. This platform presentation will present interim findings at the project s midway point.

Neither the European Union nor the granting authority can be held responsible for them.

3.01.P-Tu208 Increased (S)VOC Identification in Complex Samples Using a Dual-Ionization EI&CI-TOFMS Hyphenated with a Flow Modulated GCxGC System

*Sonja Klee[1], Steffen Braekling[1], **Eliška Ceznerová**[1], Marleen Vetter[1], Ralf Kurtenbach[2], Scott J. Campbell[3], John Moncur[3] and Arnd Ingendoh[4], (1)TOFWERK AG, Switzerland, (2)University of Wuppertal, Germany, (3)SpectralWorks, United Kingdom, (4)Bruker Daltonics GmbH & Co KG, Germany*

Hyphenation to GCxGC sets high requirements to a mass spectrometric detector. Narrow chromatographic peak widths require high mass spectral acquisition rates that are commonly achievable by EI-TOF instrumentation. Flow modulation GCxGC simplifies the experimental setup but also increases the demands to the MS due to enlarged column flows, resulting in high split ratios preceding the detector. However, when measuring complex samples or unknowns compounds an additional soft ionization technique, such as CI improves the compound identification process. For one dimensional GC the combination of EI and CI operating simultaneously on one analyzer within one single chromatographic run has been presented previously. In this study we show the combability and advantages of a fast-switching EI&CI-TOFMS coupled to flow modulation GCxGC.

Ambient air and a standard gas mixture were collected on desorption-tubes. The collected samples were desorbed, preconcentrated and injected into the GCxGC system including a flow-modulation setup. A standard GCxGC-method was provided by the collaborator. The EI&CI-TOFMS operating CI- and EI was used as detector to provide simultaneous molecular (CI) and structural (EI) information.

The hyphenation of a dual ionization EI&CI-TOFMS with a flow modulated GCxGC setup is presented. Special focus is set on: (1) characterization of the alignment of simultaneously generated EI and CI information; (2) the EI/CI switching behavior of the MS; (3) the chromatographic performance of the ionization sources; and (4) the advantages of using flow modulation GCxGC in combination with medium pressure CI sources. The complexity of the GCxGC-dual ionization MS coupling is addressed and experiments with the aim to harness the high gas flows used in flow modulation GCxGC were conducted. It can be shown that the high pumping efficiency in the CI interface can be utilized to increase the CI sensitivity by a factor of 30, by guiding the larger share of the flow ratio into the CI source. Using a specifically defined flow splitting, it was possible to maintain the flow balance within the EI pumping stage and simultaneously increase the CI performance leading to increased identification certainties as well as decreased limits of detection (LOD). The findings on the instrumental performance investigated via standard gas mixture measurements were further verified on ambient air samples collected at a federal highway in Germany.

Disclaimer/Disclosure: This presentation is part of a Transnational access project that is supported by the European Commission under the Horizon 2020 Research and Innovation Framework Program, H2020-INFRAIA-2020-1, ATMO-ACCESS Grant Agreement number 101008004.

3.01.P-Tu214 Comprehensive Pesticide Screening with Dual Ionization GC-HRMS: Bridging Targeted and Non-Targeted Analysis

***Eliška Ceznerová**[1], Sonja Klee[1], Steffen Brakling[1], Arnd Ingendoh[2], Claudio Cruzer[3] and Andreas Schurmann[3], (1)TOFWERK AG, Switzerland, (2)Bruker Daltonics GmbH & Co KG, Germany, (3)Kantonales Labor Zurich, Switzerland*

The detection and quantification of pesticide residues and contaminants in agricultural products are critical for ensuring food safety and compliance with global regulations. The growing demand for these requirements, driven by consumer awareness and stringent regulations, increases the demands on analytical screening. Chromatographic techniques coupled to high-resolution mass spectrometry (HRMS)

are becoming a most reliable analytical platforms for pesticides analysis, mainly due to their comprehensive detection, and identification of both, known and unknown residues with high sensitivity and specificity. Here, we present a new non-targeted analysis approach of volatile pesticide residues in food matrices. For unambiguous compound identification a novel gas chromatography (GC)-HRMS system generating simultaneously EI and CI information on the detected analytes was utilized.
Agricultural products were extracted using QuEChERS protocols and analyzed with a GC 8500 system (Bruker, Germany) coupled to an ecTOF detector (Bruker, Germany). The system's dual ionization capability, combining electron ionization (EI) and chemical ionization (CI) simultaneously, provides complementary structural and molecular data. CI reagent ions (N2H+, H3O+, NH4+) were used to adjust fragmentation and enhance molecular detection. A targeted library of 213 pesticides was created for targeted analysis. Data post-processing for targeted, suspect and non-targeted approaches were carried out with AnalyzerPro XD (Spectralworks, UK).
The GC-HRMS system effectively identified pesticide residues with certainties above 70% for both EI and CI traces using the created targeted library. Non-targeted analysis detected additional compounds that were analyzed using NIST library searches and accurate mass data. Added CI information improved sensitivity and enabled residue detection at low ppb levels. The dual-ionization approach enhanced compound identification certainties, reduced analysis time, and increased reliability for complex samples.
The integration of EI and CI in a single GC-HRMS workflow enhances certainties and reliability for both targeted and non-targeted pesticide residue analysis. The system shows to be a highly efficient tool for ensuring food safety and regulatory compliance, offering robust solutions for identifying pesticides in complex agricultural products.

3.01.P Innovative Analytical Methodologies to Support Next-Generation Risk Assessment and Early Warning

3.01.P-Tu196 Safe and Sustainable by Design Framework for the Next Generation of Wood Plastic Composites for Automotive Industry

Ivana Burzic[1], Claudia Pretschuh[1], Martin Lindemann[1], Hariprasad Alwe[2], ***Maria Molnar[3]*** *and Andrea Pipino[4], (1)Austria, (2)Switzerland, (3)Wood K plus - Kompetenzzentrum Holz GmbH, Austria, (4)Italy*
In recent years, the design and development of materials with advanced properties and reduced environmental impact has become a priority in different industry sectors. Achieving these objectives requires a holistic approach that integrates different advanced models addressing the materials and chemicals safety following the Safe and Sustainable by Design (SSbD) principles. This poster presentation shows how SSbD principles for safe and sustainable design can be applied to the use case of novel Wood Plastic Composites, which are developed as interior material for the automotive industry. Increased safety through reduced emissions of Volatile Organic Compounds (VOCs), reduced environmental impact and improved circularity of the developed materials are points addressed. On the one hand, it focuses on the development of renewable composites formulations with sufficient mechanical performance, considering thereby recycled polypropylene or polypropylene made from renewable resources as thermoplastic matrix in combination with micro-fibrillated cellulose and wooden fibers as a green alternative for lightweight materials to reduce dependence on oil-based materials and conflict mineral fillers and to increase material circularity. Since the addressed interior trims in the car interact with passengers in a relatively close environment, it is important to ensure that they are not a risk to human safety and health. Thus, novel composite materials based on either renewable and/or recycled plastic reinforced with cellulose and wood-based fillers will be investigated, covering emissions and hazard assessments to enable safe use of such materials from the early R&D phase without any impact on passengers. This work will also present the method development for rapid VOC screening by coupling of micro and emission test chambers with Proton-Transfer-Reaction Time-of-Flight Mass Spectrometry (VOCUS CI-TOF PTR/AIM) to analyze novel Wood Plastic Composites (WPCs).

Disclaimer/Disclosure: SSbD4CheM project has received funding from the European Union s Horizon Europe research and innovation programme under grant agreement number 101138475. UK participants in SSbD4CheM project are supported by UKRI. CH participants in SSbD4CheM project receive funding from SERI.

3.01.P-Tu197 A New Systems Approach Addressing Chemical Risks to Terrestrial Biodiversity in Europe

Guy Duke[1], *Nikiforos Alygizakis[1], Paola Movalli[2], Susan Oginah[3], Gabriele Treu[4], Nikolaos S. Thomaidis[5], Marissa B Kosnik[6], Martina G. Vijver[7], Henrik Barmentlo[7], Koos Biesmeijer[2], Peter Fantke[1],*

Anthropogenic chemicals (with other novel entities) have passed the safe operating space of the planetary boundary, since annual production and releases outstrip global capacity for risk assessment and environmental monitoring. In Europe, the number of chemicals in use far exceeds capacities of conventional risk assessment and monitoring, chemical registration data is often inadequate and risk assessment does not sufficiently consider damages to biodiversity and ecosystem services, in particular in the terrestrial compartment. To address these challenges, we propose a new systems approach, which can support regulators in accelerating delivery of the European Union s zero pollution ambition in the terrestrial compartment. This approach is being developed and tested by the Horizon Europe project TerraChem. The systems approach integrates four key elements: (1) periodic pan-European monitoring of chemicals exposure and mixture effects in selected apex species food chains across representative terrestrial biomes; (2) modelling of chemical source-to-damage pathways in terrestrial ecosystems; (3) novel tools to prioritise substances for further risk assessment and novel approaches to better address terrestrial biodiversity and ecosystem services in environmental risk assessment and risk management of chemicals; (4) a European data management and early warning system for chemicals in terrestrial biota and soils that integrates the monitoring data, modelling output and prioritisation tools. This TerraChem approach would provide a near real-time picture of which substances among the entire universe of ERACs are turning up in terrestrial biota and soils across Europe, provide early warning of emerging contaminants, prioritise substances for further risk assessment and risk management measures, and enable risk assessment and management to better take account of damages to terrestrial biodiversity and ecosystem services. TerraChem will test this systems approach, deliver a blueprint for a robust, coherent, pan-European monitoring-modelling-prioritisation-risk assessment and management scheme for chemicals in the terrestrial compartment, and identify next steps to put such a scheme in place. This platform presentation will present interim findings at the project s midway point.

3.01.P-Tu198 Integrated Solutions for Managing Contaminants of Emerging Concern: TerraChem's Approach to Data, Modeling, and Visualization in Terrestrial Ecosystems

*Nikiforos Alygizakis[1], **Guy Duke**[1], Paola Movalli[2], Susan Oginah[3], Gabriele Treu[4], Nikolaos S. Thomaidis[5], Marissa B Kosnik[6], Martina G. Vijver[7], Henrik Barmentlo[7], Koos Biesmeijer[2], Peter Fantke[1], Georgios Gkotsis[8], Romana Hornek-Gausterer[9], Olivier Jolliet[3], Oliver Machate[4], Peter Oswald[1], Laura Scherer[7] and Jaroslav Slobodnik[1], (1)Environmental Institute s.r.o., Slovakia, (2)Naturalis Biodiversity Center, Netherlands, (3)Technical University of Denmark, Denmark, (4)German Environment Agency (UBA), Germany, (5)National and Kapodistrian University of Athen, Greece, (6)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (7)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (8)National and Kapodistrian University of Athens, Greece, (9)Environment Agency Austria, Austria*
The TerraChem project addresses the pressing need for advanced monitoring and risk assessment of contaminants of emerging concern (CECs) in terrestrial ecosystems. Built on the NORMAN Database System and expanded through LIFE APEX and TerraChem innovations, the TerraChem Data Management System (TDMS) integrates tools like the Chemical Occurrence Database and the Digital Sample Freezing Platform (DSFP) to provide geo-referenced data and enable retrospective chemical screening. Following FAIR principles, TDMS connects with DiSSCo to bridge chemical and ecological data for enhanced risk evaluations. The TerraChem Early Warning System (TEWS), powered through APIs from the Chemical Occurrence Database and DSFP, and a user-friendly Dashboard translate data into actionable insights, supporting stakeholders in mitigating biodiversity loss through predictive modeling and advanced visualization tools. By identifying data gaps and providing benchmark values across Europe, TerraChem empowers decision-makers to prioritize monitoring and interventions. This integrated platform sets a new standard for chemical risk management in terrestrial ecosystems.

3.01.P-Tu199 Enhanced EASZY Assay for a Comprehensive In Vivo Endocrine Activity and Toxicity Assessment of Environmental Samples

Alizee Desrousseaux, *Benjamin Piccini, Valentin Bourges, Elise Chatillon, Abd-El-Rahman El-Mais, Nathalie Hinfray, Selim Ait-Aissa and Francois Brion, INERIS, France*

The development of specific effect-based method using in vivo bioassays to analyse complex mixtures is essential to monitor chemical pollution in the aquatic environment. Zebrafish embryo is a powerful and efficient model for such assessment due to its rapid development, transparency, and high sensitivity to a wide range of pollutants.

The standard OECD TG 250 EASZY initially designed for quantitative assessment of estrogenic activity has been enhanced by incorporating additional endpoints such as endogenous gene expression, dioxin-like activity measurements as well as developmental, sublethal and acute toxicity. This new protocol is specifically developed to maximize collection of information on in vivo impacts of environmental samples by optimising the use of embryo, while minimizing the volume of organic extracts.

Embryos are exposed in triplicate to five dilutions of organic extracts for 96 hours with daily medium renewal. Observations of developmental markers (e.g., hatching, oedema, bleeding, scoliosis) are monitored daily to assess potential developmental toxicity of environmental extracts. After 96 hours, embryos are allocated for in vivo imaging of GFP expression driven by the ER-regulated cyp19a1b gene to assess estrogenic activity, or processed for CYP1A enzyme activity measurement (EROD) to evaluate dioxin-like effects. Furthermore, embryos are preserved in RNAlater for subsequent gene expression analysis, focusing on key genes of the endocrine system such as cyp3a65 involved in intestinal metabolism regulation, cyp11c1 and fkbp5 involved in GR signalling pathways and hypothamo-pituitary interrenal axis.

The validation of this protocol, using reference molecules to assess the activity of estrogenic, dioxin-like, and glucocorticoid compounds, will be presented. The protocol will then be applied within the framework of the European PARC project to surface water samples under various anthropogenic pressures. The results will be discussed in relation to in vitro endocrine and chemical analyses performed on the same samples (see abstract by Châtillon et al. submitted for SETAC 2025).

3.01.P-Tu200 High Throughput Adaptation of Standardized Ecotoxicological Tests for the Model Freshwater Invertebrate *Daphnia magna*

Angel Daniel Ceballos Ramirez[1], *Mark Hodson*[2], *Elma Lahive*[3] *and Thomas G. Preuss*[4], *(1)University of York, York, United Kingdom, (2)University of York, United Kingdom, (3)UK Centre for Ecology and Hydrology, United Kingdom, (4)Bayer AG, Crop Science Division, United States*

Current environmental regulations require the standardized testing of chronic ecotoxicological endpoints as part of its approval processes testing, however such tests tend to be resource intensive, and new high-throughput methods are not favoured due to their lack of standardization. To address this, a high throughput experiment was designed by culturing a cohort of >200 *Daphnia magna* individuals in well plates, with the conditions specified in OECD test number 211. Five concentrations of eight chemicals with different modes of action (Polar narcosis and nAChR inhibitors) were tested over a period of 21 days, tracking growth with a spheroid counter and reproduction in the well plates. High survival was observed in controls and low concentrations for all chemicals. Despite variations in average observed size of the animals are due to their position during the scans, results show a clear dose-response effect for growth and reproduction, allowing for calculation of LOEC, NOEC and EC50. The results of this experiment demonstrate the capacity to acquire a large volume of data for chronic endpoints throughout time, while following OECD standards.

3.01.P-Tu201 Make Your Research Regulatory Relevant: How Scientists Can Contribute to Validated and Standardised Test Methods

Anna Pohl[1], *Elise Morel*[2], ***Blanca Suarez-Merino***[2], *Eric A. J. Bleeker*[3], *Sean Kelly*[4], *Rachel Smith*[5], *Claus Svendsen*[6], *Thomas Kuhlbusch*[1] *and Elisabeth Heunisch*[1], *(1)Federal Institute for Occupational Safety and Health (BAuA), Germany, (2)TEMAS Solutions GmbH, Switzerland, (3)National Institute for Public Health and the Environment (RIVM), ., Netherlands, (4)Nanotechnology Industries Association aisbl*

(NIA), Belgium, (5)UK Health Security Agency (UKHSA), United Kingdom, (6)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom
New scientific developments of methods and materials are essential contributions to approach major global challenges. The development of new materials as well as the development of new safety test methods triggers the development of harmonised standards and OECD Test Guidelines. Up-to-date test methods support innovation, reduce trade barriers and testing efforts, save resources and enable international comparison.
Despite the urgent need for regulatory relevant test methods, good science does not automatically get used in regulation. Indeed, to be integrated in regulatory oriented standards or OECD Test Guidelines, new testing methods must be validated and standardised. This involves following specific agreed processes, which define timelines and requirements. These processes are often seen as complex or time and resources consuming by the scientific community, which inhibits method developers from translating their scientific methods and protocols into standards or OECD Test Guidelines.
Numerous incentives exist for scientists to be (more) active in the standardisation process and allow regulation to keep up with new scientific developments. These include an increase in research impacts, an expansion and diversification of the international expert network, increase of citations, ideation of new research questions and access to more fundings. Our work provides guidance on how to navigate successfully through the standards and OECD Test Guidelines development process, especially including requirements for method validation, which is a common prerequisite across the different standardisation bodies. We established in the EU project NanoHarmony a freely available set of resources for scientists in the OECD Test Guideline Process Mentor (https://testguideline-development.org/).
As scientific sound test methods and data are the core of OECD Test Guidelines and standards, a scientist can contribute in various different ways. Key aspects to consider in order to be successful with the development of standards and OECD Test Guidelines are to understand the main aspects of validation studies, to be in contact with the diversity of stakeholders acting in standardisation or harmonisation and to follow the defined steps and deadlines of the development process. The active participation of scientists along the entire process towards standards and OECD Test Guidelines is key for the transfer of th e method into a wider, regulatory application and towards a safer world.

Disclaimer/Disclosure: The authors would like to thank all those who provided input in the NanoHarmony survey, interviews, workshops, webinars and meetings, the OECD secretariat, the experts of OECD WNT and OECD WPMN, NANOMET as well as all NanoHarmony partners and associated partners. This project NanoHarmony has received funding from the European Union's HORIZON 2020 research and innovation programme under grant agreement No. 885931. In part it was also support by the NanoPAT project funded by the European Union s HORIZON 2020 research and innovation programme under grant agreement No. 862583 as well as the nanoPASS and iCare projects funded under the HORIZON-CL4-2022-DIGITAL-EMERGING-01 (grant agreements No. 101092741 and 101092971 respectively).

3.01.P-Tu202 Tailored Analytical Approaches for Safety Assessment

Xiaoyu Zhang[1]*, Artem Glukharev*[1]*, Kristof Tirez*[1]*, Adrian Covaci*[2]*, Stefan Voorspoels*[1] *and Milica Velimirovic*[3]*, (1)Flemish Institute for Technological Research (VITO), Belgium, (2)University of Antwerp, Belgium, (3)Flemish Institute for Technological Research (VITO), Mol, Belgium*
To achieve the goal towards climate neutrality and a toxic-free environment, the development of novel materials that are safe for humans and the environment, while also being economically sustainable is needed. Therefore, safe and sustainable by design (SSbD) voluntary approach, introduced in a 2022 Commission Recommendation, aims to guide the creation of safer and more sustainable chemicals and materials throughout their life cycle.
A critical aspect of the SSbD framework is the safety assessment of new materials, which involves identifying, quantifying, and assessing the risks associated with these materials through their life cycle. Tailored analytical approaches are therefore crucial in this process, providing essential data for hazard classification and predicting environmental behavior of the materials.
The main objective of this study is to evaluate different analytical techniques for conducting safety assessments of new materials in the textile industry during the product life cycle. To achieve this, a set of different analytical methods such as Pyrolysis Chromatography/Mass Spectrometry (Pyr-GC-MS), Dynamic Light Scattering (DLS), Nanoparticle Tracking Analysis (NTA), Atomic Force Microscope (AFM), and Scanning Electron Microscopy (SEM) will be presented.

Disclaimer/Disclosure: SSbD4CHeM has received funding from the European Union s Horizon Europe research and innovation programme under grant agreement n° 101138475. UK participants in

SSbD4CheM project are supported by UKRI. CH participants in SSbD4CheM project receive funding from the Swiss State Secretariat for Education, Research and Innovation (SERI). 3.01.P-Tu203 Determination of Technology-Critical Elements in Urban Plants and Water using Inductively Coupled Plasma Tandem Mass Spectrometry

Simone Trimmel[1], *Philipp Sporl*[2], *Daniela Haluza*[3], *Thomas C. Meisel*[1], *Ulrike Pitha*[2], *Thomas Prohaska*[1], *Markus Puschenreiter*[4], *Elmar Rueckert*[5], *Bernhard Spangl*[6], *Dominik Wiedenhofer*[7] *and Johanna Irrgeher*[1], *(1)Montanuniversitat Leoben, Department General, Analytical and Physical Chemistry, Chair of General and Analytical Chemistry, Austria, (2)BOKU University, Department of Civil Engineering and Natural Hazards, Institute of Soil Bioengineering and Landscape Construction (IBLB), Austria, (3)Medical University of Vienna, Center for Public Health, Department of Environmental Health, Austria, (4)BOKU University, Department of Forest- and Soil Sciences, Institute of Soil Research (IBF), Austria, (5)Montanuniversitat Leoben, Department Product Engineering, Chair of Cyber-Physical-Systems, Austria, (6)BOKU University, Department of Landscape, Spatial and Infrastructure Sciences, Institute of Statistics (STAT), Austria, (7)BOKU University, Department of Economics and Social Sciences, Institute of Social Ecology (SEC), Austria*

Technology-critical elements (TCEs), e.g., Ge, Nb, Sb and the rare-earth elements (REEs), represent a non-uniformly defined group of elements that have become indispensable in various high-tech applications due to their unique chemical properties. Despite their rising use and documented instances of alterations of environmental background, the exact scope of anthropogenic releases, as well as their potential effects on ecosystems and human health, remain insufficiently characterised.
Regarding the environmental analysis of TCEs, challenges are posed by their chemical diversity, low environmental abundance, limited availability of (certified) reference materials, and spectral interferences encountered in inductively coupled plasma mass spectrometry (ICP-MS). This work addresses these challenges through the development and validation of a fast and robust measurement procedure using closed-vessel microwave-assisted acid digestion and ICP-tandem mass spectrometry (MS/MS). This validated method was employed to analyse urban environmental samples from Vienna, Austria, including plants from green facades and water from the Wienfluss river. The resulting data offers the first comprehensive assessment of certain scarcely studied TCEs in this context.
Key findings reveal patterns in the distribution of some TCEs that correlate with factors such as plant species, seasonality, and vertical positioning within the sampled sites. This work not only delivers a novel analytical approach for assessing TCEs but also presents an extensive dataset for understanding their distribution in a central European urban environment. The generated data lays the groundwork for assessments of potential ecological and human health impacts posed by anthropogenic TCE emissions.

3.01.P-Tu204 Enhancing Industrial Wastewater Monitoring: A Novel Dual Ionization GC-EI&CI HRTOFMS Approach for Comprehensive Pollutant Identification

Lucie Katharina Tintrop[1], *Marleen Vetter*[2], ***Eliška Ceznerová***[2], *Sonja Klee*[2], *Steffen Brakling*[2], *Arnd Ingendoh*[3] *and Thorsten Schmidt*[1], *(1)University of Duisburg-Essen, Germany, (2)TOFWERK AG, Switzerland, (3)Bruker Daltonics GmbH & Co KG, Germany*

Wastewater treatment plants discharge effluents that often contain hazardous pollutants, posing significant risks to ecosystems and public health. Due to the highly variable composition of wastewater, routine monitoring with both targeted and non-targeted analyses is essential. Gas chromatography-mass spectrometry (GC-MS) is often combined with liquid chromatography-mass spectrometry (LC-MS) to expand the range of detectable compounds, enabling a more comprehensive assessment of potential hazards. However, conventional GC-EI-MS has limitations especially for non-targeted approaches, including low specificity in fragmentation patterns, missing molecular ion signals, and the absence of compounds in reference libraries, which all reduce the reliability of compound identification.
Industrial wastewater effluents were collected over a two months period using 24-hour composite samples. Analytes were enriched using a novel hydrophilic-lipophilic balanced (HLB) fiber coating (CTC Analytics AG, Zwingen, Switzerland) for headspace solid-phase microextraction (SPME). Analysis was performed with an Agilent GC (7890A GC, Santa Carla, California, USA) coupled to a dual ionization high-resolution mass spectrometer (ecTOF, Bruker, Bremen, Germany). This system enables the simultaneous acquisition of standard 70 eV electron ionization (EI) and medium-pressure chemical ionization (CI) (GC-EI&CI HRTOFMS) spectra in a single GC run. Flexible selection of CI reagent ions, such as [N2H]+, [H3O]+, and [NH4]+ between different GC runs, enables adjustment of reactant selectivity and the degree of fragmentation for different analytes. This way the evidence generation for efficient compound

identification can be optimized.
Various strategies were employed to identify unknown compounds using EI and CI mass spectra acquired simultaneously. It is shown that incorporating different CI reagent ions significantly enhanced compound identification accuracy and confidence. Additionally, the novel HLB-SPME fiber enabled solvent-free headspace extraction and captures a broad spectrum of analytes. Combined with the GC-EI&CI HRTOFMS system, this approach demonstrates a high potential for detecting unknown hazardous compounds to advance industrial wastewater monitoring.

3.01.P-Tu205 Development of a Single Biofilm Extraction Method for Non-Target Analysis and Bioassays to Monitor Wastewater Micropollutants
***Anna Voiland**[1], Louise Durand[1], Selim Ait-Aissa[1], Azziz Assoumani[1], Francois Lestremau[2], Elisa Robotti[3], Abd-El-Rahman El-Mais[4] and Nina Huynh[1], (1)Institut National de l Environnement Industriel et des Risques (INERIS), France, (2)HSM, Univ Montpellier, IMT Mines Ales, CNRS, IRD, France, (3)Dipartimento di Scienze e Innovazione Tecnologica, Universit del Piemonte Orientale, Italy, (4)INERIS, France*
Passive samplers (PS) are strong tools to monitor micropollutants due to their ability to accumulate and concentrate the pollutants present in water. Among existing PS, those using biofilms as a receiving phase have gained interest for environmental monitoring, notably in waste water, for which conventional PS are limited by biofouling. Extraction and (bio)analysis of contaminants adsorbed in biofilms still need optimisation in monitoring context. Non-target analysis has been increasingly used during the last decade to detect a large range of water micropollutants, including emerging contaminants, which positions it as a great tool for environmental monitoring. However, this method does not account for the biological activities of the compounds, and the impact of mixture effects on their activity. Hence, as a complementary approach, in vitro bioassays provide a global bioactivity profile of the water samples while considering all the bio-active micropollutants and their potential mixture effect. The combination of PS with bioassays and chemical analysis has already shown its effectiveness in characterizing water. This work aims to develop an approach based on the coupling of an innovative biofilm-based PS with non-target screening and in vitro bioassays to characterize wastewater. This presentation will mainly focus on the development a single biofilm extraction method for both non-target analysis and bioassays, allowing us to have a robust correlation between the compounds analysed and the activity measured. Several solvents, extraction methods, and clean-up strategies were implemented and compared for biofilm extraction. The extracts were then subjected to chemical analysis and in vitro bioassays. For the chemical analysis performed on a liquid chromatography coupled to a high-resolution mass spectrometry, the extraction efficiency was evaluated based on characteristics such as standard recoveries, number of common and specific compounds detected with suspect screening, number of common and specific unknown features detected, and range of molecular weight or polarity. For bioassays, the evaluations were assessed on the response of four nuclear receptors (estrogenic, androgenic, pregnane X, and aryl hydrocarbon receptors).
Based on the outcome of the results obtained for these tests, a single extraction protocol offering the best efficiency compromise for both chemical analysis and in vitro bioassays will be presented.

3.01.P-Tu206 Development of an Analytical Method for Dissociative Acidic Herbicides in Agricultural Commodities for Food Safety Monitoring
***Won-Yeong Choi**, Jang-Hun Kim, Seong-Hwan Park and Hoon Choi, Wonkwang University, Republic of Korea*
Pesticides are essential for enhancing agricultural productivity and quality, with each country setting maximum residue limits (MRLs) suited to its agricultural conditions. Although global MRLs have been established for roughly 1,200 pesticides, 655 remain without MRLs in Korea, highlighting the need for analytical methods to monitor these compounds in imported foods. This study prioritizes dissociative acidic herbicides, including acifluorfen, bromoxynil, cloransulam-methyl, cyclanilide, ioxynil, picloram, propoxycarbazone (and its metabolite 2-hydroxypropoxycarbazone), pyrasulfotole (and its metabolite desmethylsulfotole), and thiencarbazone-methyl, for food safety management. These herbicides were previously incompatible with QuEChERS (Quick, Easy, Cheap, Effective, Rugged, and Safe)-based multi-residue methods due to their dissociative properties and high-water solubility. A modified QuEChERS-based analytical protocol was thus developed and optimized for five representative agricultural commodities (brown rice, soybean, potato, orange, and pepper). The workflow covering extraction, partitioning, purification, and determination was tailored for regulatory use. LC-MS conditions were optimized, including adjustments to column type, mobile phase composition, and other instrumental parameters. Given the herbicides' dissociative and acidic nature, extraction was enhanced with 1N HCl acidification followed by acetonitrile extraction. Magnesium sulfate levels were optimized to avoid

reverse partitioning into the water phase, and a buffer (EN method) stabilized the pH of agricultural extracts. Purification was refined by testing various dispersive solid-phase extraction (d-SPE) materials, including alumina, C18, PSA, PRiME HLB, and Z-sep+, with the most effective combination selected based on extraction efficiency and minimal matrix effects across the five commodities. The residue analysis method optimized in the previous steps was fully validated in terms of selectivity (no interferences), matrix effect (|ME|?50%), limit of quantitation (?0.01 mg/kg), linearities (R?0.98), accuracy (70~120%), and precision (?20% RSD) according to the criteria of the European SANTE/12682/2019 guidelines. The validated method was then applied to monitor imported agricultural products, demonstrating its suitability as a regulatory tool for compliance and food safety management.

3.01.P-Tu207 The Molecular Structure and Composition of Indoor Dust Revealed by Comprehensive Multiphase Nuclear Magnetic Resonance Spectroscopy: Implications for Indoor Chemical Exposure and Risk Assessment

William Fahy[1]*, Rajshree Ghosh Biswas*[2]*, William Wolff*[2]*, Kiera Ronda*[2]*, Andre Simpson*[2] *and Jonathan P. D. Abbatt*[1]*, (1)Department of Chemistry, University of Toronto, Canada, (2)Department of Physical & Environmental Sciences, University of Toronto Scarborough, Canada*

A significant portion of human chemical exposure occurs indoors, but large variability between indoor spaces makes risk assessment and source apportionment difficult, limiting regulatory action and public health recommendations. Indoor dust is an important reservoir of and vehicle for exposure to semivolatile chemical contaminants such as plastic additives, flame retardants, pesticides, and personal care products additives in indoor environments. As such, dust is widely studied to identify new chemical contaminants and to monitor concentrations of legacy contaminants indoors. However, dust is a highly heterogeneous mixture of macroscopic particles, sorbed organics, metals, and other components, the molecular structure of which may be highly variable depending on the location sampled. Understanding this structure and variability is important to interpreting the role of dust in the indoor environment, as it will alter how indoor contaminants partition or sorb to dust and the availability of these contaminants for indoor chemistry or human exposure.

We applied comprehensive multiphase nuclear magnetic resonance spectroscopy (CMP-NMR) to ten distinct dust samples sourced from various locations from two residences in Toronto, Canada, a standard reference dust, and several other reference materials expected to be present in indoor dust samples. CMP-NMR allows chemical characterization of solid, liquid, gel-like, and semisolid components within a material, and when coupled with 2-dimensional NMR can provide a comprehensive picture of the molecular structure and composition of a material. Our results show remarkable similarities between the solid and gel phases of the indoor dusts across the three locations due to the universal presence of humans and fabric materials. However, there are distinctions between the soluble or mobile components, particularly between dusts sourced from different locations and between dust vacuumed off floors and dust gathered from air purifiers or settled on surfaces. These mobile and semi-mobile components contain information about dust age, source, and how indoor contaminants interact with the dust samples. Our findings provide insight into the properties and composition of indoor dust, an important vehicle for indoor chemical exposure and a key matrix for assessing chemical concentrations in indoor environments and will inform indoor chemical fate models and indoor exposure and risk assessment calculations.

3.01.P-Tu208 Increased (S)VOC Identification in Complex Samples using a Dual-Ionization EI&CI-TOFMS Hyphenated with a Flow Modulated GCxGC System

Sonja Klee[1]*, Steffen Braekling*[1]*,* ***Eliška Ceznerová***[1]*, Marleen Vetter*[1]*, Ralf Kurtenbach*[2]*, Scott J. Campbell*[3]*, John Moncur*[3] *and Arnd Ingendoh*[4]*, (1)TOFWERK AG, Switzerland, (2)University of Wuppertal, Germany, (3)SpectralWorks, United Kingdom, (4)Bruker Daltonics GmbH & Co KG, Germany*

Hyphenation to GCxGC sets high requirements to a mass spectrometric detector. Narrow chromatographic peak widths require high mass spectral acquisition rates that are commonly achievable by EI-TOF instrumentation. Flow modulation GCxGC simplifies the experimental setup but also increases the demands to the MS due to enlarged column flows, resulting in high split ratios preceding the detector. However, when measuring complex samples or unknowns compounds an additional soft ionization technique, such as CI improves the compound identification process. For one dimensional GC the combination of EI and CI operating simultaneously on one analyzer within one single chromatographic run has been presented previously. In this study we show the combability and advantages of a fast-switching EI&CI-TOFMS coupled to flow modulation GCxGC.

Ambient air and a standard gas mixture were collected on desorption-tubes. The collected samples were desorbed, preconcentrated and injected into the GCxGC system including a flow-modulation setup. A standard GCxGC-method was provided by the collaborator. The EI&CI-TOFMS operating CI- and EI was

used as detector to provide simultaneous molecular (CI) and structural (EI) information.
The hyphenation of a dual ionization EI&CI-TOFMS with a flow modulated GCxGC setup is presented. Special focus is set on: (1) characterization of the alignment of simultaneously generated EI and CI information; (2) the EI/CI switching behavior of the MS; (3) the chromatographic performance of the ionization sources; and (4) the advantages of using flow modulation GCxGC in combination with medium pressure CI sources. The complexity of the GCxGC-dual ionization MS coupling is addressed and experiments with the aim to harness the high gas flows used in flow modulation GCxGC were conducted. It can be shown that the high pumping efficiency in the CI interface can be utilized to increase the CI sensitivity by a factor of 30, by guiding the larger share of the flow ratio into the CI source. Using a specifically defined flow splitting, it was possible to maintain the flow balance within the EI pumping stage and simultaneously increase the CI performance leading to increased identification certainties as well as decreased limits of detection (LOD). The findings on the instrumental performance investigated via standard gas mixture measurements were further verified on ambient air samples collected at a federal highway in Germany.

Disclaimer/Disclosure: This presentation is part of a Transnational access project that is supported by the European Commission under the Horizon 2020 Research and Innovation Framework Program, H2020-INFRAIA-2020-1, ATMO-ACCESS Grant Agreement number 101008004.

3.01.P-Tu209 Strategies and Approaches for Particulate Matter Analysis in Air

Tom Hey[1], *Ruth Merrifield*[2], *Chady Stephan*[2], *Liyan Xing*[2], *Katia Iatariene*[3] *and Kevin James Wilkinson*[4], *(1)PerkinElmer Inc. (US), Canada, (2)PerkinElmer, Canada, (3)Universite de Montreal, Canada, (4)Chemistry, Universite de Montreal, Canada*

Particulate matter (PM) in ambient air is a major environmental concern due to its impact on human health and the environment. PM levels fluctuate due to various factors, including industrial activity, vehicle emissions, and weather conditions.
Accurate monitoring and analysis of particulate matter, particularly in urban environments, remains a challenge due to the complexity of sources and the variability in PM composition.
This study explores the application of GED-SP-ICP-MS (Gas Exchange device - Single Particle - Inductively Coupled Plasma Mass Spectrometry) for the detection and analysis of particles in gaseous media. We aim to assess the viability of this technique for monitoring both environmental air samples and gas samples from industrial sources.
This poster presentation will demonstrate the potential of GED-SP-ICP-MS to improve particulate matter monitoring in air quality studies, with direct applications in public health, environmental monitoring, and industrial hygiene. This technique could lead to more accurate assessments of pollution levels and sources, guiding regulatory efforts to reduce exposure to harmful particulate matter.

3.01.P-Tu210 Identification of Urinary Biomarkers and Biotransformation Pathways of DEHCH: A Step Toward Improved Biomonitoring of Non-Phthalate Plasticizers

Sunghoon Yeo[1], *Hyeri Jeon*[1], *Eun-Ah Park*[1], *Na-Youn Park*[1], *Bongjin Moon*[2], *Kyunghee Ji*[3] *and* ***Younglim Kho***[1], *(1)Eulji University, Republic of Korea, (2)Sogang University, Republic of Korea, (3)Yongin University, Republic of Korea*

Non-phthalate plasticizers are increasingly used as safer alternatives to phthalates due to concerns about human toxicity. Among these, bis(2-ethylhexyl)cyclohexane-1,4-dicarboxylate (DEHCH) is a newer option. This study aimed to investigate the biotransformation of DEHCH in humans to identify phase I metabolites and develop biomarkers for exposure assessment. Using human liver microsomes in vitro and urinary samples collected after a single oral dose, primary and secondary metabolites were characterized. Cyclohexane-1,4-dicarboxylate-mono-2-ethyl-hexyl ester (MEHCH) was identified as the primary metabolite, formed through hydrolysis of DEHCH. Secondary oxidized metabolites included cx-MEHCH, OH-MEHCH, and oxo-MEHCH, while complete breakdown products such as cyclohexane-1,4-dicarboxylate (CHDA) were also detected. Quantitative analysis revealed that over 48 hours, urinary excretion mass fractions were 0.4% for MEHCH, 3.4% for OH-MEHCH, 0.3% for oxo-MEHCH, 0.2% for cx-MEHCH, and 51.3% for CHDA. This is the first study to identify a urinary biomarker for DEHCH exposure in humans, laying the groundwork for future biomonitoring research on non-phthalate plasticizers.

3.01.P-Tu211 Enhanced Nanoplastics Detection via Optical-Photothermal Infrared (O-PTIR) Coupled with Simultaneous Raman Spectroscopy

Miriam Unger[1], *Natalia P. Ivleva*[2], *Carolin Borbeck*[1] *and Marcel Klotz*[2], *(1)Photothermal Spectroscopy*

Corp. GmbH, Germany, (2)TU Munich, Germany
Introduction
The global prevalence of plastics has led to widespread environmental contamination with microplastics (1 µm to 1 mm) and nanoplastics (<1 µm). Nanoplastics are especially hazardous due to their ability to penetrate biological barriers and carry toxins.
Method
Traditional detection methods, such as µ-Raman spectroscopy, provide high spatial resolution but are limited by fluorescence interference, while FTIR techniques lack sufficient spatial resolution. Optical-Photothermal Infrared Spectroscopy (O-PTIR) combines the spatial precision of Raman (532 nm) with IR s chemical specificity, enabling submicron IR resolution. It allows simultaneous collection of IR and Raman spectra, offering cross-validation and reducing interference.
Results/Discussion
This study presents a powerful method for identifying diverse classes of nanoplastics, with particle sizes down to 300 nm. By leveraging O-PTIR's dual-spectroscopy capabilities, simultaneous infrared and Raman data were collected, providing detailed chemical insights. This approach enhances the reliability of nanoplastic analysis by uncovering critical information about particle coatings and embedded dyes.
Conclusions
O-PTIR with simultaneous Raman provides a powerful approach for detecting and characterizing nanoplastics, overcoming limitations of traditional methods. This technique shows promise for environmental monitoring and health studies, supporting improved risk assessments of nanoplastic pollution.

3.01.P-Tu212 Determination of Food Microplastics using Depolymerization and Ultra-Performance Liquid Chromatography/Tandem Mass Spectrometry

Yang- Hsueh Chen[1]*, Shu-Ting Lin*[2] *and Chia-Yang Chen*[1]*, (1)Institute of Environmental and Occupational Health Sciences, College of Public Health, National Taiwan University, Taiwan (Greater China), (2)Institute of Food Safety and Health, College of Public Health, National Taiwan University, Taiwan (Greater China)*

Plastics can degrade into microplastics smaller than 5 mm, potentially entering humans via the food chain and causing adverse health effects. Current microplastic detection methods, such as Fourier-transform infrared (FTIR) and Raman spectroscopy, are prone to false positives and cannot detect nanoparticles; also, results may vary due to differences in cut-off particle sizes. Depolymerization followed by monomer analysis offers a potential solution, but existing studies mainly focus on environmental samples. This research thus aims to develop a depolymerization method to detect microplastics of polyethylene terephthalate (PET), polycarbonate (PC), polylactic acid (PLA), Polyamide 6 (PA 6), and Polyamide 66 (PA 66) in food matrices.
This investigation employs conventional reflux and microwave-assisted acid digestion methodologies for plastic depolymerization. PET, PC, and PLA microplastics were treated with 1.0 g of KOH in 20 mL of 1-pentanol at 135°C for 45 minutes using a reflux condenser. The resultant decomposed monomers of PET, PC, and PLA are terephthalic acid (TPA), bisphenol A (BPA), and lactic acid (LA), respectively. PA 6 and PA 66 underwent a reaction with 2 mL of 20% hydrochloric acid (HCl)(aq) using CEM MARS for microwave-assisted depolymerization at 170°C for 45 minutes, yielding 6-aminocaproic acid (6-ACA) and adipic acid (AA) monomers, respectively.
The monomer concentrations were determined utilizing Waters ultra-performance liquid chromatography-MS/MS (UPLC-MS/MS) with UniSpray ionization. TPA, AA, and LA were separated on a Waters ACQUITY UPLC BEH Amide column, whereas BPA and 6-ACA were separated on a Supelco Ascentis Express F5 column.
The basic depolymerization efficiencies of PET, PC, and PLA attained 99%, 116%, and 180%, respectively, demonstrating that this procedure could fully depolymerize the three plastics. The elevated efficiency of PLA resulted from the presence of LA from reagents. For PA6 and PA66, the acid microwave-assisted depolymerization achieved 91% and 85% efficiencies, respectively.
This investigation presented a methodology for quantifying the concentrations of five categories of microplastics, yielding comparable results. The obtained concentration measurements were valuable for exposure assessment and provided empirical evidence to inform the development of regulations to mitigate microplastic pollution.

Disclaimer/Disclosure: The Taiwan National Science and Technology Council supported this study (112-2621-M-002-013-MY3).

3.01.P-Tu213 Enhanced Digital Quantification of Microplastics using Sequential Nile Red and Rose Bengal Staining

Benedetta Villa[1]*, Gaia Bolla*[1]*, Isabella Gambino*[2]*, Elisa Terzaghi*[2]*, Antonio Di Guardo*[2] *and Roberta Bettinetti*[3]*, (1)Department of Science and High Technology, University of Insubria, Italy, (2)Environmental Modelling Group, Department of Science and High Technology, University of Insubria, Italy, (3)Department of Human Sciences, Innovation and Territory, University of Insubria, Italy*

Despite microplastics (MPs) being an increasingly prominent global concern, there are currently no standardized methods for their visual analysis. This is a crucial step towards understanding the extent of pollution and its environmental impacts. In the context of the project LIFE CASCADE, the authors explored an innovative visual analysis technique utilizing a digital microscope instead of a conventional optical microscope. To enhance optical quantification, they employed the Keyence Series VHX-7000 digital microscope, paired with the Keyence VHX-7100 camera and VHX-E100 lens, which offers a remarkable resolution of up to 2 ?m. This setup simplifies the basic operations necessary for quantifying MPs, making it user-friendly and accessible, even for beginners. The high-resolution images produced are comparable to those obtained from scanning electron microscopy (SEM).

Furthermore, the quantification process was refined through the sequential use of two of the most commonly utilized dyes in microplastics analysis: Nile Red and Rose Bengal. Nile Red is a well-established dye for MP quantification, providing a straightforward method to reduce the number of particles that require confirmation through analytical techniques such as Fourier-transform infrared (FTIR) or Raman spectroscopy. However, its affinity for biogenic materials can sometimes result in false positives, leading to an overall overestimation of particle counts. In contrast, Rose Bengal exhibits a stronger affinity for natural organic matter, which helps to mitigate the errors associated with Nile Red. By integrating the digital microscope and employing a sequential combination of these two dyes, the authors aimed to present an enhanced approach to visual quantification of microplastics. This method facilitates the rapid differentiation between plastic particles and natural organic materials after digestion, providing a fast and more reliable tool for counting microplastic fragments in environmental water samples.

3.01.P-Tu214 Comprehensive Pesticide Screening with Dual Ionization GC-HRMS: Bridging Targeted and Non-Targeted Analysis

Eliška Ceznerová[1]*, Sonja Klee*[1]*, Steffen Brakling*[1]*, Arnd Ingendoh*[2]*, Claudio Cruzer*[3] *and Andreas Schurmann*[3]*, (1)TOFWERK AG, Switzerland, (2)Bruker Daltonics GmbH & Co KG, Germany, (3)Kantonales Labor Zurich, Switzerland*

The detection and quantification of pesticide residues and contaminants in agricultural products are critical for ensuring food safety and compliance with global regulations. The growing demand for these requirements, driven by consumer awareness and stringent regulations, increases the demands on analytical screening. Chromatographic techniques coupled to high-resolution mass spectrometry (HRMS) are becoming a most reliable analytical platforms for pesticides analysis, mainly due to their comprehensive detection, and identification of both, known and unknown residues with high sensitivity and specificity. Here, we present a new non-targeted analysis approach of volatile pesticide residues in food matrices. For unambiguous compound identification a novel gas chromatography (GC)-HRMS system generating simultaneously EI and CI information on the detected analytes was utilized.

Agricultural products were extracted using QuEChERS protocols and analyzed with a GC 8500 system (Bruker, Germany) coupled to an ecTOF detector (Bruker, Germany). The system's dual ionization capability, combining electron ionization (EI) and chemical ionization (CI) simultaneously, provides complementary structural and molecular data. CI reagent ions (N_2H^+, H_3O^+, NH_4^+) were used to adjust fragmentation and enhance molecular detection. A targeted library of 213 pesticides was created for targeted analysis. Data post-processing for targeted, suspect and non-targeted approaches were carried out with AnalyzerPro XD (Spectralworks, UK).

The GC-HRMS system effectively identified pesticide residues with certainties above 70% for both EI and CI traces using the created targeted library. Non-targeted analysis detected additional compounds that were analyzed using NIST library searches and accurate mass data. Added CI information improved sensitivity and enabled residue detection at low ppb levels. The dual-ionization approach enhanced compound identification certainties, reduced analysis time, and increased reliability for complex samples. The integration of EI and CI in a single GC-HRMS workflow enhances certainties and reliability for both targeted and non-targeted pesticide residue analysis. The system shows to be a highly efficient tool for ensuring food safety and regulatory compliance, offering robust solutions for identifying pesticides in complex agricultural products.

3.02.A Advances in Exposure Modelling Toward a Safe and Sustainable Tomorrow for Both Humans and the Environment

3.02.A.T-01 Exposure Modelling in Europe: How to Pave the Road for the Future as Part of the European Exposure Science Strategy 2020–2030

*Karen S. Galea[1], **Urs Schluter**[2], Gerald Bachler[3] and Dorothea Koppisch[4], (1)Institute of Occupational Medicine (IOM), United Kingdom, (2)Federal Institute for Occupational Safety and Health (BAuA), Germany, (3)EMSEA Training, Finland, (4)German Social Accident Insurance (IFA), Germany*

Exposure modelling is essential in almost all relevant contexts of exposure science. To address the numerous challenges that exist, exposure modelling is one of the priority areas of Europe Chapter of the International Society of Exposure Science (ISES Europe). Therefore, a strategy was developed, focussing on this priority area, with four strategic objectives:
(1) improvement of existing models and modelling tools,
(2) development of new methodologies and support for understudied fields,
(3) improvement of the use of models and training for model users, and
(4) development of models to fulfil regulatory needs and improve acceptance
Exposure modellers from a wide range of European countries and institutions, active in the fields of occupational, general population (humans via the environment and exposure due to handling chemicals by consumers) and environmental exposure science pooled their expertise under the umbrella of the ISES Europe working group on exposure models. This working group assessed the state-of-the-art of exposure modelling in Europe. They developed an inventory of exposure models used in Europe and reviewed the existing literature on pitfalls associated with exposure modelling, in order to identify crucial modelling-related strategy elements. Additionally, an online survey was conducted and disseminated to the European exposure science community to identify modelling training needs and a repository of guidance and standard for regulatory exposure modelling was developed.
Decisive actions were defined for ISES Europe stakeholders focused on achieving the long-term goal of developing a best practice in exposure modelling. Additionally, to the four strategic objectives, the working group developed an action plan and roadmap for the implementation of the European Exposure Science Strategy for exposure modelling. This strategic plan shall foster a common understanding of modelling-related methodology, terminology, training and education, as well as future research in Europe, and have a broader impact on strategic considerations globally.

3.02.A.T-02 Identification of Environmental Release Hotspots Along the Product Life Cycle Through HotSpot Scan Tool

***Neeraj Shandilya**, Lia de Simon, Tom Ligthart, Eugene van Someren and Wouter Fransman, TNO, Netherlands*

Early identification and quantification of potential harmful emissions to environmental compartments (including air, water and soil) throughout a product s life cycle are crucial for a safe and sustainable by design approach. The in silico HotSpot Scan tool facilitates this by offering a quick, and low-input assessment, using an extensive data inventory to pinpoint life cycle stages and environmental compartments with potential emissions. These are identified as hotspots or focal points during the life cycle of a product.
Its applicability was demonstrated on the development of perovskite-based solar cell devices which show high solar power conversion efficiency with low production costs (i.e., highly interesting from cost v/s performance perspective), but suffer from poor operational and structural stability and the toxicity of the used materials (i.e., major concerns for safety and sustainability), which can hinder their practical commercialization and widespread application.
The results show that approx. 80% of the total emissions to the environment occur during the end-of-life phase of the device, mainly affecting ground water. Thus, a viable recycling method is critical for improving the device safety and sustainability. Lead emissions were estimated throughout the device life cycle. Several toxic substances used during the device production were also estimated to be emitted (approx. 10% of the total emission), mostly to the wastewater. This includes lead nitrate, lead halide, methylammonium halide, dimethylformamide and precursor ink. Substituting these chemicals with less hazardous ones is thus needed. The released amounts to (particularly indoor) air were estimated to be relatively lower due to the risk management measures put in place during synthesis and manufacturing of the perovskites, and even lower to the soil. The remaining emissions were linked to the device use and breach of the perovskite encapsulation layer which can lead to leaching of the lead ions into the soil. Thus, structural stability of the encapsulation layer is critical.
This case study demonstrates that HSS is a valuable tool for quickly assessing mass flows and environmental releases throughout a product s life cycle. The publicly available online tool allows

innovators to proactively adjust designs, minimizing releases and supporting safer and more sustainable products.

Disclaimer/Disclosure: This work was supported by the EU H2020 PeroCUBE project [grant number 861985].

3.02.A.T-03 Predicting the Fate of 40 Emerging Contaminants: A Case Study of SimpleTreat and TOXCHEM

***Pinelopi Savvidou**, Pablo Campo and Tao Lyu, Faculty of Engineering and Applied Sciences, Environment, Agrifood and Water Theme, Cranfield University, United Kingdom*

Modelling micropollutant fate during wastewater treatment can help practitioners improve treatment conditions and maximise micropollutant removal. We evaluated two fate models, SimpleTreat and TOXCHEM, for predicting removal efficiencies of 40 micropollutants (19 pharmaceuticals, 7 PFAS, 6 flame retardants (BDEs), 2 heavy metals, 2 PAHs, 1 pesticide, 1 antifungal, 1 corrosion inhibitor, and 1 plasticiser). Predicted values were compared with observed values obtained from monitoring studies of 36 sewage treatment plants across the United Kingdom as part of the National Chemicals Investigations Program (CIP) conducted from 2011 2021. Predicted removals exhibited average variance from observed removals at 28.5% for SimpleTreat and 37.4% for TOXCHEM. The results indicate that SimpleTreat is more fit for purpose. However, both models exhibit discrepancies between simulated and observed values. For micropollutants, where practitioners have a better understanding of their chemical properties, i.e., pharmaceuticals, both models had better predictions closer to reality with deviations of less than 30% (e.g., Erythromycin observed value 18% vs predicted TOXCHEM value at 15%). However, for BDEs and PFAS, the error reached up to 100% (e.g., PFHxA estimated 91.6% (SimpleTreat) or 22.5% (TOXCHEM) compared to the observed negative removal at -42%). In both fate models, it was observed that the predictions were more sensitive to a compound's input chemical properties rather than the treatment plant's input operating conditions (flow rate, BOD, suspended solids). That verifies that the derived discrepancies are due to the models physicochemical properties used to predict micropollutant fate. For instance, in the case of PFAS, micropollutants with complex structures, it is difficult to obtain accurate information about their chemical properties in the environment. Improving accuracy requires a better understanding of micropollutants' behaviour in real environmental conditions. Another way to improve predictions is to incorporate data-driven models (machine learning) into current fate models. Data-driven approaches make predictions based on measured values and do not rely on chemical properties minimising the errors derived from input chemical properties.

3.02.A.T-04 A Framework for Projection of Future Chemical Emissions Under the UK Shared Socioeconomic Pathways

***Hongyan Chen**, Jacky Chaplow, Sam Harrison and STEPHEN LOFTS, UKCEH, United Kingdom*

Chemical emissions into the environment pose risks to human health and ecosystems. Understanding these emissions and exploring their evolution under the uncertainties of future climate and socioeconomic changes is critical for effective long-term management. However, few studies have focused on this issue, particularly at finer spatial scales. This study introduces a novel framework to address these challenges, integrating use profiles of chemicals to identify emission proxies based on release pathways, a scenario analysis toolkit to estimate proxy trends under selected representative concentration pathways (RCPs) and shared socioeconomic pathways (SSPs), and a downscaling approach to spatialise trends and emissions at a 5 km grid scale in the UK. The scenario analysis toolkit, a key component, enables users to select proxy drivers from 50 semi-quantitative variables in UK_SSPs, define their effects, including their direction and weight, and automatically generates proxy trends through weighted sums. This process is transparent, efficient, and repeatable, fostering stakeholder engagement, which is crucial for informed decision-making. The framework is demonstrated through a case study analysing Fipronil emissions to freshwaters from flea treatments for household pets in the UK. The resulting spatiotemporal emission data provide a foundation for further modelling of chemical fate and impacts, supporting the prediction and management of chemical risks.

Disclaimer/Disclosure: This work was funded by the UK Natural Environment Research Council under grant NE/X015866/1.

3.02.A.T-05 Towards the Assessment of Risk of Contaminants of Emerging Concern in Surface Waters using HydroFATE, a Global Contaminant Fate Model

***Heloisa Ehalt Macedo**, Bernhard Lehner, Jim Nicell and Guenther Grill, McGill University, Canada*

Contaminants of emerging concern in surface waters pose significant risks to both the environment and human health. While comprehensive monitoring of such contaminants in surface waters is essential, resource and analytical constraints often hinder the feasibility of widespread assessments, thereby necessitating the use of contaminant fate models as a basis for risk assessment. Existing models generally require specialized technical expertise and substantial computing power, limiting their accessibility for stakeholders involved in water management. To address these challenges, we introduce HydroFATE, a global contaminant fate model designed as an accessible tool for screening risks associated with contamination of surface waters due to chemicals associated with human consumption. HydroFATE enables stakeholders including chemical and pharmaceutical industries, wastewater treatment facility operators, regulatory agencies, policymakers, and environmental consultants to efficiently prioritize monitoring and regulatory compliance efforts. Although the development of a more user-friendly interface is currently underway, HydroFATE s current framework already allows for scientifically robust and rapid assessments, making it a valuable resource for informed decision-making. Initial applications of the model have demonstrated its effectiveness in predicting antibiotic pollution in surface waters worldwide. Ongoing efforts to expand HydroFATE to model a broader range of contaminants will further enhance its utility across the globe. By fostering collaboration with government agencies, non-profit organizations, and industry stakeholders, we aim to encourage the widespread adoption of HydroFATE. This initiative will support evidence-based policy development, ultimately contributing to the preservation and improvement of the global water quality and ecosystem health.

3.02.B Advances in Exposure Modelling Towards a Safe and Sustainable Tomorrow for Both Humans and the Environment

3.02.B.T-01 An Integrated Water and Air Modelling Study for a Comprehensive Evaluation of Shipping Environmental Impacts in the Northern Adriatic Sea

Loris Calgaro[1]*, Elisa Giubilato*[1]*, Manuel Aghito*[2]*, Jukka-Pekka Jalkanen*[3]*, Elisa Majamaki*[3]*, Christian Ferrarin*[4]*, Risto Hanninen*[3]*, Yuliia Palamarchuk*[3]*, Mikhail Sofiev*[3]*, Elena Semenzin*[1] *and Antonio Marcomini*[1]*, (1)University Ca' Foscari of Venice, Italy, (2)Norwegian Meteorological Institute, Norway, (3)Finnish Meteorological Institute, Finland, (4)CNR National Research Council of Italy, ISMAR Institute of Marine Sciences, Italy*

Marine transport is a cornerstone of the global economy, carrying around 90% of world trade by volume and facilitating the movement of people, essential goods, raw materials, and energy resources across continents. However, marine water quality and coastal air quality degradation due to shipping activities have been recognized as a significant concern and related to negative effects on both the environment and human health.

The aim of this study was to investigate using high-resolution modelling tools the impact of shipping on air and water quality in the Norther Adriatic Sea with respect to other land-based sources. In detail two metals (i.e., cadmium Cd and lead Pb), two polycyclic aromatic hydrocarbons (i.e., benzo-a-pyrene BaP, and fluoranthene Fl), and four air pollutants (i.e., ozone O3, sulphur dioxide SO2, nitrogen oxides NOx, and particulate matter PM2.5) were selected due to data availability for model development and validation. The Ship Traffic Emission Assessment Model (STEAM) model was used to estimate the discharge of liquid wastes and the emission to the atmosphere of air pollutants from shipping activities, while data on other sources was obtained from monitoring data and international emission inventories. Water quality modelling was carried out by applying the ChemicalDrift module of the OpenDrift suite using forcing data from the Shallow water HYdrodynamic Finite Element Model (SHYFEM) model and Copernicus Marine Services. The System for Integrated modeLling of Atmospheric composition (SILAM) model used to track shipping emissions into the atmosphere using meteorology data from the European Centre for Medium-Range Weather Forecasts (ECMWF) and from the Weather Research Forecasting (WRF) model.

The applied modelling framework allowed to comprehensively evaluate the combined impacts of shipping to water and air quality in the Northern Adriatic Sea. Shipping traffic was shown to contribute significantly to air quality, especially to SO2, NOx, and PM2.5 concentrations, as well as to NOx, Cd, and Pb deposition in the open sea. Shipping contribution to water pollution was shown to be significant especially along shipping lanes, while the contribution to sediments quality was more limited. While shipping has been identified as a significant source of several pollutants, further studies should also consider the inherent ecotoxicological effects of all shipping effluents (e.g., scrubber water, bilge water, and ballast water).

3.02.B.T-02 Reconciling Plastic Release: Comprehensive Modeling of Macro- and Microplastic Flows to the Environment

Danyang Jiang[1] *and Bernd Nowack*[2]*, (1)EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (2)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland*

The presence of plastic all over the world is one of the major environmental issues of the 21st century. In order to tackle this problem, knowledge about environmental emissions is crucial. Material flow analysis combined with release assessments is one way to quantify plastic emissions from a whole product life cycle perspective. This study integrates recent research on key emission pathways into a plastic release model based on probabilistic material flow analysis, and comprehensively models macro- and microplastic emissions of seven polymers in Switzerland for the year 2022. Our model estimates that 222 ± 50 g/capita/year plastics are released into the environment, with PET contributing 37%, followed by PP of 22%, PVC 13%, HDPE 12%, LDPE 8%, EPS 4%, and PS 3%. Fiber release from textiles and pellet loss during pre- and post-consumer processes were identified to be primary microplastic release pathways. For macroplastics, the main release processes are littering of packaging products and losses during post-consumer collection. Soil is identified as the primary receiving compartment for plastic emissions, accounting for 98% of macroplastics and 94% of microplastics, respectively. A comparison with previous release estimates shows a large variability of per-capita emissions, mainly caused by inclusion or not of rubber release from tyres and differences in modeling the littering and dumping processes.

3.02.B.T-03 PROTEX: Chemical Safety and Sustainability Assessment from Production Lines to Human and Ecological Receptors

Li Li[1]*, Zhizhen Zhang*[2]*, Dingsheng Li*[1]*,* ***Alessandro Sangion***[3]*, Jon A. Arnot*[3] *and Frank Wania*[4]*, (1)University of Nevada, Reno, United States, (2)ExxonMobil Biomedical Science, Inc., United States, (3)ARC Arnot Research and Consulting Inc., Canada, (4)University of Toronto Scarborough, Canada*

Understanding human and ecological exposures to human-made chemical substances necessitates holistic and systematic information about chemical emissions from multiple lifecycle sources, fate in multimedia environments at multiple scales, multiple sources of exposure, and multiple pathways of intake and elimination. These components are governed by the complicated interactions between chemical properties, environmental conditions, and human and ecological characteristics. Such multidimensionality and complexity warrant a systematic, mechanistic perspective in exposure modeling and necessitate a holistic approach to track a chemical s journey from the production line to the body burden. In this presentation, we introduce a state-of-the-science model named PROduction-To-EXposure (PROTEX), which supports characterizing the entire continuum from chemical production, lifecycle multi-source emissions, multi-scale multimedia environmental fate and transport, and multi-pathway exposure, to the presence in humans and other organisms. PROTEX builds on theories of substance flow analysis, multimedia fate and transport, bioaccumulation, and exposure and toxicokinetics, and it integrates mechanistic descriptions of various physical, chemical, biological, and socioeconomic processes. Its mechanistic nature allows PROTEX to be parameterized for a wide range of chemical substances (both neutral and ionizable chemicals) in a wide range of regional environments (e.g., the subtropical U.S., the Canadian side of the Lake Ontario basin, central China, and the western Baltic drainage basin) for a wide range of populations (Whites, Blacks, Asians, etc.). When supplied with time-variant production or use data, PROTEX provides dynamic time-dependent estimates, allowing users to reconstruct the long-term history of chemical contamination. By considering interindividual variabilities in human anthropometrics, behavior, and physiology, PROTEX additionally supports predicting the distribution of chemical exposure within a population. Outputs from PROTEX support science-based risk assessment and decision-making. The presentation serves as a knowledge hub for PROTEX s rationale and mechanism, applications and case studies, and user tips.

Disclaimer/Disclosure: The authors gratefully acknowledge financial support from the U.S. Environmental Protection Agency, the European Chemical Industry Council, and the American Chemistry Council over the past years, which made the work described in this abstract possible.

3.02.B.T-04 Exploring the Long-term Human Exposure to Short-, Medium-, and Long-chain Chlorinated Paraffins Under Variant Environmental Release Trends and Patterns

***Chengkang Chen*[1]**, *Li Li*[2] *and Frank Wania*[1], *(1)Department of Physical & Environmental Sciences, University of Toronto Scarborough, Canada, (2)School of Public Health, University of Nevada Reno, United States*

Chlorinated paraffins (CPs) have been extensively released into the environment, resulting in pervasive and long-term human exposure on a global scale. Patterns of CP use and release vary significantly across regions, differing by chain length (short-, medium-, or long-chain CPs), usage context (indoor vs. outdoor), and temporal trends. In this presentation, we apply a modeling approach to investigate how these regional differences influence the extent and pathways of long-term CP exposure in human populations. Focusing on three case regions China, Canada, and Northern Europe we specifically examine: (1) the relative contributions of far-field versus near-field exposure across regions, driven by differing CP use and release patterns; (2) variations in temporal trends of human body burdens within longitudinal cohorts, identifying which generations experience the highest exposure levels; and (3) whether our modeling approach can explain the cross-sectional body burden trends with age observed during biomonitoring studies. Release trends for SCCPs, MCCPs, and LCCPs that vary across the three regions translate to highly divergent longitudinal concentration age trends. For example, Chinese cohorts born after the 1990s experience rapid whole-body concentration increases, whereas European cohorts show declining concentrations over their lifetimes. Predicted peak body concentrations occur at different times in different regions and or different CP groups. Regional differences in CP use contexts do not appear to significantly alter the relative importance of far-field versus near-field exposure pathways. By identifying key exposure drivers and vulnerable populations, this work supports the efficient management of CP-related health risks and offers a valuable framework for evaluating the effectiveness of future CP emission reduction strategies.

3.02.B.T-05 What Does the Next Generation of Environmental Exposure Models Look Like?

Ogden*[13], *Gordon Blair*[1], *Gregory Tucker*[2], *Huichan Lin*[7], *Jacqueline Otto*[8], *Joe Marsh Rossney*[1], *Mark Piper*[2], *Michael Holloway*[1], *Nahum Ashfield*[14], *Nans Addor*[15], *Qianhui Lin*[1], *Ricardo Torres*[16], *Rolf Hut*[17], *Sarah Boulton*[18], *Stephanie Orellana Bello*[19], *Suryodoy Ghoshal*[18] *and William Kearney*[20], *(1)UKCEH, United Kingdom, (2)CSDMS, University of Colorado Boulder, United States, (3)Department of Earth Sciences, University of Oxford, United Kingdom, (4)Netherlands eScience Center, Netherlands, (5)Department of Earth Sciences, VU University Amsterdam, Netherlands, (6)Deltares, Netherlands, (7)School for Marine Science & Technology, University of Massachussets Dartmouth, United States, (8)Lancaster Environment Centre, Lancaster University, United Kingdom, (9)Creative Exchange, United Kingdom, (10)Institute of Computing for Climate Science, University of Cambridge, United Kingdom, (11)Deltares, United States, (12)Roma Tre University, Italy, (13)NOAA-NWS Office of Water Prediction, United States, (14)Department of Environment and Geography, University of York, United Kingdom, (15)Fathom, United Kingdom, (16)Plymouth Marine Laboratory, United Kingdom, (17)Delft University of Technology (TU Delft), Netherlands, (18)School of Geography, Earth and Environmental Sciences, University of Plymouth, United Kingdom, (19)Cienciambiental, Chile, (20)University of Potsdam, Germany*

Environmental models and software are essential tools for understanding the complex interactions of the natural world. They empower us to foresee potential futures, unravel intricate trends and expand our scientific knowledge, ensuring we make informed decisions for a sustainable future. This includes environmental emissions and exposure models, which tell us how chemicals and other potential pollutants enter, move around and behave in the environment. To achieve accurate, efficient, collaborative and integrative insights into this pollution and its sources, it is imperative that our models and software keep pace with scientific and technological advances, the increasing availability of data and a heightened importance on assessing complex, interconnected systems under a changing climate. But often our models follow outmoded programming paradigms and technological setups that makes this difficult. They are often monolithic codebases rather than flexible, standalone modules, making them difficult to adapt to emerging risks or integrate with other models to predict, e.g., the societal drivers and One Health impacts of pollution. Furthermore, modelling efforts often overlook ethical and sustainability issues, like the carbon footprint of running complex simulations or the societal impacts of using model predictions to inform policy. These considerations framed a workshop that took place in October 2024, bringing together interdisciplinary environmental modellers from around the world to discuss the question: what does the next generation of environmental models look like?

The focus was interactive sessions, where participants discussed this question by referering to six pillars:

Software engineering and collaborative platforms; Interdisciplinary learning; Cloud-based and exascale computing; Citizen science; Artificial intelligence, and; Big data and better monitoring. In this presentation, we reflect on the outcomes, placing them in the context of emissions and exposure modelling.
The workshop was part of broader efforts to build an international community of practice around environmental modelling. A priority identified is that training, education and knowledge transfer are vital to ensuring that we empower the next generation of environmental modellers, as well as the models themselves, and we hope this community will provide a space to enable this.

Disclaimer/Disclosure: The authors thank the NERC Global Partnerships Seedcorn Fund, UKCEH National Capability and the Centre of Excellence in Environmental Data Science (CEEDS) for funding the workshop. Co-authors are listed in alphabetical order according to their first names.

3.02.P Advances in Exposure Modelling Toward a Safe and Sustainable Tomorrow for Both Humans and the Environment

3.02.P-We172 Overall Persistence as a Time-Dependent Parameter

***Stefan Hahn**[1], Judith Klein[2], Dimitrios Alexander Skodras[3] and Michael Klein[2], (1)Fraunhofer ITEM, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany*

Chemical persistence plays a key role in the determination of environmental exposure making it an important endpoint in risk assessment and regulation. For persistence assessment information is required on the degradation rates in different compartments (soil, water, sediment, air). However, degradation rates are prone to wide variability depending on environmental conditions, and evaluating degradation half-lives using a compartment-by-compartment approach is overly simplistic, and neglects dynamic multimedia exchanges and degradation processes. According to the REACH guidance R.11, results from multi-media modelling could be used case-by-case in order to evaluate the environmental exposure and compartment(s) of specific concern. Overall persistence (Pov) has been proposed to be a suitable replacement metric for the compartment-specific half-lives in persistence assessment. However, overall persistence at steady state depends heavily on the release pattern, whereas the temporal remote state, defined as the state of the model system long after the stop of emissions, is independent of the release pattern of a chemical.
In this presentation, influencing parameters of overall persistence over time will be illustrated. The multimedia model MUST (level III and IV) is applied on case studies taking into account different properties (degradation half-lives, volatility, solubility, adsorption), and different mode of entries. Sensitivity analysis will support evaluation of most important input parameters. In addition, emission scenarios such as emission stop are used to evaluate the impact on the overall persistence and the relevant compartment.
Overall persistence is given usually for the steady-state concentration, and will usually be given as residence time, which has to be converted into half-lives to be comparable with persistence triggers. However, overall persistence at steady-state depends on release pattern, Moreover concentration in the different compartments will change over time due to change in release pattern, distribution and different degradation rates. For this reason, overall persistence is a time-dependent parameter (Pov(t)) as well, which can be illustrated by Level IV simulations. Further influencing factors determined by sensitivity analysis will be presented.

3.02.P-We173 Enhancing Practice: The ISES Europe Repository of Good Modelling Practice (GMP)

*Gerald Bachler[1], **Stefan Hahn**[2], Angelika Derler[3], Susana Viegas[4] and Maryam Zare Jeddi[5], (1)EMSEA Training, Finland, (2)Fraunhofer ITEM, Germany, (3)Environment Agency Austria, Austria, (4)NOVA National School of Public Health, Portugal, (5)Shell International BV, Netherlands*

Background: The European Exposure Science Strategy 2020 2030 aims to enhance the use of computational exposure models by providing model users with essential resources, including standardized exposure scenarios, guidance on exposure modelling, regulatory guidelines, and efficiency factors for risk management measures.
To support these objectives, a dedicated subgroup was formed within the Exposure Models Working Group of the International Society of Exposure Science (ISES) Europe Chapter.
Methodology: The subgroup's first goal was to create a free resource that promotes Good Modelling Practices (GMP) in exposure science. As outlined by the subgroup, this involves identifying suitable model input parameters, selecting and using exposure models effectively, evaluating models and results

appropriately, and clearly interpreting and communicating outcomes to all stakeholders.
Results and Discussion: Over the past two years, the subgroup populated a Repository of Good Modelling Practice (GMP) with input from the ISES Europe community. It includes links to over 300 resources, such as guidance documents, scientific publications, databases, and webpages. The focus is on European references published after 2000. Launched in late 2024, the Repository is freely accessible on the ISES Europe website. It is organized into five key themes to support the modelling process: (1) Substance Parameters, (2) Exposure Factors, (3) Exposure Modelling, (4) Model Evaluation, and (5) Result Communication.
Future: As a living document, the Repository of Good Modelling Practice (GMP) will be updated periodically. Conference participants are encouraged to provide feedback and share additional references.

3.02.P-We174 From Complexity to Simplicity Toward Streamlining Safe and Sustainable by Design (SSbD) Implementation - The ECETOC Task Force's Approach to Practical Tools for Evaluating the Safety Dimension

*Maryam Zare Jeddi[1], **Johannes Tolls Dir**[2], Eric Bergmann[2], Anastasia Weyrich[3], Petra Kern[4], Mathijs Smit[1], Jennifer Kreutz[5] and Sergio Leon Perez[6], (1)Shell Global Solutions International BV, Netherlands, (2)Henkel AG & Co, Germany, (3)BASF SE, Experimental Toxicology and Ecology, Germany, (4)Procter & Gamble, Belgium, (5)DuPont de Nemours, Luxembourg, (6)ECETOC, Belgium*

The European Union s Chemicals Strategy for Sustainability (CSS) aims to transition towards a safe and sustainable approach for chemicals. Central to this strategy is the Safe and Sustainable by Design (SSbD) concept, which promotes a holistic approach integrating safety, circularity, and functionality of chemicals, materials, products, and processes throughout their entire life cycle to minimize environmental footprints. SSbD is a rapidly evolving field requiring interdisciplinary collaboration and the integration of multiple perspectives and tools. Successful implementation depends on balancing regulatory requirements with business realities while maintaining a focus on meaningful safety and sustainability improvements. Despite the availability of numerous tools, challenges persist including identifying suitable tools and interpretations of assessments. The ECETOC Safe and Sustainability Task Force aims to evaluate existing tools from different perspectives including data requirements from supply chains, complexity of assessments, interpretation and comparison of outcomes, integration of safety and sustainability considerations, and clear boundaries in both safety and sustainability assessments through a series of case studies. These studies are designed to assess each tool s effectiveness and usefulness in real-world settings and to identify areas for refinement for safety dimentions. As a starting point, the task force has defined case studies using the ProScale tool as a Tier 1 assessment method for chemicals, mixtures, formulations, and articles to establish a methodology for comparing the safety of alternative product solutions and to evaluate the usefulness of the comparison outcomes. The proposed method focuses on formulations based on readily available safety information on ingredients, making it broadly applicable. This approach complements current methods, such as those tested by the Joint Research Centre (JRC), which focus on single chemicals and require extensive data and expertise.
This initiative seeks to bridge the gap between theoretical tool development and practical application. By inspiring and equipping stakeholders with the mindset, knowledge, and tools needed to drive meaningful change, it aims to ensure a safer and more sustainable future for both, humans and the environment. Additionally, it provides new ideas for testing of the advancements in practical case studies, deriving lessons learned, and showcasing success stories.

3.02.P-We175 Finding Practical Answers to Environmental Exposure Assessment Questions

***Johannes Tolls Dir**[1], Chris Bogi[2], Susan A Csiszar[3], Craig Warren Davis[4], Carolina Di Paolo[5], Sylvia Gimeno[6], Todd Gouin[7], Leen Jansen[8], Elke Jensen[9], Amanda Kuczynski[10], Diederik Schowanek[11], Mathijs Smit[12], Frederik Verdonck[13] and Matthias Wormuth[14], (1)Henkel AG & Co, Germany, (2)BASF SE, Germany, (3)Procter and Gamble, United States, (4)ExxonMobil Biomedical Science, Inc., United States, (5)Dow Benelux B.V., Toxicology and Environmental Research and Consulting, Netherlands, (6)DSM-Firmenich, Belgium, (7)TG Environmental Research, Sharnbrook, Bedfordshire, United Kingdom, (8)ARCHE Consulting, Belgium, (9)Dow Chemical, Toxicology and Environmental Research and Consulting, United States, (10)SC Johnson, Racine, Wisconsin, United States, (11)Procter & Gamble Brussels Innovation Centre, Belgium, (12)Shell Global Solutions International BV, Netherlands, (13)ARCHE Consulting, Ghent (Wondelgem), Belgium, (14)Syngenta Crop Protection AG, Switzerland*

"ECETOC s Targeted Risk Assessment (TRA) tool is a widely accepted screening tool to assess chemical exposure risks for workers, consumers, and the environment in a regulatory context (e.g., under the REACH Regulation).
ECETOC assigns high priority to maintaining the TRA tool as a trusted resource in chemical safety assessments and to advancing the science of exposure assessment as a whole. To drive progress in this

field, ECETOC has established three expert Task Forces focused on identifying and addressing key challenges in exposure assessment for workers, consumers and the environment using the latest science. Exemplifying ECETOC s versatility in working with partners, the TRA Environment Task Force has recently investigated the following two significant questions using diverse collaborative frameworks.

3.02.P-We176 SimpleBox in R: A Multimedia Fate Model for Molecules, Engineered Nanoparticles and Microplastics

Anne Hids, *Jaap Slootweg, Johannes Meesters, Matthias Hof, Valerie de Rijk, Yvette Agnes Maria Mellink, Lotte Bakker, Julius Defares, Thomas Breed, Joost Bakker, Eric Verbruggen and Joris T.K. Quik, Dutch National Institute for Public Health and the Environment (RIVM), Netherlands*

SimpleBox is a screening level multimedia fate model for chemical substances (molecules, engineered nanoparticles and microplastics) that supports (European) chemical regulation (e.g., REACH) and Life Cycle Impact Assessment modelling (e.g., ReCiPe). The model comprises of boxes, which represent environmental compartments at different geographical scales. The original versions (1993, 1996, 2004, 2016) are implemented in Excel, which allows easy adaptation for specific use, for instance a version for nanomaterials or microplastics. But such implementations have several disadvantages, most importantly version control of both the data and the model and limiting the use to calculating deterministic steady-state masses and concentrations. We present a novel implementation of SimpleBox in R that overcomes the mentioned disadvantages and has other advantages as a bonus.

The design of the R version is object-oriented enabling a single codebase for general and specific use, and easy integration with R-shiny as user-interface for users not specialized in programming. Furthermore, SimpleBox in R has the advantage that the fate process algorithms are transparent and easily adapted for the intended scenario. This supports further model development.

The main features of SimpleBox in R: the ability to estimate masses in compartments steady-state and dynamically, both deterministically and probabilistically. Concentrations are quickly calculated using the included concentration module. SimpleBox is easily coupled with emission models, such as material flow analysis (MFA) models, both dynamically and probabilistically. The model uses one code base for chemicals, nanomaterials and microplastics, containing functions specific to the substance types.

SimpleBox in R is available via https://github.com/rivm-syso/SBooScripts and https://github.com/rivm-syso/SBoo

3.02.P-We177 The Evolving Full Multi: Flexibly Simulating Microplastic Exposure in Aquatic Environments

Xiaoyu Zhang[1], *Michael Whelan*[2], *Antonia Praetorius*[3] *and Matthew MacLeod*[1], *(1)Department of Environmental Science, Stockholm University, Sweden, (2)School of Geography, Geology and the Environment, University of Leicester, United Kingdom, (3)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands*

Plastic pollution is pervasive in rivers, lakes and the global ocean, and threatens environmental and human health. The high complexity and heterogeneity of plastic pollution means it is challenging to monitor in the field, and understanding of source-to-concentration relationships is lacking. Computational models are essential for understanding the emission, transport and transformation of these novel entities in aquatic systems. The open-source Full Multi framework, first released in 2022, is a process-based mass-balance model that can comprehensively describe the behavior of microplastics with varying physical properties in multiple size ranges and multiple aggregation states in lakes, rivers or the ocean. First-order kinetics are used to describe the exchange of microplastic particles between model compartments. When applied to river systems, the model includes compartments representing flowing water at the surface, the flowing water column, stagnant water near the sediment surface, and sediments. In the original Full Multi model, the description of settling and mixing of plastic particles in rivers was simplistic - based on a generic parameterization of Stokes law - and failed to account for turbulent mixing. Here, we describe an improved description of mixing and resuspension in rivers in the Full Multi which relates vertical transport rates to river velocity. In the new version of the model, rates of microplastic deposition and erosion from bed sediment to the water column and burial in sediment are dependent on horizontal flow velocity of the river. Model results are consistent with expectations derived from the well-known Hjulström Curve and the dimensionless shear stress baseline. This suggests that the evolving Full Multi model will be able to dynamically simulate the fate and transport of microplastics in river systems, and ultimately, estimate microplastic transport rates from rivers to the oceans with better fidelity to the real environment.

Disclaimer/Disclosure: This research is funded by the Swedish Science Foundation (Vetenskaprådet) 2023-05085 (MÅPPET) and The European Chemical Industry Council (CEFIC) Long Range Initiative (CEFIC-LRI ECO48).

3.02.P-We178 Simulating Chronic Exposure to DEHP with a PBPK Model: First Steps Toward Aggregate Exposure with PK-Sim

***Lara Lamon**[1], Leonie Lautz[1], Stella Fragki[1], Raphaelle Lesage[1], Marco Siccardi[1] and Maryam Zare Jeddi[2], (1)ESQlabs, Germany, (2)Shell Global Solution, Netherlands*

Aggregate exposure (AE) is an individual s combined exposure to a single chemical by different routes of exposure (topical, oral, and inhalation) from various pathways (air, water, food, soil, dust, and contact with surfaces) that occur at other times and locations, as the result of multiple sources of exposure. AE varies across individuals, and over time, assessments of populations are described in terms of distributions of short-term doses (acute exposures) and long-term average doses (chronic exposures). Di-2-ethylhexyl phthalate (DEHP), an industrial chemical extensively used in polyvinyl chloride (PVC) plastics, presents a significant concern for AE assessment due to its widespread presence in consumer products such as shoes, gloves, packaging materials, building materials, pharmaceuticals, personal care products, food contact materials, paints, and adhesives.

In this study, we apply an open-source physiologically based kinetic (PBK) model, specifically PK-Sim, to predict the overall internal dietary and consumer AE of DEHP. PBK models are particularly relevant for AE assessments as they can account for exposure from various sources, routes, and timeframes, providing accurate estimations of exposure levels. Furthermore, PBK models can support the prediction of plasma and tissue levels across different populations and life stages, enabling quantitative estimates for individuals with higher exposure risks.

Our PBK model incorporates key parameters related to DEHP metabolism, including the synthesis of its hydrolysis product mono-2-Ethylhexyl phthalate (MEHP) and its elimination through renal excretion. By integrating available estimates of consumer and dietary exposure over prolonged periods, we aim to simulate chronic exposure scenarios more accurately.

To validate our model predictions, we propose a comparison with human biomonitoring data collected through the European Information Platform for Chemical Monitoring (IPCHEM). This comparison will assess the predictive capability of our PBK model in estimating internal doses of both DEHP and its metabolite MEHP.

By providing insights into DEHP exposure levels and dynamics, our study contributes to a better understanding of the potential health risks associated with this ubiquitous industrial chemical. Ultimately, these findings can inform risk assessment strategies and regulatory decisions aimed at mitigating DEHP exposure and safeguarding public health.

3.02.P-We179 Chemical Fate and Transport on Mars: Review of Key Processes to Inform Model Development

***John Daniel Hader**[1], Alberto Fairen[2], Marlene Ågerstrand[3], Matthew MacLeod[3] and Bernd Nowack[4], (1)EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (2)Centro de Astrobiolog a (CSIC-INTA), Spain, (3)Stockholm University, Sweden, (4)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland*

There is increasing interest among governments and private companies in sending humans to Mars in the coming decades. This would cause a massive increase in humanity's environmental footprint in the Martian environment compared to the total of 16 uncrewed robotic missions sent to Mars since the 1970s. A recent perspective highlighted the need to expand international requirements around contamination prevention on Mars which currently only cover microorganism contamination to address anthropogenically-introduced chemical and material pollution. As has been the case for policy setting on Earth, fate and transport modeling will be a key component of chemical and material management on Mars. In this study, we review processes in the Martian environment relevant for chemical and material fate and transport modeling, highlighting key differences with Earth-relevant processes. Examples of factors impacting chemicals include partitioning to dust and dust-borne transport, chemical interactions with CO2 surface ice and "snow" precipitation (known to occur in the Mars Polar Regions), and extreme temperature gradients in the near-surface environment (on the order of 30 K from the surface to 1.5 meters above the surface) which could impact partition ratios between air and dust at and near the surface. Furthermore, persistence of chemicals in the Martian environment would likely differ from that on Earth, considering the lack of (known) surface microbial activity, no surface hydrological processes, and a more intense radiation environment (e.g., UV-C). Regarding environmental processes impacting material fate and transport, the presence of UV-C radiation and intense dust erosion processes could result in differential micro- and nano-particle formation from bulk materials compared to Earth conditions.

Furthermore, the lower air density compared to Earth (6 hPa versus 1010 hPa) and the roughly one third gravity on the surface could impact particle long-range transport efficiency compared to Earth. Additional research is needed to improve understanding of these and other processes, prior to their incorporation into regional or planetary-scale fate and transport models. Such models will be key in informing the engineering or other mission requirements that should be incorporated into expanded regulations addressing chemical and material pollution on Mars.

3.02.P-We180 Critical Review of Measured Data and Models for Predicting Chemical Partitioning Properties

***Trevor N. Brown**, Jon A. Arnot and Alessandro Sangion, ARC Arnot Research and Consulting Inc. AND University of Toronto, Canada*

Physical-chemical property data are fundamental to determining chemical exposure and risk assessment. Among the most common partitioning properties required are the octanol-water (KOW), octanol-air (KOA), and air-water (KAW) partition ratios. Reliable physical-chemical property data are required for chemical evaluations and uncertainty is inherent whether the data are measured or modelled. The freely available on-line Exposure And Safety Estimation (EAS-E) Suite platform (www.eas-e-suite.com) contains approximately 85,000 discrete organic chemicals complied from regulatory programs world-wide. The experimental property data have been curated in this work and pre-calculated predictions from quantitative structure-property relationships (QSPRs) are provided for all chemical in the database. The QSPR packages with predictions are IFSQSAR, EPI Suite, and OPERA. Experimental measurements are only technically possible within a range of values, e.g., log KOW range from about -5 to 11, but QSPR predictions can span many of orders of magnitude outside of these bounds. Possible minimum and maximum values for the commonly used partition ratios are suggested which can be applied to flag QSPR predictions as unreliable. For data-poor chemicals the QSPR predictions are compared individually and as a consensus prediction to the experimental data in EASE Suite. In addition, the applicability domains of the predictions are investigated to determine which data-poor chemicals in the database have the most uncertainty in their predicted values and are in the most need of further research and experimental measurements. Chemicals which are large and are solids have the most uncertain partitioning properties, in addition certain chemical classes and functional groups are identified to have more uncertain p roperties.

Disclaimer/Disclosure: Funding from the American Chemistry Council Long-Range Research Initiative.

3.02.P-We181 Long-Range Transport Potential of Volatile Methylsiloxanes: Negligible Transfer and Accumulation in Remote Areas

***Jaeshin Kim**, Debra Ann McNett and Kathleen Plotzke, The Dow Chemical Company, United States*

The long-range transport potential (LRTP) of chemicals has been evaluated in source regions and remote areas. Since various pathways exist for the fate and transport of chemicals to remote areas without direct emissions, environmental multimedia models are essential for accurate LRTP assessments of different chemical compounds. For the assessment of LRTP of volatile methylsiloxanes (VMS), this study employed the Emissions Fractions Approach (EFA) that enhances the existing OECD Pov and LRTP Screening Tool. The EFA provides LRTP metrics in terms of fractions of dispersion (?1), transfer (?2), and accumulation (?3) in remote surface media, with threshold values recommended based on the assessments of existing persistent organic pollutants (POPs). Realistic emission scenarios for VMS as well as the three basic modes of emissions (100% to air, water, or soil) were evaluated with the model. Since LRTP of VMS is significantly influenced by the emission mode, a sensitivity analysis was also conducted. Due to unique physico-chemical properties of VMS (i.e., high volatility and high hydrophobicity), linear and cyclic VMS are predominantly distributed in air and may travel long distances in air, as indicated by dispersion fraction (?1) exceeding the threshold values. On the contrary, the fractions of transfer (?2) and accumulation (?3) for realistic emission scenarios of VMS are 10-100 times smaller than their maximum values from emission scenarios of 100% to air, water, and soil. More importantly, ?2 and ?3 for realistic emission scenarios are 2-4 and 3-6 orders of magnitude smaller than the respective threshold values, indicating that deposition to the surface media and accumulation of all tested VMS are expected to be negligible. Thus, it is highly unlikely that VMS would accumulate in remote environments.

3.02.P-We182 Seamless Forward Assessment of Toxic Risks in River Networks for Mixtures of Chemicals Originating from Wastewater Treatment Plant Effluents

*Olaf Buttner[1], Saskia Finckh[2], Nils Klüver[3], Dietrich Borchardt[1] and **Wibke Busch**[4], (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Chemicals in the Environment Research*

Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (4)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany
Chemicals in the aquatic environment can be harmful to organisms and causing toxic risks to the aquatic ecosystem. A main source of these chemicals are point sources (households and small industries), some are permanently introduced depending on the number of people connected to wastewater treatment plants (WWTPs), other have seasonal concentration differences. Especially at low water situations the toxic risk may increase due to lower dilution.
We test the hypotheses that the accumulated urban discharge fraction (UDF) in a river network is a robust proxy for the toxic risk induced by discharged chemicals. To prove this we used available catchment data like stream network and related WWTPs, the amount of wastewater and discharge data as well as data from a European reference mixture data set containing concentrations of chemicals typical in European wastewater treatment plant effluents. Based on these data we calculated mixing concentrations and toxic units for 80 chemicals, among them pesticides, biocides and pharmaceuticals, besides other typical wastewater-related compounds, such as sweeteners and corrosion inhibitors. Measured data (WFD, 2015 - 2021) at 87 stations in Thuringia were compared with the modelled ones and showed good correlations for pharmaceuticals and no correlation with pesticides. This data supports the identification of different sources of compounds occurring jointly as mixtures in aquatic systems which is important for pollution and risk management.

3.02.P-We183 Predicting the Input of Sunscreen Components into a Recreational Lake
***Farzaneh Hosseini**, Allan Philippe and Maxi Paleit, iES Landau, Group of Environmental and Soil Chemistry, University of Kaiserslautern-Landau (RPTU), Germany*
Sunscreens contain UV filters which vary in physical and chemical properties influencing not only their contribution to skin protection but also their environmental fate and potential toxicity. Common UV filters are titanium dioxide (TiO2) and zinc oxide (ZnO2), in nano scale, and organic molecules such as avobenzone, octinoxate and oxybenzone used in commercial sunscreens. These UV-filters are directly released into water bodies, especially recreational lakes, during bathing, where they can exert an adverse effect on aquatic microbial communities. Currently there is a lack of data about the pollution of these filters, especially inorganic ones, from sunscreen in recreational lakes. In particular, small lakes with long water retention times are expected to be especially sensitive to pollutions such as nano TiO2 because they are not biodegradable and dissolve only under extreme conditions. Therefore, it is urgent to estimate the concentration and input of UV-filters in recreational lakes to facilitate the ecological risk assessment. To address these issues, we modelled the amount of the released UV-filters in typical recreation lake in south Germany by combining information from survey, bathers monitoring, local weather data and experimental determination of the release from the skin (wash-off rate). The collected data were then used to train a predictive model to predict the amount of UV-filters released in the lake depending on the weather and the date and accounting for the adaptative behaviour of bathers. For example, collected data shows 76% of people visiting the study lake (Bassin des Mouettes, Lauterbourg, France) use sunscreens. Preliminary data of wash-off rate experiments indicates the maximum rate for inorganic UV filter, in this case n-TiO2, was almost 32%. The proposed model is a first essential step to determine the relevance of UV-filter released from bathers for lake ecosystems.

3.02.P-We184 Fate and Transport Modelling of Trifluoroacetic Acid in the Hudson and Cauvery Watersheds Due to HFO-1234ze(E) Emissions from Potential Pressurized Metered Dose Inhalers Usage
*Shivendra Tewari[1], Krish Vijayaraghavan[2], Kun Zhao[2], Liji David[2], Katie Tuite[2], Yuan Zhuang[2], Felix Kristanovich[2], Benjamin Yang[2], Cecilia Hurtado[2], Andrew Li[2], Shang Shi[2], Jaishree Gupta[2], Nida Rizvi[3], John Bell[4], Ian Ashworth[4], Andy Rignall[4], **Irene Bramke**[4], Paul Giffen[4], Megan Gibbs[1], Holly Kimko[1] and Stefan Platz[5], (1)AstraZeneca, United States, (2)Ramboll, United States, (3)Ramboll, India, (4)AstraZeneca, United Kingdom, (5)AstraZeneca, Switzerland*
HFO-1234ze(E) is a near-zero global warming potential, next-generation medical propellant in development for use in pressurized metered-dose inhalers (pMDIs). HFO-1234ze(E)-containing pMDIs have a very low carbon footprint akin to a dry powder inhaler. Due to the presence of a CF3 moiety within its structure, atmospheric degradation of HFO-1234ze(E) is recognised to liberate low levels of trifluoroacetic acid (TFA). To quantify the levels of environmentally formed TFA following HFO-1234ze(E) emissions from future pMDIs, we used TFA deposition fluxes from the global model around the Hudson (USA) and Cauvery (India) watersheds to estimate total TFA accumulation in surface water of these rivers due to 20-years of continuous HFO-1234ze(E) emissions from future pMDI usage. Our detailed watershed modelling predicts that the resultant concentration of pMDI-based TFA in Hudson River subbasins would vary between 0.002 0.005 ppb. In comparison to the Hudson, watershed modelling

over the same period predicts slightly higher accumulation of TFA in surface water of the Cauvery River, varying between 0.009 0.019 ppb. Analysis of TFA mass allocation suggests that the larger increase in TFA accumulation in the Cauvery watershed (which has lower HFO-1234ze(E) emissions than the Hudson) is likely to be due to lower transport of TFA into the oceans (Hudson: 63% of TFA was deposited in ocean; Cauvery: 19% of TFA was deposited in ocean). Using the German Environment Agency s precautionary measure for TFA in drinking water (10 ppb), these results suggest that the Margin of Exposure (MoE) for TFA due to future usage of pMDIs is 2000 in the Hudson watershed and 500 in the Cauvery watershed.

3.02.P-We185 An Attempt at Model-Based Comparative assessment of PFAS Exposure Potential

***Monami Kondo**, Kazuya Inoue, Shigeki Masunaga and Wataru Naito, National Institute of Advanced Industrial Science and Technology, Japan*

The environmental and human risks of per- and polyfluoroalkyl substances (PFAS) is drawing considerable attention both scientifically and from regulatory perspectives. There are numerous types of PFAS in society, many of which contribute to improving our quality of life. Regulating all these compounds simultaneously is impractical. Although the amount of biomonitoring data on specific PFAS, such as PFOS and PFOA, is increasing, the exposure levels of many PFAS remain unknown. To prioritize which PFAS compounds require risk management in the future, exposure and risk assessments based on realistic scenarios are essential. While a modeling approach could be effective in evaluating the effectiveness of measures such as substance substitution, there are currently few assessments focused specifically on PFAS. Additionally, there are very few studies evaluating the applicability of models, originally developed for persistent organic chlorinated compounds, to PFAS. In this study, we aimed to assess and compare the exposure potentials of PFASs using existing exposure models. We report on the results of the comparative exposure assessment of various PFASs based on model-based approach under specific environmental scenarios. In the presentation, we will discuss the advantages and limitations of the model-based exposure assessment for PFASs, as well as the areas where further research is needed, based on the results of the comparative assessment under specific environmental scenarios.

3.02.P-We186 Investigating Mosquitoes as Bioindicators for PFAS Contamination Across Environmental and Biological Systems

***Isabella Beasley**, Michella Paige Salvitti, Joseph Pitula, Mobolaji Okulate and Eguono Wayne Omagamre, University of Maryland Eastern Shore, United States*

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental contaminants resistant to degradation. Their bioaccumulation in ecosystems and biomagnification in organisms pose significant toxicological and reproductive risks to wildlife. In humans, PFAS exposure is increasingly associated with damage to the liver, kidneys, and reproductive systems. The detection of PFAS in human blood serum raises public health concerns; however, comprehensive monitoring is limited by resource constraints and challenges in reaching underserved populations. This study aims to assess the feasibility of using mosquitoes as biomonitoring tools for PFAS exposure, investigating their potential to reflect environmental and biological contamination. We evaluate whether mosquitoes acquire PFAS through blood feeding and examine the contribution of environmental exposure to their PFAS body burden. To distinguish between these pathways, mosquitoes are reared in PFAS-spiked water to adulthood to determine the extent of PFAS uptake from water. A separate colony, reared in uncontaminated water, is fed blood meals spiked with the same PFAS mixture to assess uptake via blood feeding. Field collections of adult mosquitoes from five sites near sewage treatment plants on Maryland s eastern shore were analyzed for PFAS compounds using liquid chromatography-mass spectrometry (LC-MS) based on EPA Method 1633. Preliminary data revealed total PFAS loads ranging from 12.5 to 78.7 ppb across the sites, identifying 14 unique PFAS compounds. PFOS was the most prevalent, with an average concentration of 17.3 ppb (±2.6). Long-chain PFAS dominated the samples, with three short-chain types also detected. Of these, eight were carboxylates, two were sulfonates, and three were fluorotelomers. Preliminary findings demonstrate that mosquitoes naturally accumulate PFAS, suggesting their potential as biomonitoring tools. By evaluating PFAS uptake through environmental exposure and blood feeding, this study lays the foundation for future investigations into mosquitoes suitability as bioindicators of contamination in diverse settings.

3.02.P-We187 Helping the Risk Assessor: Improvements to Tools for Environmental Risk Assessments of Metals

*Iain Wilson[1], Graham Merrington[1], **Adam Peters**[1], Elizabeth Middleton[2], Chris Cooper[3], David Boyle[4], Stijn Baken[5], Jasim Chowdhury[6], Jelle Mertens[7], Paul Marsh[8], Kelly E Croteau[9] and Charlotte Nys[10], (1)wca environment Ltd, United Kingdom, (2)NiPERA Inc, United States, (3)International Zinc*

Association, Belgium, (4)Cobalt Institute, United Kingdom, (5)International Copper Association, Belgium, (6)International Lead Association, United States, (7)European Precious Metals Federation, Belgium, (8)International Aluminium Institute, United Kingdom, (9)Windward Environmental LLC, Seattle, United States, (10)ARCHE Consulting, Belgium
A tiered approach under the European Water Framework Directive has been developed for implementing bioavailability-based Environmental Quality Standards (EQS) for metals. As part of Tier 2, simplified tools to account for bioavailability can be used. bio-met is one of the simplified tools that has been developed for use as part of Tier 2 to assess the potential freshwater risks and compliance with EQSbioavailable for cobalt, copper, nickel, lead and zinc. While Tier 2 provides an opportunity for the use of simplified tools it has certainly been the case that simplified tools have not always been simple or user friendly. To use bio-met, freshwater chemistry data is needed; although large amounts of data are generated by environment agencies, data are not always publicly available or in a format that is easy to use. To remedy this, the EU Physicochemical Database Tool was launched in 2020 containing freshwater monitoring data from European countries to assist practitioners in performing risk assessments. Data are continually being generated; thus, it is important that the database is routinely updated and that the spatial coverage is as extensive as possible to deliver continent-wide assessment of potential metal risks.

Based on feedback from users, bio-met has been extensively updated covering both scientific and useability updates. The applicability range of bio-met has been increased for nickel, zinc and cobalt via updates to the full Biotic Ligand Models (BLMs) and the look-up tables within bio-met. Additionally, an assessment of when bio-met provides outputs has been performed, and the conditions where predictions are provided have been refined. Useability updates have also been integrated to include metal selection, result export functionality, clearer guidance, and a built-in hardness conversion tool.
The EU Physicochemical Database has been updated with an additional 36 datasets, covering 33 European countries, and encompasses over 2,300,000 additional samples (compared to ~1,000,000 after the initial compilation) from more than 84,000 sites. All monitoring data have been reliability and relevance assessed for inclusion in the database.
The updates to both bio-met and the Physicochemical Database have been designed to improve the user experience in applying regulatory guidance, with a goal of increasing useability and ensuring high-quality, evidence-driven conclusions can be made when evaluating the potential risks of metals in European waters.

3.02.P-We188 Dietary Exposure Estimation: A Probabilistic Approach for Exposure Assessment to Pesticide Residues Across Europe
Shiva Sabzevari[1]*, Daniel M. Figueiredo*[2]*, Anke Huss*[2] *and Jakub Hofman*[1]*, (1)RECETOX, Masaryk University, Czech Republic, (2)Institute for Risk Assessment Sciences (IRAS), Utrecht University, Netherlands*
Accurate dietary exposure assessment is vital for understanding the health implications of pesticide residues in food. Pesticides frequently occur in the foods people consume daily, resulting in constant exposure via their diets. While dietary exposure has been extensively addressed using conservative approaches as part of risk assessment studies, realistic levels of dietary exposure to pesticides among the European population remain underexplored. Furthermore, the presence of unquantifiable pesticide residues in food commodities, which frequently arises from the limitations of analytical methods, detection thresholds, and instrumentation capabilities, results in a substantial portion of residue data being missed. This issue further compounds the challenge of accurately estimating the true levels of dietary pesticide exposure.
To address the above-mentioned gaps and challenges, this research offers a comprehensive probabilistic estimation of human dietary exposure to pesticides, incorporating the complete range of residue concentrations detected in food commodities. This approach, verified against measured pesticide concentrations in duplicate food portions, offers a more accurate representation of pesticide intake among the European population.
To achieve this goal, open-access datasets from the European Food Safety Authority (EFSA) on pesticide residue concentrations and food consumption were utilized. An integrated computational approach was employed to impute undetectable residues (below the limit of quantification). A Monte Carlo simulation framework was then applied to combine the imputed residue concentrations with food consumption data. This produced probabilistic exposure distributions that capture variability across demographic groups and dietary patterns in European countries from 2011 to 2020.
Our approach enhances precision by moving beyond deterministic estimates to probabilistic modeling. It provides useful information not only for regulators seeking a more nuanced understanding of potential

dietary risks but also for epidemiological research and studies requiring the evaluation of temporal or spatial trends in dietary exposure.

3.02.P-We189 A LLM-Based Toolbox for Automated Text Mining on the Uses of Chemicals

Huadong Xing[1], *Zhanyun Wang*[1] *and Bernd Nowack*[2], *(1)EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (2)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland*

Chemical and material technologies are integral to modern life, offering countless functionalities. However, many chemicals and materials pose risks to human health and the environment. Assessing their safety and replacing hazardous substances with safer alternatives is critical but challenging. Globally, over 350,000 chemical substances are registered for use, yet fewer than 25% have undergone safety assessments. A significant barrier to the assessment and management of chemicals is the lack of accessible and reliable data on chemical uses. Such data are crucial for evaluating potential environmental releases, human exposure, and designing safer alternatives. Current manual approaches to collating such information are time-consuming and prone to omissions. This study presents a novel toolbox leveraging fine-tuned large language model (LLM) to systematically extract and map chemical use data from scientific and regulatory texts. This approach facilitates exposure modeling and improves safety assessment workflows.

The toolbox is built upon a fine-tuned LLM optimized for chemicals. It uses natural language processing (NLP) techniques, including named entity recognition (NER), relationship extraction, and context-aware classification, to identify chemical entities, usage contexts and relevant parameters. The model was trained on a curated dataset of peer-reviewed publications and public databases. Post-processing modules structure the extracted data for downstream exposure modeling applications. Future work will focus on expanding the model s training corpus, improving multilingual capabilities, and integrating predictive features for emerging chemical applications.

3.02.P-We190 Determination of Vial Surface Contamination of Commonly Used Antineoplastic Drugs in Türkiye by LC/MS-MS Method

Orhan Ziya[1], *Tuba ReCber*[2], *Emirhan Nemutlu*[2] *and Merve Gudul Bacanli*[1], *(1)University of Health Sciences Turkey Gulhane Faculty of Pharmacy Department of Pharmaceutical Toxicolgy, Turkiye, (2)Hacettepe University Faculty of Pharmacy Department of Analytical Chemistry, Turkiye*

The number of people diagnosed with cancer is increasing worldwide. Accordingly, the use of antineoplastic drugs is also increasing. It is known that antineoplastic drugs pose a risk to the personnel working in the process from the production stage to the disposal of their wastes and regulations have been implemented to eliminate this risk. This study aims to determine the levels of drug contamination and cross-contamination on the surfaces of vials containing six commonly used antineoplastic drugs active ingredients in Türkiye: 5-fluorouracil, doxorubicin, etoposide, gemcitabine, ifosfamide, and cyclophosphamide. Samples were taken from the vial surfaces of the drugs by wiping method and analyzed by LC/MS-MS. Based on the analysis results, a statistically significant level of contamination/cross-contamination was detected on the vial surface of the drug with six different active ingredients used in the Turkish market with the active ingredient of the drug and other cytotoxic drug active ingredients originating from the production process. Contamination with the active drug substance was detected in 41 out of 65 samples (63.08%), and cross-contamination with other drug active substances was found in 37 out of 75 samples (49.33%). The highest contamination level was detected on the surface of a 5-fluorouracil vial at 2276.920 ng/cm^2 / 133199.848 ng/vial. The presence of drug vials in which no contamination was detected indicates that contamination can be prevented to a very high extent if the necessary precautions are taken during the production phase. In order to precisely demonstrate the prevalence of contamination, there is a need to conduct studies with antineoplastic drugs with active ingredients other than the six active ingredients used in the study.

Disclaimer/Disclosure: This study was supported by the University of Health Sciences Scientific Research Projects Unit (BAP 2023/080).

3.02.P-We191 Aerosol Deposition and Risk Assessment from Humidifier

Yurim Choi[1], *Ha Ryong Kim*[2] *and Jung-Hwan Kwon*[1], *(1)Division of Environmental Science and Ecological Engineering, Korea University, Republic of Korea, (2)College of Pharmacy, Korea University, Republic of Korea*

Humidifier is widely used in daily life, and the aerosols they generate can enter the respiratory system. This study aims to calculate the mass concentration and regional deposition of aerosols in the respiratory tract from a humidifier and explore their relationship with 3D cell models for in vitro toxicity assessment. Benzalkonium chloride (BAC), didecylmethylammonium chloride (DDAC), polyhexamethylene guanidine (PHMG), and paraquat were selected as test substances and were dispersed using an ultrasonic humidifier. Aerosol distribution in the 0.01–10 µm range was measured over 60 minutes using scanning mobility particle sizer (SMPS) and optical particle sizer (OPS) in a 0.125m³ acrylic test chamber. Deposition fractions for different respiratory regions were calculated using the multiple path particle dosimetry (MPPD Ver 3.04) model by US EPA, and the deposition mass was derived accordingly. For BAC, the deposition mass in the head, tracheobronchial, and pulmonary regions was calculated as 3.81×10^{2}, 1.29×10^{1}, and 1.04×10^{-1} µg/cm², respectively. DDAC showed deposition values of 1.14×10^{4}, 5.96×10^{1}, and 4.97×10^{-1} µg/cm². The largest deposition occurred in the head region and the smallest in the pulmonary region, implying removal of larger particles in the upper respiratory tract (URT). The proposed approach can be used to convert ambient concentration resulted from continuous emission by a humidifier into internal dose at different respiratory tissues, relating to the external exposure concentration and the dose metric used for in vitro test assays.

Disclaimer/Disclosure: This research was supported by "Development of in vitro inhalation (respiratory) toxicity testing methods for biocide" through the Korea Environmental Industry & Technology Institute(KEITI) funded by the Ministry of Environment (MOE).

3.02.P-We192 Enabling Improved Worker Exposure Modeling During Powder Handling Operations

*Floris Pekel, Xavier Pinho and **Neeraj Shandilya**, TNO, Netherlands*

Dust generated during powder handling is a major worker exposure risk. The "dustiness" of a powder its tendency to become airborne is key in determining exposure levels. Current exposure models depend on dustiness estimates or measurements, but obtaining accurate dustiness measurements is often time-consuming, leading to overly conservative exposure predictions.

To address this, we report the first development of an in silico dustiness prediction model which is inter-operable with existing exposure or risk assessment models. The model estimates the relative change in the dustiness with the change(s) in physiochemical properties of a powder and the energy applied during its handling. The first results from testing the model with eight commercial powders showed both mass-based and number-based dustiness estimates to be generally underestimated, with experimental values mostly falling out of the 95% confidence interval. However, when used with exposure models (e.g., ECETOC-TRA, Stoffenmanager, ART), these estimates led to more accurate, less conservative exposure predictions. Though promising, the model currently offers semi-quantitative estimates and requires further development for absolute dustiness quantification, specifically to refine/alleviate some of the underlying assumptions about powder flowability and interdependencies between powder properties.

Aligned with a tiered approach, the model supports safe-by-design principles from early innovation stages, allowing users to optimize powder and process parameters to reduce exposure. When developed as a fully quantitative model, future prospects can include integrating it with PBPK or MPPD models to translate external exposure levels into internal organ concentrations.

Disclaimer/Disclosure: The work was supported by the EU s Horizon 2020 HARMLESS project under grant agreement No 953183.

3.02.P-We193 Assessment of PM1-Bound PAH Levels in a Primary School: A Comparative Study of Mechanical and Natural Ventilation

***Çağrı Şahin**[1], Begum Can Terzi[1], Nur Cobanoglu[2], Ziya Haktan Karadeniz[3], Aysun Sofuoglu[4] and Sait C. Sofuoglu[1], (1)Department of Environmental Engineering, Izmir Institute of Technology, Turkiye, (2)Department of Management and Engineering, University of Padua, Italy, (3)Department of Energy System Engineering, Izmir Institute of Technology, Turkiye, (4)Department of Chemical Engineering, Izmir Institute of Technology, Turkiye*

Indoor air quality in primary schools significantly impacts children's health due to their physiological vulnerabilities and extended indoor exposure. This study investigated PM1 and PM1-bound PAH concentrations in two primary school classrooms - one with mechanical ventilation (MV) and one with natural ventilation (NV) - in an industrial area exposed to vehicular emissions and residential combustion. PM1 samples were collected using Harvard impactors during 50 days of the fall academic term, with PAH analysis performed via GC/MS. Results showed that MV maintained more stable PM1 levels (2.75-25.5 µg/m³) compared to NV (2.17-198.2 µg/m³) and outdoor environments (1.39-182.5 µg/m³). Total PM1-bounded PAH concentrations were highest outdoors (9.30 ± 8.29 ng/m³), followed by NV (3.93 ± 4.57

ng/m³) and MV (2.57 ± 1.76 ng/m³). Naphthalene and benzo[a]anthracene were the predominant PAH compounds. CFD analysis revealed optimal ventilation performance at 30° diffuser angles. The study demonstrates that mechanical ventilation effectively reduces PM1 levels and recommends upgrading to F9 filters for enhanced PM1 capture while highlighting the importance of diffuser angle optimization for uniform air distribution.

Disclaimer/Disclosure: This research was supported by The Scientific and Technological Research Council of Türkiye (TÜBITAK) under Grant No. 120R040.

3.02.P-We194 Estimating Global Spatially Resolved Marine Emissions and Exposure to Down the Drain Chemicals

*Juliet Hodges[1], Christopher M. Holmes[2], Logan Insinga[2], Simran Sandhu[3], David Sheffield[3], Emma Langley[4], Richard Dannatt[4], **Geoff Hodges**[5] and Kevin Mcgovern[4], (1)Safety & Environmental Assurance Centre, Unilever, United Kingdom, (2)Applied Analysis Solutions LLC, United States, (3)Unilever, United Kingdom, (4)Intertek Metoc, United Kingdom, (5)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom*

Domestic wastewater discharged to the environment may contain chemical substances that are the result of human activity. While many discharges are to freshwater rivers and lakes, some facilities in coastal areas discharge directly into the marine environment. however many down-the-drain exposure models assume 100% of the chemical mass discharged from STPs or untreated populations is released into the freshwater environment A dataset was developed to understand what fraction of the population in coastal areas are served by STPs that discharge directly to a marine environment. Information on STP location, population served, and effluent flow were collected for 44,000 STPs across 34 countries serving almost 800 million people.

Chemical substances are also discharged into freshwater which then may travel through the hydrological network to the marine environment. Hydrologic travel distance/time for each inland STP as well as untreated mass was developed along with estimated aquatic half-lives, to estimate discharges into rivers moving to coastal waters. The developed emission model is a mass balance model.

The third phase of the study developed two exposure models for 3436 regions covering 75 coastal countries to generate Predicted Environmental Concentrations (PEC s). The Moving Prism Model is a steady-state box model that calculates a PEC by advecting a triangular wedge of coastal water past a chemical discharge point, with the speed of advection being determined by net ambient current speeds using bathymetry data, long term (365-day average) scaler current speeds and near coast hydrodynamics. The Mixing Zone Model is an alternative steady-state box model that calculates a PEC should a chemical be discharged into still water (i.e., with no ambient current speed). Some initial comparisons to monitoring data show good agreement.

This work shows that it is possible to use country-based datasets including geo-referenced STP and wastewater discharge types to refine emissions estimates for use in environmental exposure models and risk assessments at a refined sub-country spatial scale.

The exposure model provides a screening level, globally-consistent approach for assessing the potential impact of down-the-drain chemicals on the marine environment. These models generate estimates of Predicted Environmental Concentration and represent an intermediate level between generic, multi-media models and detailed, data hungry process-based models.

3.03.A Measuring, Modelling and Monitoring the Environmental Behaviour and Exposure of Pesticides

3.03.A.T-01 SPOTMOD: Modelling the Reduction Effect of Spatially Distributed Spot Applications on Pesticide Runoff Losses with a 2D Probabilistic Framework

*Rafael Munoz-Carpena[1], Jorge Olivares-Rivas[2], **Stefan Reichenberger**[3], Tyler J. Schultz[1] and Robin Sur[4], (1)University of Florida, United States, (2)knoell Germany GmbH, Germany, (3)knoell France SAS, France, (4)Bayer AG, Germany*

Field spot treatments of agrochemicals, e.g., by automated weed detection in combination with precision application technology, can significantly reduce chemical application rates in the field. Localized, high-resolution chemical application reduces off-field drift and surface runoff to adjacent water bodies and terrestrial habitats. While quantification of drift reduction is advancing, very limited work exists for the quantification of potential pesticide runoff reduction from spot application practice in the regulatory context.

Particularly for crops with dense surface cover (e.g., cereals), the untreated field area can act as a sink for dissolved and adsorbed pesticides before the surface runoff exits the field. Part of the difficulty in quantifying the potential reduction of pesticide runoff stems from the (quasi-)random pattern of spot applications on the field during each crop season and across years during long-term regulatory assessments. A new 2D mechanistic-probabilistic modeling framework, SPOTMOD, has been developed that considers (1) sources: pesticide runoff generation from treated spots in the field, (2) sinks: infiltration, sedimentation and pesticide trapping on downslope segments (after spots) of the field, (3) variable vegetation conditions during the cropping period and their effects on infiltration and sedimentation, (4) variable spot size and treated area fraction, (5) variable spatial application patterns (random, quasi-random and observed), (6) long-term exposure calculations (PECsw). In a first step, an application pattern on the field is generated based on spot size and treated area fraction. The field is then divided into strips in slope direction with the same width as the treated spots. These strips are subsequently simulated with a coupled PRZM-VFSMOD modelling system, which can deal with complex sequences of treated spots (sources) and untreated areas (sinks) along the flow path. For each runoff event, the edge-of-field runoff hydrographs and associated sediment and pesticide loads are summed up and fed into a TOXSWA metamodel. Different realizations of the application pattern allow to construct a probability distribution of PECsw for each event and thus identify realistic worst-case application patterns. Parallel optimization of SPOTMOD on a High-Performance Computer allows for systematic exploration of key settings. An end-user solution around a metamodel created from millions of runs is also developed for quick assessments.

3.03.A.T-02 Harmonised Framework for the SETAC Spatially Distributed Leaching Modelling of Pesticides Initiative: 2025 Update

Aaldrik Tiktak[1]*, Anton Poot*[2]*, Bernhard Jene*[3]*, Gerco Hoogeweg*[4]*, Maarten Braakhekke*[5]*, Louise Wipfler*[5]*, Pavan Cornelissen*[5]*, Judith Klein*[6]*, Michael Stemmer*[7]*, Amy Ritter*[8]*, Robin Sur*[9]*, Gregor Spickermann*[10]*, Gerard Heuvelink*[11]*, Gregory Hughes*[12]*, Stephan Marahrens*[13]*, Stefan Reichenberger*[14]*, Nicoleta Suciu*[15] *and Michelle Morris*[16]*, (1)PBL Netherlands Environmental Assessment Agency, Netherlands, (2)Ctgb, Netherlands, (3)BASF, Germany, (4)Modeling, Corteva Agriscience, Moon Township, United States, (5)Wageningen Environmental Research, Netherlands, (6)Fraunhofer, Germany, (7)AGES, Austria, (8)Waterborne, United States, (9)Bayer AG, Germany, (10)Adama, Germany, (11)ISRIC, Netherlands, (12)GeoSpatial Analytics, United Kingdom, (13)UBA, Germany, (14)knoell, Mannheim, Germany, (15)University of Piacenza, Italy, (16)Health & Safety Executive Chemicals Regulation Division, United Kingdom*

Spatially Distributed Leaching Modelling (SDLM) of pesticides is a methodology to estimate the leaching potential over a large spatial extent such as national or European scale. SDLM can help to put groundwater monitoring programs into context. It is described in the FOCUS groundwater report and foreseen to be used as a higher tier leaching risk assessment. SDLM is already used as a higher tier assessment in the national authorization procedure in some EU countries and will probably become more important in the future. At the SETAC Europe 2020 online meeting, the initiative was officially formalised as a SETAC working group, consisting of a triad of members from regulatory agencies, academia, and the private sector. The main products of the working group will be a harmonised modelling framework including the data needed to run these models, and documents describing the use of the framework in regulatory assessments. The framework will serve two different tiers of the groundwater risk assessment scheme, i.e., Tier-3b and Tier-4. This year we will present final results for both tiers of the risk assessment scheme.

At Tier-3b, the leaching models PEARL and PELMO were used to calculate the 80th-percentile of the leaching concentration at 1-m depth in each FOCUS zone. The models were run for approximately 10,000 scenarios. These scenarios are unique combinations of land-cover, climate and soil data. Results show that the leaching concentration simulated at Tier-3b is generally lower than the leaching concentration simulated for the FOCUS scenarios at Tier-1 of the groundwater assessment scheme. This means that the FOCUS scenarios are sufficiently conservative and that an update of these scenarios is not necessary.

At Tier-4, SDLM can be used to set monitoring sites into context. For this purpose, simulations will be carried out with PEARL and/or PELMO for each of the monitoring sites. In these simulations, site-specific soil, crop and climate data will be used. The simulated leaching concentration will be plotted at the cumulative frequency distribution of the leaching concentration simulated with SDLM to show if the monitoring sites represent vulnerable conditions. During the presentation at the SETAC 2025 Annual Meeting, a real-world example will be shown.

3.03.A.T-03 Using Different Spatial Layers to Derive pH Values for Modelling: A Critical Review of EFSA's Spatial Dataset

Fabrizio Rama[1]*, Fabienne Ericher*[1]*, Gregor Spickermann*[2]*, Sebastian Gebler*[3]*, Nils Kehrein*[4]*, Raghu Vamshi*[5] *and Dieter Schaefer*[6]*, (1)Syngenta, United Kingdom, (2)ADAMA Agricultural Solutions Ltd,*

Israel, (3)BASF SE, United States, (4)Division Crop Science, Bayer AG, Research Triangle Park, United States, (5)Corteva Agriscience, United States, (6)Bayer AG, United States
Regulation 283/2013 mandates the investigation of chemical fate and behaviour in soils across three pH ranges (pH 5-6, 6-7, and 7-8 in CaCl2 solution) to assess the potential of pH dependency. When pH-dependent behaviour is identified, it must be incorporated into the risk assessment. However, current guidelines lack standardised methods for deriving modelling parameters in that case. For this reason, a spatial analysis of the available geodata layers of pH in Europe is presented (EFSA 2012, ESDAC/JRC 2019), to assess their accuracy against real soil measurements (LUCAS 2018). This work aims to check the robustness of the 10th- and 90th-percentile estimations of pH on arable land, using the EFSA spatial dataset, proposed as an option to estimate substance properties in the risk assessment. The results showed it was possible to replicate the values suggested by EFSA 2020 at the EU scale (EU: 5.1,6.5,8.0) but not the figures provided by UBA at the regulatory zone level (Northern: 4.4,6.2,7.5; Central: 5.1,6.5,7.8; Southern: 5.4,6.9,8.0). This suggests a methodological inconsistency in the derivation of endpoints, which needs to be addressed before guidance on pH dependency is noted. The work also indicated that changing the geodata layers used in the analysis affects heavily the derivation of modelling endpoints. It demonstrated, once again, that the EFSA spatial dataset has the worst fit vs real data, compared to any other geolayer available at the moment in Europe ($R2 = 0.32$ of EFSA 2012 vs $R2 = 0.61$ of ESDAC/JRC 2019). The comparison with other geodata layers also suggested conceptual flaws in the use of categorical values (i.e., median of the pH distribution for a soil) applied to extended regions, as done in EFSA 2012, for statistical purposes. Given that the EFSA spatial data are a cornerstone in several recent guidance developments, the outcomes of this work highlighted how discussing the quality of geodata is not only a technical issue of the GIS community but has far-reaching regulatory implications in e-fate. Therefore, the authors urge a broader scientific discussion around the use of GIS layers in risk assessment of plant protection products, to reduce the gap between regulatory requirements and agronomical realities, by considering the most recent advances in soil mapping in Europe and setting a version control group like the FOCUS one

3.03.A.T-04 Conduct and Use of a Tier 4 Monitoring Programme in the FOCUS Regulatory Framework

George Mahoney[1]*, Fabrizio Rama*[1]*, Sarah McManus*[1] *and Victor Rincon*[2]*, (1)Syngenta Crop Protection, United Kingdom, (2)Syngenta Crop Protection, Spain*
Groundwater (GW) monitoring is the highest tier (Tier-4) in the leaching assessment of plant protection products in Europe, providing a realistic exposure assessment, and, if well-performed, can be used to prove safe uses in risk assessments. Given a current lack of European guidance, uncertainties remain about Tier-4 interpretation, deterring broader implementation of monitoring in the regulatory process. Nonetheless, uncertainties can be addressed scientifically and pragmatically, to reduce reliance on arbitrary safety factors which deviate from established FOCUS framework approaches. An open scientific discussion on FOCUS Tier-4 data assessment is presented using data from an in-flight pan-European programme. The rationale behind this work is to gain a robust and realistic understanding of environmental GW concentrations that maintains the consistency of the FOCUS scheme across tiers. The study, conducted since 2015, collected thousands of samples from 70 edge-of-field sites in vulnerable cereal regions across the EU. The network assessed pinoxaden and its metabolites in shallow GW under actual use conditions and practices. Sites were selected in vulnerable regions that also had cereal cropping and shallow GW, aiming for an approximate 90th overall percentile of vulnerability. Various uncertainties identified post-initiation, including hydraulic connectivity, GW flow variability, and differences between intended/actual uses, were subsequently addressed during the life of the programme. Thus, to maintain consistency across FOCUS tiers, the 80th percentile of the annual average concentration was calculated, along with the 90th overall percentile of all the samples in each regulatory zone (using both original concentrations and those normalized to account for different application rates and frequencies). This specific pinoxaden programme demonstrates that interpretation of monitoring data for the FOCUS Tier-4 assessment can be robust and scientific, and can be made sufficiently vulnerable through purposeful design choices. Targeted, conservative monitoring programmes represent a robust and realistic approach to data generation that is coherent within the tiered FOCUS framework and add evidence to support and prove safe uses at the European level. This approach reinforces scientific robustness and public confidence in a well-established tiered risk assessment approach that includes environmental GW monitoring in risk assessment and management decisions.

3.03.A.T-05 Steps Toward a Re-validation of Methods and Models Used in the Risk Assessment of Plant Protection Products in the Light of Climate Change

Gunnar Kahl[1]*, Kristina Bohm*[1]*, Stefan Reichenberger*[2] *and Nadja Stadlinger*[3]*, (1)knoell Germany GmbH,*

Germany, (2)knoell France SAS, France, (3)Kemikalieinspektionen, Sweden
Many methods and models used in the risk assessment of plant protection products (PPP) (under Regulation (EC) No 1107/2009) were developed more than 20 years ago, describing the environmental and agricultural conditions at that time or prior to that time. The project had the objective to identify climate-sensitive parameters and processes, perform a gap analysis and define work packages to enable the Nordic zone to reevaluate and possibly adapt the current risk assessment to be fit for purpose in the coming decades.
Responsible authorities of member states (MS), industry, and research institutions were contacted about relevant projects. Their feedback was evaluated and summarised. A list of climate-sensitive parameters and procedures used in the risk assessment was compiled and prioritised for importance or impact. To identify the direct impact of climate data on Predicted Environmental Concentrations in groundwater (PECgw) an impact assessment of two climate projections for the FOCUS PELMO Hamburg scenario was performed for nine test substances with varying soil DT50 values and KFOC values. A gap analysis was performed to identify the information lacking to assess whether the climate-sensitive parameters used in the risk assessment are still representative, in which way they are expected to be changed, and to specify further work and specific tasks that need to be performed to conclude on these points.
The direct impact assessment of changed weather data in PELMO yielded that PECgw values decreased with increasing temperature despite increasing rainfall. Temperature changes enhance degradation and evapotranspiration, while precipitation changes increase leaching. Changes in rainfall intensity were not considered in this exercise.
Indirect impact is expected from changes in soil microbial communities due to drought and flooding, shifts in agronomic dates or an extension of agricultural land further north into potentially vulnerable areas. Further it is expected that new management practices will become more important. This may include precision farming techniques like application via drones and spot applications, and mitigation options such as micro-dams or conservation tillage.
Prioritised work packages were identified for the authorities in the Nordic zone including literature reviews, updates and development of guidance, updates of weather files and agronomic dates in FOCUS, as well as re-evaluation of the relevance of FOCUS crops and scenarios.

Disclaimer/Disclosure: The project was assigned to knoell group by the Swedish Chemicals Agency (KEMI) after a direct procurement and is funded by the Nordic Working Group for Chemicals, Environment and Health (NKE)

3.03.B Measuring, Modelling and Monitoring the Environmental Behaviour and Exposure of Pesticides

3.03.B.T-01 EFSA Drinking Water Treatment Guidance – Approaching the Environmental Exposure Assessment

Lydia Pape *and Kristina Hoffmann, knoell Germany GmbH, Germany*
The new EFSA guidance document (GD) on drinking water treatment assessment will be applicable for plant protection products (PPP) active substance (a.s.) (re)approval dossiers submitted on or after 1 April 2026. It is applicable to all uses with emissions to groundwater (gw) and/ or surface water (sw) for the a.s. and all metabolites listed in the residue definition for gw and sw. Applicants are facing tight timelines and high workload due to the overall complexity of the GD and the additional requirements for the environmental exposure assessment (EEA). In this presentation, we will discuss the impact of the GD on the EEA based on first experience and conclude on further recommendations.
The EEA follows the FOCUS modelling framework. The predicted environmental concentrations (PEC) are compared against a trigger value of 0.1 µg/L. Any compound exceeding the trigger in gw and/ or sw, needs to be assessed further, and the related PECs are directly used in the subsequent assessment steps. For gw, the modlling results are used directly for comparison. For sw, the GD proposes to use the 4-day time-weighted average (twa) PECsw and additionally, the application of dilution factors which vary depending on use type and EU regulatory zone.
First experience with the GD shows that complexity and required work increase for both, gw and sw modelling. For gw modelling, now, toxicologically non-relevant metabolites need to be assessed further. For sw modelling, many metabolites that were so far only assessed at FOCUS Steps 1 and 2, now require extensive simulations at FOCUS Steps 3 and 4, and the implementation of complex degradation pathways can be challenging. Additional refinements and mitigation measures are required, e.g., restrictions in application rate, frequency or timing, use restrictions related to soil properties, additional buffer zones, refined modelling input parameters, or higher-tier assessments, e.g., GIS based approaches to derive lower

PECs or higher dilution factors.
The EEA according to the EFSA GD requires substantial additional time, work, computational resources, and costs. The challenge is to balance different options, for the EEA as well as for the overall assessment. Comprehensive preliminary EEA can support decision making when developing robust srategies. In this context, it is highly recommended to include the whole product portfolio and if relevant, the biocidal uses of the a.s. to establish overall worst-case concentrations.

3.03.B.T-02 Photolysis in PELMO: Conceptional Review on the Implementability of Scientific Guidance on Photo-Transformation Products in Groundwater

***Judith Klein**, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Soil photolysis is a critical degradation pathway for the environmental fate of pesticides, particularly in surface soils under sunlight exposure. The European Food Safety Authority (EFSA) has emphasized the importance of incorporating photolytic transformation processes in pesticide fate models to improve groundwater risk assessments, especially considering photolytic metabolites. This study evaluates the implementation of soil photolysis within the FOCUS PELMO model, emphasizing parameter sensitivity and environmental influences.
Using the offered EFSA guidance (2022) case study, the analysis examined how parameters like photodegradation half-life (DegT50photo), adsorption coefficient (Kfoc), and precipitation volume and timing affect predicted environmental concentrations (PECs). The model assumes photolysis acts only on substances remaining on the soil surface, with rainfall transporting compounds to deeper layers and reducing photolytic effects. The sensitivity analysis reveals how delayed and lower rainfall increases cumulative photolysis, while higher precipitation volumes or earlier rainfall reduce degradation by shielding substances from sunlight.
The results underscore the importance of considering photolysis in environmental fate models for pesticides and their metabolites, particularly for substances with high Kfoc and extended surface half-lives in soil (DegT50bio). By accounting for dynamic environmental variables like radiation and precipitation, this study demonstrates the need for robust modeling frameworks to support regulatory decision-making and mitigate environmental risks associated with pesticide use.

3.03.B.T-03 Leveraging Irradiated Water-Sediment Study for Environmental Modelling and Exposure Assessment

***Xin You**, Johannes Karcher, Louisa Ngounda Manga, Martin Brueggemann, Mahsa Namini-Moritz and Klaus Hammel, Bayer AG, Crop Science Division, Germany*

Environmental fate (efate) studies of plant protection products (PPPs) for regulatory purpose often require the separation of abiotic and biotic factors. As a higher-tier option under Regulation (EC) No 1107/2009, the irradiated water-sediment study is one of the few exceptions and offers a feasible study design in exploring the real-world interplay between aqueous photolysis and microbial degradation. Despite the existing OECD TG 308 on (an)aerobic transformation in aquatic sediment system and OECD TG 309/316 on aqueous mineralization/photolysis, no formal testing guideline exists for this study type, leaving high flexibility on the study design, but also substantial concern on the relevance and reliability for its regulatory use in efate. Here, we aim to reduce the uncertainty of using this study type as a higher-tier option in regulatory context. As irradiation is the key element distinguishing it from OECD TG 308, we firstly set up a realm of representative EU irradiation scenarios to aid the experimental design on source of irradiation. In a second step, we reviewed existing irradiated water-sediment studies with varying substance profile, experimental design and source of irradiation. Although degradation is often expected to be faster in this study type than OECD TG 308, less is known when it is compared to irradiated OECD TG 309/316 study types. Thus, we also evaluated the impact of this refinement option on degradation half-lives and metabolite profile compared to the other study types and identified the main drivers for change of degradation behaviour. Special attention was paid to evaluate the reliability of using this study type in persistence assessment as well as to derive realistic worst-case modelling endpoints for (photo-)metabolites compared to tests conducted in the dark. Overall, we aimed to offer recommendations from lessons learnt on this study type for a robust design of fit-for-regulatory-purpose irradiated water-sediment studies.

3.03.B.T-04 Field Test of the TOXSWA Pesticide Fate Model: Comparison of Simulated and Observed Linuron in Water and Sediment in Ditches with Stagnant and Flowing Periods

***Maarten Braakhekke**, Anna Huang, Mechteld Ter Horst, Wim Beltman, Almir Nunes and Pauline Iris Adriaanse, Wageningen Environmental Research, Wageningen University and Research, Netherlands*

TOXSWA (TOXic substances in Surface Waters) is a numerical model describing pesticide behavior in an edge-of-field waterbody. Despite its widespread use in predicting exposure for regulatory risk assessments

of aquatic ecosystems, few evaluations of the TOXSWA model's performance using field data have been conducted. In this study, we explore the applicability of TOXSWA for predicting the fate and behaviour of linuron, a highly water-soluble pesticide with low sorption capacity. The experimental observations were obtained from an outdoor ditch study which includes both stagnant and flowing periods and involves three applications. Water samples were taken at five distances from the inlet of each ditch, and sediment samples were taken at four layers of depth. We assess TOXSWA's capability to accurately simulate the spatial (both horizontal and vertical) and temporal dynamics in water and sediment with this case study. An initial parametrization based on data from field observations, lab-measurements and literature captured the general patterns of the observed concentrations in time and space. However, the model underestimated the height and timing of the peak concentration in the sediment, particularly for deeper layers. Therefore, we carried out several calibrations in which various parameters were optimized, including the half-lives for degradation in water and sediment and the diffusion coefficient in (pore)water. This led to an improved fit to the observations, but with an unrealistic parametrization. We hypothesize that a transport mechanism other than diffusion in porewater may be responsible for downward movement in the sediment, for example bioturbation. To investigate this, we are currently modifying TOXSWA to introduce a separate diffusion coefficient for the sediment. We expect that optimizing this diffusion coefficient will result in an improved fit with a plausible parametrization.
Based on these preliminary results, we are confident that TOXSWA will be able to adequately predict linuron behaviour in outdoor ditches in both the water and the sediment layer, capturing temporal changes through periods with varying flow regimes and multiple applications.

3.03.P-Mo172 Effect of Soil Particle Size and Organic Matter on Pesticide Sorption Behavior in Agricultural Soils

Marija Gadzimuradova[1], *Valentina Sechi*[2], *Peter van der Maas*[3] *and Nora B. Sutton*[1], *(1)Wageningen University, Netherlands, (2)Wetsus, European Centre of Excellence for Sustainable Water Technology, Netherlands, (3)Van Hall Larenstein, University of Applied Sciences, Netherlands*

Intensive agricultural practices heavily rely on land exploitation and high inputs of pesticides to produce crop monocultures. Some applied compounds persist in soil, whereas the more mobile pesticides run off or leach through the soil profile and enter surface and groundwater sources. While the overarching mechanisms of pesticide sorption to soil constituents are acknowledged, there remains a lack of understanding regarding the relative contributions of specific soil size fractions and their associated organic matter.
To address this gap, and to discern how the physical characteristics of the soil fractions and their organic matter content contribute to pesticide retention, our research investigates the differences in pesticide sorption between coarse and fine soil size fractions with and without organic matter. Using wet sieving, we first fractionate the soil into the coarse (> 53 μm) and fine (< 53 μm) soil physical fractions. After removing organic matter from soil size fractions, we obtain the coarse and fine mineral fractions. We perform batch sorption tests to determine the efficiency of 12 pesticide removal from soil solution using separated and treated soil fractions. Our approach allows a comparison between the effects of organic matter and mineral fractions, providing a clearer understanding of the contributions of each component to the overall sorption process.
Our hypotheses are: (1) separated soil fractions with intact organic matter will perform better in pesticide sorption than mineral fractions; (2) the extent of pesticide sorption efficiency will be different between the coarse and fine soil fractions; (3) we will be able to identify patterns regarding the most efficient fractions for the studied compound sorption. The findings of this research provide new insight into the effect of soil properties in reducing pesticide runoff, leaching, and subsequent environmental contamination and thus have important implications for choosing agricultural land-management practices (tillage, animal manure application, etc.).

3.03.P-Mo186 Challenges for Soil Photolysis Modelling in Groundwater Risk Assessment: An Analysis of Surface Layer Dynamics in FOCUS Models

Edna Rödig[1], ***George Mahoney***[2] *and David Patterson*[3], *(1)Syngenta Agro GmbH, Germany, (2)Syngenta Crop Protection, United Kingdom, (3)Science Strategy, Syngenta, United Kingdom*

The European Food Safety Authority (EFSA) guidance on soil phototransformation products in groundwater (GW) recently mandated the use of a soil photolysis module within FOCUS PELMO. Initial tests indicate that the extent of photolysis in FOCUS PELMO simulations is highly sensitive to environmental processes governing the duration for which chemical mass is retained within the photolytically active topmost one millimeter of soil. Notably, this guidance was implemented despite EFSA's acknowledgment that FOCUS GW models were not developed nor calibrated to accurately predict chemical fate and environmental processes in the surface layer.

This study analyses water, soil, and compound behaviour within the surface layers of FOCUS PELMO and compares it to the predicted behaviour in FOCUS PEARL. As the photolysis module has not been implemented in FOCUS PEARL, precluding direct comparison of photodegradation between the models, we assess models' susceptibility to photolysis by analysing the residence time of substances in the surface layer, i.e., the exposure to photodegradation. In the absence of true validation for either model against environmental data in the topmost layer of soil, this analysis provides model cross validation.
A direct comparison of the two models reveals that while soil temperature correlates strongly ($R = 0.85$-0.94), soil moisture ($R^2 = 0.07$-0.33) and water fluxes ($R^2 = 0.33$-0.83) differ substantially. The hydrological disparities between the models result in differences in substance residence time in the soil surface, significantly impacting susceptibility to photolysis.
We conclude that implementing a photolysis module within PEARL would likely yield PECs that differ significantly from those produced by FOCUS PELMO. Thus, both models will require calibration at the topmost soil layer similar to that performed at 1m depth. This therefore raises concern regarding the reliability of risk assessment decisions based on the current in force guidance.

3.03.P-Mo195 Global Pesticide Application Data as Input for Assessing Ecosystem Exposure and Impacts

Yuyue Zhang[1], *Anja Gladbach*[2], *Marissa B. Kosnik*[3], *Luke Settles*[4], *Ulf Norinder*[5], *Daniel Glas*[2], *Olivier Jolliet*[1] *and Peter Fantke*[6], *(1)Technical University of Denmark, Denmark, (2)Bayer AG, Crop Science Division, Germany, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (4)Bayer CropScience LP, United States, (5)Örebro University, Sweden, (6)substitute ApS, Denmark*

Agricultural pesticide applications significantly impact terrestrial and aquatic ecosystems, yet comprehensive data on actual field applications remains fragmented. We address this knowledge gap by developing the first global dataset of agricultural pesticide applications at country-crop-chemical level, incorporating detailed information on crop growth stages, application timing, and methods. This dataset aims to support the development of approaches that can predict how different application scenarios influence exposure and impact patterns across species and trophic levels in terrestrial and aquatic ecosystems.
By synthesizing field-level application records from agricultural monitoring programs (2016-2020) and employing machine learning approaches including XGBoost and conformal prediction, we created a comprehensive dataset on pesticide application, including a spatially-explicit mapping at 5×5 arcminute resolution for each country-crop-chemical scenario. Our methodological framework integrated different datasets into a consistent format capturing application parameters, environmental conditions, and agricultural practices.
The resulting database encompasses more than 2.9 million tonnes of annual average pesticide use across 180 countries and 130 crops, involving 1077 distinct compounds. Four compounds dominate global usage: glyphosate (0.64 million tonnes), sulphur (0.17 million tonnes), mancozeb (0.16 million tonnes), and atrazine (0.1 million tonnes), with China, USA, and Brazil accounting for 46% of total mass application despite covering only 25% of global crop treated area. To address data gaps, we developed estimations for 81 nations, predominantly in sub-Saharan Africa, and supplemented missing application details for over 50% of country-crop-chemical combinations. The dataset provides compound-specific application patterns, including detailed timing and methods, exemplified by Acephate usage in US cotton and soybean production.
This comprehensive resource enables reconstruction of exposure scenarios, identification of chemical accumulation hotspots, and assessment of spatial and temporal exposure variations. The dataset uniquely supports development of targeted risk mitigation strategies and evidence-based policies for protecting biodiversity from chemical stressors, directly contributing to objectives such as the EU Zero Pollution Strategy and Biodiversity Strategy.

3.03.C Measuring, Modelling and Monitoring the Environmental Behaviour and Exposure of Pesticides

3.03.C.T-01 Exposure Route Assessment for Non-Target Arthropods in Ecotoxicity Testing and Field Residue implications

Steven Droge[1], *Dick Belgers*[1], *Nina Jansen*[1], *Kas Swinkels*[1], *Marie-Claire Boerwinkel*[1], *Louise Wipfler*[1], *Andreas Focks*[2], *Artur Miguel Paiva Sarmento*[3], *Antonio Cubells*[3], *Mykola Rasko*[3], *Maria Mendes*[3] *and Jose Paulo Sousa*[3], *(1)WENR, Netherlands, (2)Systems Science Group, Osnabruck University, Germany, (3)CFE Centre for Functional Ecology, University of Coimbra, Portugal*

The first Tier of the pesticide environmental risk assessment for non-target terrestrial arthropods (NTAs) has a data requirement on effect studies with two standard test species involved in pest control, using contact exposure to dried spray residues on glass plates. The glass plate residue is considered a worst-case exposure scenario compared to the exposure that NTA experience after a downward spray event in the field via contact with residues on (3D-structured) natural substrates, such as plant leaves and soil. This exposure scenario may still underestimate the dietary intake from food residues (e.g., in plant material for herbivorous NTA and prey material for predaceous NTA), as well as direct exposure to the spray droplets during pesticide-application (and spray drift), as discussed in the EFSA Scientific Opinion on NTA risk assessment.1 This study aimed to follow the chemical accumulation in NTA over a 1 week period using different exposure routes. A single (non-toxic) spray dose was applied using a Potter tower spray system to expose NTA via (1) direct insect overspray, (2) a dried residue on natural substrate surface (leaf or soil), (3) dietary intake of oversprayed food items. A binary mixture of two strongly sorptive herbicides (diflufenican - and prosulfocarb) was tested on larvae of two NTA species: Mamestra brassicae (herbivorous moth caterpillar, pollinating species as adult) and Coccinella septempunctata (predatory ladybird). Diflufenican accumulation in moth larvae via dietary intake was higher than via natural substrate contact alone. The more volatile prosulfocarb showed 3-10x lower residue unit dose (RUD) than the co-applied diflufenican for each exposure route in moth larvae. Ladybirds showed several deviating accumulation trends compared to moth larvae. Exposure via overspray, leaf contact and particularly contaminated food items, resulted in a relatively higher accumulation of prosulfocarb in ladybirds compared to moth larvae. For both species RUD for several exposure routes were above the 90-percentile RUD values measured in field studies. Topical overspray exposure on the short term, and dietary intake during most of the 7 day exposure tests, resulted in higher pesticide accumulation in NTA compared to contact with natural substrate surface residues. Based on these findings we suggest to take additional exposure routes into account in NTA risk assessment, while differentiating between organism groups.

Disclaimer/Disclosure: The authors thank European Food Safety Authority for funding and guiding the AENEAS project.

3.03.C.T-02 3D Spray Drift Exposure Data for Non-Target Terrestrial Organism Risk Assessment
***Carola Schriever**[1], Clare Butler Ellis[2], Andrew Lane[2], Christine O'Sullivan[2], Lindsay Fogg[3], Nadine S. Taylor[4] and Neil Mackay[5], (1)BASF SE, Germany, (2)Silsoe Spray Applications Unit Ltd, United Kingdom, (3)Cambridge Environmental Assessments, United Kingdom, (4)Cambridge Environmental Assessments, Boxworth, United Kingdom, (5)FMC Agro Ltd., United Kingdom*
The Guidance Document on Terrestrial Ecotoxicology (SANCO/10329/2002) is currently under revision. A more sophisticated risk assessments for non-target terrestrial plants (NTTPs) and arthropods (NTAs) needs a better understanding of actual exposure in off-field areas, especially concerning the quantity and distribution of spray deposited on plant surfaces downwind of treated fields. Key factors influencing plant exposure include drift profiles, spray deposition efficiency, distance from the application site, and environmental conditions, including nearby vegetation like hedgerows.
This study aimed to establish a robust experimental protocol for measuring plant exposures in real-world settings, conduct a field trial, and analyze data to inform regulatory assessments for NTTPs and NTAs. Sodium fluorescein was sprayed on a field of cut rye grass, which had been prepared three days prior, leaving a 20 m uncut strip on the northwest edge for wind considerations. The experimental layout included three replicate treatment plots, each receiving separate spray applications. Samples were collected at various distances from the sprayed area to assess drift penetration, using horizontal chromatography paper, vertical stainless steel rods, and above-ground vegetation quadrats. Meteorological conditions were monitored throughout the process.
Analysis of the spray liquid revealed that airborne spray collected by rods was significantly higher than that on horizontal papers but decreased more rapidly with distance, indicating the filtering effect of the vegetation. The rods showed varying penetration of spray drift droplets, with capture declining from the surface downward. A clear trend of reduced spray deposits with increasing distance from the treated area was evident. Strong correlations between collector types indicated relationships between airborne and sedimenting spray measures. Wind speed was an important factor but did not significantly affect spray deposit results across different runs.
A good correlation between deposits on artificial collectors and vegetation will allow further exploration of collection efficiencies of different plant species, and simplification of experimental protocols. Further refinements to the methodology explored here should consider incorporation of techniques for characterisation of vegetation to support development of flexible modelling representations of penetration, capture and deposition of spray drift within margin habitats.

3.03.C.T-03 Comparison of Simulated and Observed Downwind Deposits of Spray Drift in Orchard Crops Across Europe

Henk Jan Holterman[1], *Mechteld Ter Horst*[1], *Pauline Iris Adriaanse*[1], *Laura Padovani*[2] *and Csaba Szentes*[2], *(1)Wageningen University and Research (WUR), Netherlands, (2)European Food Safety Authority (EFSA), Italy*

EU Regulation 1107/2009 requires assessing pesticide exposure for several groups of non-target organisms. Spray drift deposition, a highly variable and significant exposure route, has not yet been reliably estimated at the European level. This variability in exposure arises from differences in crops, crop height, agronomic practices and agro-environmental conditions. Currently, the EU employs the Ganzelmeier-Rautmann drift deposition curves for regulatory environmental exposure assessments. However, these curves, based on experiments conducted in Germany, may not adequately represent the diverse meteorological and crop conditions across Europe. Modelling offers an alternative to experimental drift curves for regulatory purposes, yet no ready-to-use model exists to predict spray drift depositions for upward and sideways sprayed crops at the EU level. The statistical model SPEXUS, originally developed for Dutch apple orchards, reflects conditions in the Netherlands but can be adapted for other fruit crops and climate zones by integrating crop development stages and local weather conditions. The broader model s applicability was tested by comparing the results of SPEXUS to six EU datasets, covering spray drift experiments in pome fruit, citrus fruit and vines, across four countries in two EU regulatory zones (Central, South). These datasets were kindly provided by research groups in Europe. For these data, regression models were developed, resulting in spray drift curves for different crop groups and growth stages. These regression models were compared to the SPEXUS model and the Ganzelmeier-Rautmann curves. Comparisons showed that SPEXUS predictions differed from experimental deposits but aligned with the model's basic assumptions about meteorological conditions and deposition processes. In contrast, the Ganzelmeier-Rautmann curves both underestimated and overestimated the measured drift deposits, while overestimation was the most observed outcome. This implies that for upward and sideways sprayed crops the use of Ganzelmeier-Rautmann curves is a conservative approach from a regulatory perspective, thus defensible. Still, a more advanced model like SPEXUS offers clear advantages in describing spray drift by accounting for variable weather, application techniques and crop types and structures. Further development of such models represents the most promising path towards an EU-wide framework for spray drift predictions in upward and sideways sprayed crops.

3.03.C.T-04 Generating Field-Realistic Predictions of Exposure for Off-field Soil Organisms Using a Spatiotemporally Explicit Modeling Approach

Christopher M Holmes[1], *Thorsten Schad*[2], *Sascha Bub*[3], *Gregor Ernst*[2] *and Julian Heinrich*[2], *(1)Applied Analysis Solutions LLC, United States, (2)Bayer AG, Germany, (3)Rheinland-Pfalzische Technische Universitat, Kaiserslautern-Landau, Germany*

Natural and semi-natural habitats of soil living organisms in cultivated landscapes can be subject to unintended exposure by active substances of pesticides used in adjacent fields. The European Food Safety Authority released a scientific opinion in which spray-drift and runoff are identified as the most relevant potential exposure routes of off-field soil organisms. It outlined a first approach to estimate off-field soil exposure, designed closely to the FOCUS surface water model approach. This approach assumes independent conservative estimates on local spray-drift and runoff entries and adds them at a single location. This means that 100% of individuals in a population occurring 'off-field' in a cultivated landscape receive worst-case exposures. This does not consider real-world variability of exposure in space and time. These two risk dimensions and their scales are essential when assessing effects and risk according to Specific Protection Goals. We developed a model (xOffFieldSoil, built on the xLandscape platform) and associated scenarios to estimate exposure of off-field soil habitats at flexible levels of realism. The modular approach consists of components each addressing a specific aspect of exposure processes. These components are based on established models in regulatory exposure and operate at scales ranging from local edge-of-field to large landscapes. Presented scenarios start with a schematic edge-of-field situation and extend to real-world landscapes of up to 5x5 km. xOffFieldSoil represents an initial spatiotemporally explicit approach to assess exposure/risk of off-field soil organisms due to spray-drift and runoff entries. The approach is flexible and able to operate at any desired spatial and temporal resolution. Study results are intended to inform the scientific discussion on design of off-field soil exposure, effect and risk characterization approaches in a tiered RA scheme and support the development of Assessment Endpoints for regulatory risk assessment, while the impact of risk mitigation options can be analyzed in detail. The modular architecture of xOffFieldSoil model allows the use of individual process components of different complexity (and reality) levels and validation status. The presented xOffFieldSoil model, scenarios and case study can inform more realistic risk assessment for off-field soil organisms. xOffFieldSoil is publicly available on GitHub https://github.com/xlandscape/xOffFieldSoilRisk.

3.03.P-Mo198 Occurrence, Spatial Distributions, and Influencing Factors of Neonicotinoid insecticides in Soils from Agricultural Farmlands in China: A National Study

***Jie Hou** and Wenxin Liu, Key Laboratory for Earth Surface Processes, College of Urban and Environmental Sciences, Peking University, China (Mainland)*

Neonicotinoid insecticides (NEOs) are widely used in crop production in China, raising concerns about their health and ecological risks due to persistent residues in agricultural soils. Previous research has reported NEO contamination in soils of China s coastal regions, but national-scale data and information on NEO metabolites remain limited. On the other hand, both NEOs and microplastics (MPs) are commonly found in agricultural fields, but their co-occurrence characteristics under realistic fields have not been reported.

This study found that at least one NEO was detected in all soil sample. Imidacloprid was the most common parent NEO, with imidacloprid-urea as its primary metabolite. Results showed higher NEO concentrations in coastal areas at similar latitudes compared to inland regions. The extent of agricultural film cover (i.e., greenhouse, farmland with film mulching, and farmland without film mulching) and microplastics (MPs) might influence pesticide residues in soil. This study revealed an association between MPs and NEOs in realistic agricultural settings. Random forest models offered more reliable predictions than linear models and indicated that MPs, farmland type, and total nitrogen are key contributors to NEO levels.

Disclaimer/Disclosure: The authors would like to thank all responsible editors and reviewers for their helpful comments on the manuscript. This work was supported by the Natural Science Foundation Committee of China (No. 41991310).

3.03.P-Mo199 Analysis of the Contamination and Reduction of Pesticide Residues During Transition from Conventional to Organic Rice Production in the Mekong Delta of Vietnam

***Linda Klamann**[1], Björn Thiele[2], An Giang Cao Dinh[3], Khoi Chau Minh[3] and Lutz Weihermüller[2], (1)Research Center Julich GmbH, Germany, (2)Forschungszentrum Jülich GmbH, Germany, (3)Can Tho University, Viet Nam*

Rice cultivation in the Mekong Delta of Vietnam plays a critical role in both food security and the national economy. However, intensive agricultural practices, including the widespread use of pesticides and fertilizers, have raised concerns regarding environmental sustainability and human health. This study aims to evaluate pesticide residues in the Mekong Delta, with a focus on the three provinces Vinh Long, An Giang an Dong Thap, and assess the feasibility of transitioning from conventional to organic rice farming practices. Household surveys were conducted in the three provinces to understand farmers' pesticide usage patterns. Therefore, the farmers were asked for information about which pest dominates on their farm, which pesticides are being used, on the frequency of the pesticide usage, and their application dose. Additional information about major crop, crop rotation, number of harvest per year, and farm size were also provided. The surveys revealed a diverse array of 85 different pesticide brands corresponding to 51 active ingredients, with insecticides comprising the majority, followed by fungicides and herbicides. Additionally, soil and water samples were collected for pesticide residue analysis in rice fields in each province respectively. Pesticide residues were extracted using solid-phase extraction for water samples and accelerated solvent extraction for soil samples. For the analysis of pesticides a non-target screening was carried out using LC-MS/MS and the Quanpedia data base, which contains the information of 750 widely used pesticides. The non-target screening identified 74 active compounds belonging to the categories Fungicides, Herbicides, Acaricides, Insecticides. Moving forward, ongoing farmers survey s will help to assess regional variations in pesticide usage, while targeted quantification of select compounds will provide insights into contamination levels. Ultimately, this study contributes to our understanding of pesticide pollution in rice farming regions and informs strategies for promoting sustainable agriculture and safeguarding environmental and human health in the Mekong Delta.

3.03.P-Mo200 Pesticides Contamination in the Irrigation System of Arequipa, Peru

*Victor Hugo Rodriguez Uro[1], Betty Paredes[1], Cesar Ranilla[1], Mario Lopes Araujo[2], Alexandre Campos[2], Mostafa Soliman[3], Vaidotas Kisielius[4] and **Pedro N Carvalho**[5], (1)Universidad Nacional de San Agustin de Arequipa, Peru, (2)Interdisciplinary Centre of Marine and Environmental Research, Portugal, (3)QCAP Ministry of Agriculture and Land Reclamation, Egypt, (4)Environmental Science, Aarhus University, Aarhus, Denmark, (5)Environmental Science, Aarhus University, Denmark*

Agriculture is the second-largest economic activity in Peru, playing a significant role in the country's exports. Yet, agricultural practices in the country rely heavily on using pesticides and other chemicals to enhance and secure food production, raising public health and environmental concerns. Therefore, in this study, we aimed to detect the presence of various pesticides in the irrigation system of Arequipa, Peru. A sampling campaign was conducted in May 2022, analyzing water samples from key areas, including the Chili River, water ponds, and the Aguada Blanca and El Pañe reservoirs. Pesticide analysis involved water filtration, solid-phase extraction (C18 SPE cartridges), and a quantitative LC-MS/MS workflow. A total of 15 pesticides were analyzed in 26 samples. Results revealed the presence of 7 pesticides not approved under European regulations, although none of them are restricted by Peruvian regulation. Furthermore, Peruvian water quality standards do not include the monitoring of these pesticides, highlighting regulatory gaps. The detected pesticides included diuron, tebuconazole, propiconazole, carbendazim, azoxystrobin, and imidacloprid, confirming contamination of irrigation water bodies. This contamination suggests the existence of risks to farming workers, to consumers and to the ecosystems directly associated with the irrigation system. Further ongoing work is applying suspect screening analysis to a larger number of pesticides and other organic contaminants. The findings denote the need for stronger pesticide monitoring and regulatory measures in Peru and serve as critical evidence for governmental institutions to improve risk management and environmental protection policies.

3.03.P Measuring, Modelling and Monitoring the Environmental Behaviour and Exposure of Pesticides

3.03.P-Mo171 Sorption-Mediated Bioavailability and AMPA Influence on Bacterial Glyphosate Transformation

Kleanthi Kourtaki[1], *Daniel Buchner*[1], *Philipp Martin*[2], *Katharine Thompson*[3] *and Stefan B. Haderlein*[1], *(1)Department of Geosciences, Eberhard Karls University of Tubingen, Germany, (2)Division for Environmental Geosciences, Centre for Microbiology and Environmental Systems Science, University of Vienna, Austria, (3)Institute of Sanitary Engineering, Water Quality and Solid Waste Management (ISWA), University of Stuttgart, Germany*

Glyphosate (N-Phosphonomethyl-glycine)- the most widely used herbicide globally - and its transformation product, aminomethylphosphonic acid (AMPA), frequently coexist in various environments. While the biotransformation of glyphosate has been well-demonstrated under phosphorus (P)-limiting conditions, the ubiquity of other organophosphorus compounds that can also serve as P-sources raises questions about its actual biodegradation potential in real-world scenarios. This study investigated the biodegradability of glyphosate in batch cultivation experiments, focusing on the co-presence of AMPA, with or without a sorbent mineral. Experiments were conducted using the bacterial strain Achromobacter insolitus Kg 19 (VKM B-3295) that is able to utilize both glyphosate and AMPA as P- sources. The influence of goethite, a widely distributed iron oxyhydroxide in the environment, was evaluated for its potential to restrict biotransformation by sorbing glyphosate and/or AMPA. Preliminary findings indicated that glyphosate and AMPA exhibited a strong affinity towards goethite, influencing their bioavailability and subsequently the observed transformation kinetics. Additionally, in the absence of sorbent, AMPA was a more preferred P-source compared to glyphosate for the strain A. Kg 19. These results provide valuable insights into the environmental persistence of glyphosate in the presence of AMPA while emphasizing the need to consider the interplay between sorption and biotransformation a factor that requires further systematic investigations. Given the widespread occurrence of AMPA and other OP compounds, our findings suggest that their presence may hinder glyphosate biotransformation, potentially leading to lower transformation rates than those indicated by existing literature.

The findings of this research provide new insight into the effect of soil properties in reducing pesticide runoff, leaching, and subsequent environmental contamination and thus have important implications for choosing agricultural land-management practices (tillage, animal manure application, etc.).

3.03.P-Mo173 UAV Spray Applications as Innovative Solution for Heroic Vineyards: A Case Study in Northern Italy

Nicoleta Suciu[1]*, Margherita Furiosi*[2]*, Ghada Arbi*[1]*, Sonia Gaaied*[1]*, Marco Grella*[3]*, Eric Mozzanini*[3]*, Gian Maria Beone Prof*[1] *and Tito Caffi*[2]*, (1)Department for Sustainable Food Process, Universit Cattolica del Sacro Cuore, Italy, (2)Department of Sustainable Crop Production, Universit Cattolica del Sacro Cuore, Italy, (3)Department of Agricultural, Forest and Food Sciences (DiSAFA), University of Turin (UNITO), Italy*
In Italy, several vineyards are in hills and mountains, and their management is mainly conducted through manual operations. The European Commission is hypothesizing to allow aerial products application in critical vineyards to manage diseases. This work aims to determine if UAV spray may represent an alternative to manual spray in this context.
During season 2024 a UAV spray system, fixed to the ground, was compared to a ground spray for grapevine downy mildew control during different three phenological stages. The trials were conducted in two vineyards, located in Grugliasco (TO) and Piacenza (PC) (Italy), comparing two commercial products, a contact copper-based fungicide (CU) and a systemic (metalaxyl-m) fungicide (MET), both sprayed from the ground (CU and MET) and from above canopy (UAV Cu and UAV MET). Leaves were collected from the vineyards after treatment at fixed intervals and artificially inoculated in the laboratory with a suspension at 5x104 of P.viticola, the causal agent of grapevine downy mildew. Then leaves were incubated at 20°C until symptoms were visible. Disease control was evaluated in terms of fungicide efficacy (%). At the same fixed intervals from fungicide application, other leaves were collected, about 20 g of fresh leaves, and used for the analytical determination of the products deposited on leaves.
An analysis of variance (ANOVA) was performed on efficacy data, post hoc Tuckey test was conducted to separate means ($p = 0.05$).
Based on the first trial results, ground spray copper-based and metalaxyl-m fungicides showed the highest efficacy, above 85% in Torino vineyard, not significantly different from UAV MET efficacy (about 70%), but significantly higher ($p = 0.04$) than the efficacy of copper-based fungicide from aerial spray (about 40%). In Piacenza vineyard, the efficacy was generally lower than Torino, between 50 and 65%, without significant differences among treatments, even if UAV CU presented the lowest efficacy. Even if aerial spray may have possible issues in covering the canopy, as found for the copper efficacy from aerial spray. UAV spray system seems to provide good disease control.
Two additional trials are running to evaluate the fungicide application during different phenological stages and different canopy heights and to optimize product distribution.

3.03.P-Mo174 Environmental Parameter-Calibrated Models for Predicting Sediment-Water Partitioning Behaviors of Diverse Emerging Contaminants in Lotic Waterways

***Huizhen Li** and Jing You, Jinan University, China (Mainland)*
The partitioning behavior of organic contaminants is critical to their mobility, bioavailability, and ecological risk in aquatic environment. However, developing robust models for predicting sediment-water partition coefficients (Koc) in field waterways is challenging due to complex impacts of environmental factors on partitioning behavior. Here, we developed environmental parameter-calibrated models to predict the Koc values of 10 classes of emerging contaminants (log Kow ranging from -1.8 to 10.2) in the Guangzhou reach of the Pearl River, South China. Traditional models based on physiochemical properties

poorly predicted the field measured Koc values. By calibrating using climate change related environmental parameters, i.e., temperature, dissolved oxygen, pH, conductivity, and salinity, the prediction accuracy pronouncedly improved from 22% to 81%. This calibration effectively reduced the impact of season variations on Koc predictions, except for herbicides in both seasons and polycyclic aromatic hydrocarbons in wet season, suggesting that additional parameters are needed for these contaminants. Temperature was characterized as the principal factor influencing Koc predictions, except for per- and polyfluoroalkyl substances (PFASs) and neonicotinoids, which were mostly affected by pH. Salinity also exhibited significant effects on PFASs and herbicides. With measured water concentrations and water quality parameters, the developed model was validated to successfully predict sediment concentrations in lotic waterways. These findings provide insights into the effects of environmental factors on distribution of organic contaminants in highly dynamic waterways, aiding in predicting their fate and risk in aquatic ecosystems under the influence of climate change.

3.03.P-Mo175 Effect of Fertilizers on Dissipation Kinetics of Imidacloprid in Cultivated and Non-Cultivated Arid Soils

*Hamed A. Halieb[1], **Hattan Alharbi**[1], Abdulqader Bazeyad[1], Khaled D. Alotaibi[2], Fahad Alotaibi[2] and Garry Codling[3], (1)Department of Plant Protection, College of Food and Agriculture Sciences, King Saud University, Saudi Arabia, (2)Department of Soil Science, College of Food and Agriculture Sciences, King Saud University, Saudi Arabia, (3)Centre for Resilience in Environment, Water and Waste (CREWW), Exeter University, United Kingdom*

Imidacloprid (IMI) is a systemic pesticide, that is widely used in plant protection around the world. After its application, several factors affect IMI degradation, such as soil characteristics and agricultural practices. This study explores the impact of fertilizer types on IMI dissipation in cultivated soil (CS) and non-cultivated soil (NCS) from Saudi Arabia. Four fertilizer treatments were used: three inorganic fertilizers (urea, monoammonium phosphate (MAP), and diammonium phosphate (DAP)), and one an organic fertilizer (compost) were applied to long-term CS and NCS, followed by IMI addition and a 45-day incubation period. The results indicate that IMI degrades notably faster in CS treated with compost, exhibiting a half-life of 14.3 days compared with 20.1 days in NCS with the same treatment. For other treatments, CS half-lives ranged from 25.0 to 35.5 days, while NCS half-lives ranged from 34.7 to 40.5 days. For the controls fortified with IMI but no fertilizer, half-lives of 39.1 and 43.0 days were observed for CS and NCS, respectively. Both compost and urea addition accelerated dissipation, possibly due to enhanced microbial activity and growth post-treatment. Conversely, NCS exhibited slower dissipation attributed to lower organic matter and nitrogen content. Compost enhances IMI degradation, especially for nutrient-deficient soils; thus, the temporal efficacy of IMI will vary by soil and amendment types. Future research should investigate the synergistic effects of organic and inorganic fertilizers in facilitating the breakdown of IMI residues across soils from different origins. With further research, specific metrics for the application of IMI to meet the aim of pesticide application without excess pesticide residue could be developed.

3.03.P-Mo176 A Simplified Approach to Represent Bioturbation Effects on Pesticide Contents in Upper Sediment by the TOXSWA Model

***Almir Nunes**, Wim Beltman and Pauline Iris Adriaanse, Wageningen Environmental Research, Wageningen University and Research, Netherlands*

Bioturbation is recognized as a critical process influencing pesticide transport within upper sediment layers. Traditional pesticide fate models often represent this as a diffusive process, with the biodiffusion coefficient (D_b) serving as a key parameter. However, obtaining accurate values for D_b can be challenging, especially when limited information about benthic organisms is available.

This study introduces a fast and simplified approach to represent bioturbation effects on pesticide contents in sediment layers. The approach is specifically tailored for mobile compounds, i.e., with a low adsorption capacity. We calculate an effective diffusion coefficient as the sum of molecular diffusion (accounting for tortuosity) and a faunal activity diffusion component (independent of tortuosity). The faunal activity diffusion can be calibrated using experimental data, and the resulting calibrated value can be compared to literature on compounds primarily present in pore water, to assess whether bioturbation is indeed the primary process involved or if other processes may better explain the observed transport.

We implemented this approach within the TOXSWA model, which simulates pesticide fate and transport in small surface water systems. This adapted TOXSWA version will be applied to simulate linuron penetration in sediment of two experimental ditches in Renkum, the Netherlands and results will be presented on the poster. Earlier simulations suggested the occurrence of additional transport processes, next to molecular diffusion and sorption.

The implemented approach is designed for mobile substances, as it focuses on pore water concentrations without addressing sediment reworking (with attached sorbed substance). While initially motivated by observations of linuron in experimental ditches, future work could extend the approach to sediment transport processes. The study emphasizes the importance of including additional processes, such as bioturbation, in regulatory frameworks, where they are currently not considered. The proposed TOXSWA version offers a practical way to investigate such processes and their implications for pesticide exposure assessments.

3.03.P-Mo177 Global Meta-Analysis and Machine Learning Reveal the Critical Role of Soil Properties in Influencing Biochar-Pesticide Interactions

Jingyu Wang[1]*, Trine Norgaard*[1]*, Lorenzo Pugliese*[1]*, Pedro N Carvalho*[2] *and Shubiao Wu*[1]*, (1)Department of Agroecology, Aarhus University, Denmark, (2)Department of Environmental Science, Aarhus University, Denmark*

Biochar application is widely promoted for its dual benefits of boosting agricultural productivity and sequestering carbon. However, concerns remain about its environmental impact, especially regarding interactions with pesticide residues in soil. Previous research has shown elevated pesticide residues and prolonged persistence in biochar-amended soils, suggesting a potential negative impact on pesticide degradation, though conclusive evidence is lacking. To address this, a comprehensive assessment combining meta-analysis and machine learning was conducted, synthesizing data from 58 studies and 386 observations across field, pot, and incubation experiments worldwide. Contrary to initial concerns, our findings revealed no definitive increase in soil pesticide concentrations with biochar use. Additionally, pesticide concentrations in soil organisms, such as plants and earthworms, were reduced by 66%. Our research stands out for its thorough consideration of the variability in soil, pesticide, and biochar properties when assessing biochar application. Soil properties were identified as critical factors governing the fate of pesticides affected by biochar application. Additionally, we explored how different types of biochar and pesticides may exert varying effects. The quantitative analysis emphasized three key aspects in understanding biochar-pesticide interactions: (1) Soil Properties: The impact of biochar on pesticide residues is significantly influenced by soil properties such as soil organic matter (SOM) and pH. Soils rich in SOM were less likely to show increased pesticide persistence with biochar, while low-SOM soils often exhibited higher pesticide retention, raising potential risk. (2) Pesticide Properties: Biochar s impact on pesticide behavior varies with the physicochemical properties of the pesticides. Triazole and organofluoride pesticides showed increased persistence, potentially raising risks, while triazine and organophosphorus pesticides exhibited reduced persistence. (3) Biochar Properties: Wood-derived biochars generally showed stronger pesticide adsorption, underscoring the role of biochar composition in modulating pesticide persistence. By investigating the interactions between biochar and pesticides across varying soil conditions, this study provides a valuable reference for developing risk-assessed and informed strategies for biochar application.

Disclaimer/Disclosure: This study was performed under the project Novel rhizosphere-activated hydroxyl radical oxidation of pesticides (OHiROOT) supported by the Independent Research Fund Denmark [grant no. 2035-00039B].

3.03.P-Mo178 SWAN's Evolution: Bridging Recent Modelling Advances and Regulatory Risk Assessment

Robin Sur[1]*, Horatio Meyer*[2]*, Andrew Bailey*[3]*, Peter Rainbird*[4]*, Rafael Munoz-Carpena*[5]*,* ***Stefan Reichenberger***[6]*, Neil Mackay*[7]*, Igor Kondzielski*[8]*, Amy Ritter*[9] *and Fabienne Ericher*[10]*, (1)Bayer AG, Crop Science Division, United States, (2)Bayer AG, Crop Science Division, Germany, (3)Capgemini, United Kingdom, (4)Syngenta Crop Protection, Switzerland, (5)University of Florida, United States, (6)knoell, Mannheim, Germany, (7)FMC, United States, (8)IOS-PIB, Poland, (9)Waterborne, United States, (10)Syngenta Crop Protection, United Kingdom*

SWAN (Surface Water Assessment eNabler), sponsored by CropLife Europe (CLE) and developed by Hybrid Intelligence (formerly Tessella), has been a cornerstone in surface water regulatory risk assessment modelling since 2006. This poster presents recent advancements in SWAN, highlighting CLE s commitment to computational excellence and user-centric improvements.

SWAN provides a user-friendly interface, allowing the user to reliably apply modifications to STEP 3 runs, reflecting mitigation measures (drift-reducing nozzles, vegetative buffer strips, no-spray buffer zones), to subsequently run scenarios integrating these mitigations at STEP 4. SWAN itself does not perform the calculations but acts as an intermediary by modifying existing STEP 3 run files in a transparent and consistent manner. Every new SWAN release is validated and all processes are fully documented; SWAN efficiently automates the calculations but is reproducible manually by advanced modellers.

VFSMOD, a tool for simulating pesticide runoff mitigation through vegetative filter strips, has been an option in SWAN since 2012. VFSMOD has undergone various mechanistic upgrades in recent years including a mechanistic pesticide trapping, a dynamic predictor for runoff sediment inputs based on site conditions, and a new soil leaching and surface residue remobilization algorithm. To better integrate these advances into regulatory risk assessments, new vegetative filter strip scenarios were developed for FOCUS scenarios R1-R4.
With the expansion in regulatory interest of this increasingly sophisticated risk analysis tool, it is essential to balance complexity with sound software engineering and transparency. Previously, SWAN interfaced with VFSMOD through an external wrapper. In SWAN 5.2, the wrapper has been fully integrated into SWAN's core codebase, marking a significant improvement in the software's architecture. In addition to a gain in performance (typically 90% or greater reduction in runtime across our test scenarios), the incorporation also improves testability and transparent reporting, with the aim to maintain confidence in the tool s compliance with regulatory requirements.
The upcoming SW Repair version of SWASH will be coupled with a concurrent release of a new FOCUS-SWAN, ensuring closer alignment with SWASH release cycles and consistent compatibility.

3.03.P-Mo179 Derivation of Updated SWAN-VFSMOD Scenarios for FOCUS Step4 Simulations
Stefan Reichenberger[1]*, Robin Sur*[2]*, Thorsten Pohlert*[3]*, Jorge Olivares-Rivas*[4] *and Rafael Munoz-Carpena*[5]*, (1)knoell France SAS, France, (2)Bayer AG, Germany, (3)knoell Germany GmbH, Germany, (4)knoell Germany GmbH, Germany, (5)University Florida, United States*
The SWAN tool for higher-tier surface water exposure assessment implements runoff and erosion reduction efficiencies according to the report of the FOCUS Landscape and Mitigation Working Group. Since 2012 SWAN also includes the option to apply mitigation using the mechanistic, dynamic and event-based vegetative filter strip (VFS) model VFSMOD. VFSMOD simulations had been performed to develop realistic worst case VFS scenarios for the four FOCUS runoff scenarios, which were subsequently included in SWAN. The current version of SWAN (v.5.0.1) still uses the same VFSMOD version as in 2012. However, since then substantial scientific developments have been made to further improve VFSMOD and its underlying assumptions and process descriptions. Moreover, the population of the spatial cumulative distribution functions (CDFs) needed updating. The objective of this study was therefore the corresponding update and improvement of the SWAN-VFSMOD scenarios for EU pesticide risk assessment.
The FOCUS scenario shapefiles were intersected with CORINE Land Cover and subsequently linked with the SPADE2 and SPADE14 soil profile databases. The valid 1897 scenario/profile combinations were simulated with VFSMOD. First, two rainfall/runoff events (duration 1 h and 8 h) for each R scenario were created with the tool UH v.3.07. VFSMOD was run for the above events, two example compounds (Koc = 100 L kg-1 and 10000 L kg-1), a VFS length of 10 m, and two different variants: A) profiles with hard rock in < 100 cm depth were simulated with the shallow water table option; B) all profiles were simulated with classical Green-Ampt infiltration.
In a next step, area fractions per Soil Mapping Unit were calculated for each scenario/profile combination. These area fractions were subsequently used to calculate spatial CDFs of the target variable ?P (relative reduction of pesticide load by the VFS). Finally, from each CDF the profile corresponding to the 10th spatial percentile of ?P was extracted. From the created CDFs the following combination was selected for the new SWAN-VFSMOD scenarios: Koc = 100 L kg-1, duration = 8 h, and variant B.
A set of updated 90th percentile worst case VFSMOD scenarios for FOCUS step4 simulations has been derived. The updated VFSMOD scenarios are both more realistic and more conservative than the old scenarios (a comparison of ?P will be presented) and are ready to be integrated in SWAN 5.2. A technical report and a peer-reviewed publication are in preparation.

3.03.P-Mo180 Modelling Framework to Identify FOCUS Step 3 Surface Water 'Screening' Scenarios Following Use of REACH-IN LET
Abdul Abu[1]*, Olha Khomenko*[1]*, Katie Balmer*[1]*, Mercedes Franey-Gardiner*[1]*, Adrian Simon Terry*[1] *and Matthias Wormuth*[2]*, (1)Cambridge Environmental Assessments, RSK ADAS Ltd., United Kingdom, (2)Syngenta Crop Protection AG, Switzerland*
Substances used as co-formulants in plant protection products (PPP) must be registered in the European Union under the REACH Regulation (EC) No 1907/2006. The standard environmental exposure assessment for chemicals under REACH uses a multicompartmental mass-balanced model and, at the local-scale, is based on urban (wide dispersive) or industrial (point source) emissions. However, environmental releases of co-formulants used in PPP to agricultural soil and indirectly to waterbodies adjacent to treated fields are not in scope of this assessment framework. The surface water module of CropLife Europe Local Environment Tool (LET) was developed to assess local environmental exposure to

co-formulants in surface water and sediment based on the standard FOCUS Step 2 model used for PPP. It combines the local PECs with regional PECs resulting from emissions of other nonagricultural uses of the same substance, to perform risk characterizations on the local scale which conform to REACH requirements.
To facilitate refined assessment of surface water exposure to co-formulants, a framework has been developed to identify FOCUS Step 3 screening scenarios based on three substance sorption (KOC) categories: KOC = 100 L/kg, KOC = 1000 L/kg, and KOC = 10000 L/kg; and three biodegradability categories: Readily Biodegradable, Inherently Biodegradable, and Not Biodegradable. Application methods (i.e., ground spray and air blast), application timings covering each month of the year, and representative crops including pome fruit, fruiting vegetables, winter cereals, potatoes, and field beans were assessed. The application schemes were developed into a simple framework allowing selection of reasonable worst-case scenarios for surface water assessment of co-formulants at FOCUS Step 3. For co-formulants with KOC ? 100 ? 1000 L/kg, spray drift was the main exposure route for crops with air blast application, whereas drainage or runoff was the major route of exposure for crops with ground spray application. The proposed scheme for these co-formulants is to select application timing from the product GAP or in case of a wide application window, application timing dependent on KOC category. For readily or inherently biodegradable co-formulants with KOC > 1000 ? 10000 L/kg, spray drift was the major exposure route for all crops and application methods assessed. The proposed scheme for these co-formulants is to select application timing from the product GAP.

3.03.P-Mo181 Reduction of Complexity: Variance-based Sensitivity Analysis for FOCUS STEP 3
***Dimitrios Alexander Skodras**[1] and Judith Klein[2], (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*
To standardize the role of models in the European Union (EU) plant protection product authorization process, the Forum for the Co-ordination of pesticide fate models and their use (FOCUS) has established guidelines, including the FOCUS STEPS models for surface water risk assessment. Conservative scenarios representing EU member states are used, with a 4-tier approach to assess limit value exceedances. While higher-tier calculations provide greater accuracy by requiring more information, they do not incorporate the uncertainty of model parameters, potentially leading to significant inaccuracies if sensitive parameters.
The project employs sensitivity analysis using the Sobol' method to identify influential parameters in FOCUS STEPS models. Model parameters are sampled using low-discrepancy sequences, and Sobol' indices are calculated to determine the sensitivity of the FOCUS STEPS models to parameter variances. The analysis centers on the first order Sobol' indices representing the main effects, providing insights into parameter influence. Higher order indices are examined too.
FOCUS STEP 3 incorporates the TOXSWA model, which calculates pesticide concentrations in surface water by receiving input on pesticide fluxes from drift and runoff (calculated with PRZM) or drainage (calculated with MACRO). These simulations are run for three types of surface waters across 10 representative scenarios encompassing the meteorological and soil diversity in Europe.
For the sensitivity analysis, both substance and scenario parameters are included to explore regions in parameter phase space where the models show high sensitivity to certain parameters over others. A key purpose of this analysis is to flag highly sensitive scenario parameters, allowing for more precise information gathering and improved control over environmental variabilities and uncertainties. Additionally, the project aims to simplify the user interface by highlighting sensitive substance properties for which the reduction of uncertainty would be beneficial and less sensitive properties for which a central value might be sufficient. Thus, guiding a more focused allocation of resources.

Disclaimer/Disclosure: We thank EU-PARC for funding this project.

3.03.P-Mo182 Probabilistic Spray Drift Model for Realistic Spray Applications in Arable Crops in the Netherlands
***Henk Jan Holterman**[1], Louise Wipfler[2], Mechteld Ter Horst[1], Pauline Iris Adriaanse[1] and Jan Van De Zande[1], (1)Wageningen University and Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands*
Deposits of spray drift onto edge-of-field watercourses contribute significantly to the exposure to pesticides for aquatic organisms. For regulatory purposes, still the major approach in exposure assessment is to use average drift deposition curves with wind direction perpendicular to the field edge. Few years ago, in a more realistic approach, a probabilistic exposure model has been developed for downwind deposits of spray drift for spray application in fruit orchards in the whole of the Netherlands, involving

upward/sideways directed spray applications. Recently, this approach was applied to spray application for downward sprayed crops (arable crops). In principle, the IDEFICS spray drift model for arable crops is suitable to be used in this probabilistic method. However, the method typically involves 100,000 simulation runs for a single countrywide probability estimation, which are impossible to carry out using IDEFICS. Therefore, first a statistical metamodel was derived from IDEFICS, for an appropriate number of simulation runs with relevant parameter settings. The metamodel was calibrated to closely fit the WUR Drift Calculator (WDC) for parameter settings equivalent to those used in the WDC. Next, the metamodel was implemented in the newly developed countrywide probabilistic model, named PROSPEX. The latter model required as inputs the frequency distributions of meteorological factors (wind speed, wind direction, temperature, relative humidity) for different regions across the Netherlands. Distributions of edge-of-field watercourses next to arable fields across the Netherlands were required inputs as well. Crop related aspects were based on Ctgb s list of all crops grown in the Netherlands (DTG list). WDC s drift mitigation measures were implemented as well. In this way, the PROSPEX model can be considered as an extension of the WDC for more realistic simulations. Currently, it is being implemented in the DRAINBOW model, which combines different pesticide exposure routes and fate in edge-of-field watercourses for higher-tier regulatory use in the Netherlands.

3.03.P-Mo183 Assessing Connectivity of Uncertain Field Sites in Groundwater Tier-4 Programmes using Conservative Tracers

*Florian Hegler[1], **Fabrizio Rama**[1] and Federico Ferrari[2], (1)Syngenta Crop Protection, United Kingdom, (2)Aeiforia srl, Italy*

Groundwater (GW) monitoring is the highest tier (Tier-4) in the leaching assessment of plant protection products (PPPs) in the FOCUS GW assessment scheme. To ensure GW monitoring sites are fit for purpose (i.e., to address vulnerable real-world worst-case scenarios), proving hydraulic connectivity between the field and sampling well may be necessary. GW monitoring sites are installed in real-world conditions and can face variability in hydrogeological settings, which can impact their use as vulnerable monitoring locations. To address this issue tracer tests can be performed on sites where GW flow assessment is variable or site design is questioned. By establishing the degree of hydrogeological connectivity between treated fields and wells, the accuracy of leaching estimates in groundwater risk assessment can be supported.

In this case study four sites with uncertain connectivity in Italy were selected. These sites are part of an ongoing GLP GW monitoring programme (edge-of-field setting), providing realistic and quantitative information for Tier-4 monitoring programmes. A common tracer, Potassium Bromide (KBr), was applied to sub-plots at each site. GW samples were collected from three or four wells installed around the field edge. At each site GW samples were collected regularly (weekly to quarterly) over one year to track the movement of bromide ions in the subsurface. At each site information on site characterization (e.g., depth to water, weather and rainfall) and other ancillary data (e.g., ditch status and rivers) was also collected. Ion chromatography was used to analyse for Bromide.

Initial results suggest that three out of four sites have wells hydrologically connected to the surface of the field. The fourth site shows a complex behaviour, being influenced by nearby surface features, and is still under investigation. This work shows how to design and perform a connectivity assessment at hydrogeological sites for a Tier-4 GW monitoring study aimed at evaluating the potential leaching of PPPs. By addressing uncertainties at the field scale, trust in the employment of Tier-4 data in plant protection product risk assessment will contribute to informed decision-making processes of PPPs.

3.03.P-Mo184 Groundwater Dilution Factor Evaluation in the EU Using the Spatial LUCAS PEARL Modelling Framework

***Chunming Sui**, Trung-Hieu Mai, Sebastian Gebler and Tom Schroder, BASF SE, Germany*

In 2023, EFSA and ECHA have published a new guidance on the impact of water treatment of Plant Protection Products (PPPs) residues for drinking water. The guidance assumes that PECgw at 1m soil depth (Tier 1/2/3 of FOCUS GW) will be the final exposure indicator for evaluation, without considering any dilution factor (DF) across different EU regulatory zones. The attenuation of PPP concentrations along the flow path from the regulatory PECgw,1m to the potential raw groundwater abstraction location has been scientifically discussed on varies scales through either data analysis or modelling assessment. However, there is currently no systematic study available at the EU level for estimating groundwater DFs. Furthermore, the recent EFSA statement on groundwater monitoring and exposure assessment from 2023 suggests that a depth of 1 2m below the shallow groundwater table (i.e., GWT < 10 m) can be used as a conservatively representative depth for aquifer quality evaluation. In light of this, we have developed a spatial modelling framework to investigate the EU-level groundwater DFs from PECgw,1m to PEC in the 2m thickness aquifer below GWT (PECgw,2m-aquifer).

Over 5,000 virtual well catchments (VWCs) were derived using LUCAS 2018 soil points as pour points for drainage area calculation, utilizing the EU digital elevation model through hydrological assessment. In the soil unsaturated zone of each VWC, the LUCAS soil data was implemented in the 1D leaching model FOCUS-PEARL 5.5.5 for calculating the maximum PECgw,1m over a 100-year simulation period, as well as the total leaching mass over entire agriculture land to aquifer at the year when maximum PECgw,GWT occurs. In the aquifer of each VWC, a simple well-mixing reservoir model was employed to calculate the PECgw,2m-aquifer, considering spatially distributed porosity in deriving aquifer storage volume. Nine dummy substances scenarios with varying DT50 values ranging from 10 to 200 d and Kf,oc values from 10 500 mL/g were used for quantifying DFs by equation of maxPECgw,1m/PECgw,2m-aquifer for each VWC. Our calculated 50th percentile DF reached 26 (n = 12,199) in the Northern Zone, 87 (n = 25,413) in the Central Zone, and 117 (n = 21,866) in the Southern Zone. Our findings indicate that using PECgw,1m as the final exposure indicator for drinking water abstraction evaluation is overly conservative even under the EFSA recommended representative groundwater depth for shallow aquifer.

3.03.P-Mo185 Enhancing Groundwater Exposure Assessments for Pesticides: Addressing the Challenges of Monitoring Studies in the Absence of Harmonized Guidance Document
***Gabriella Carlotta Fait**, Roberto Lava, Christopher Lythgo, Jose Oriol Magrans Soria, Vincenzo Padricello and Laura Padovani, European Food Safety Authority (EFSA), Italy*
Groundwater monitoring represents a higher-tier option in the groundwater exposure assessment of Plant Protection Products (PPPs) in the context of the peer review process for evaluating active substances and their metabolites in the EU. However, a harmonized guidance document on how to conduct such monitoring and interpret the results is missing. A scientific paper on the design and conduct of groundwater monitoring studies supporting pesticide groundwater exposure assessment was published by Gimsing et al. (2019). This paper set the basis for developing a guidance document on pesticides groundwater monitoring. At the request of the European Commission, EFSA PPR Panel reviewed the paper by Gimsing et al. (2019) and wrote a statement (EFSA, 2023).
According to the EFSA statement well-conducted monitoring studies provide more realistic exposure assessments, potentially superseding findings from lower-tier studies. However, the lack of Exposure Assessment Goals (ExAG) hampers the development of an harmonized guidance on designing, conducting, and evaluating monitoring studies for regulatory purposes. In the absence of a specific guidance document, the evaluation and use of submitted monitoring studies during the peer review is challenging.
This study is based on the most recent discussions from expert meetings held during the peer review process, following the publication of the EFSA statement. These meetings focused on the evaluation of monitoring data and their acceptance for higher-tier groundwater risk assessments. Unresolved issues on study design were addressed, including uncertainties on monitoring depth, site selection, groundwater flow direction variability, and application patterns. Emphasis was put on the need for harmonized models and guidelines for vulnerability assessments to support site selection and context setting. A positive outcome was the agreement on how to present result tables. However, no final agreement was reached on a specific type of regulatory endpoint, and it was concluded that the use of the 90th (spatial/temporal) percentile concentration is not defensible for groundwater monitoring data. A higher percentile might provide a more robust regulatory outcome. Finally, it was stressed that the absence of ExAG for groundwater leaching at the EU level remains a significant limitation. Without clear ExAG, it is difficult to establish standardized procedures and evaluate monitoring studies consistently for regulatory purposes.

3.03.P-Mo186 Challenges for Soil Photolysis Modelling in Groundwater Risk Assessment: An Analysis of Surface Layer Dynamics in FOCUS Models
*Edna Rödig[1], **George Mahoney**[2] and David Patterson[3], (1)Syngenta Agro GmbH, Germany, (2)Syngenta Crop Protection, United Kingdom, (3)Science Strategy, Syngenta, United Kingdom*
The European Food Safety Authority (EFSA) guidance on soil phototransformation products in groundwater (GW) recently mandated the use of a soil photolysis module within FOCUS PELMO. Initial tests indicate that the extent of photolysis in FOCUS PELMO simulations is highly sensitive to environmental processes governing the duration for which chemical mass is retained within the photolytically active topmost one millimeter of soil. Notably, this guidance was implemented despite EFSA's acknowledgment that FOCUS GW models were not developed nor calibrated to accurately predict chemical fate and environmental processes in the surface layer.
This study analyses water, soil, and compound behaviour within the surface layers of FOCUS PELMO and compares it to the predicted behaviour in FOCUS PEARL. As the photolysis module has not been implemented in FOCUS PEARL, precluding direct comparison of photodegradation between the models, we assess models' susceptibility to photolysis by analysing the residence time of substances in the surface

layer, i.e., the exposure to photodegradation. In the absence of true validation for either model against environmental data in the topmost layer of soil, this analysis provides model cross validation.
A direct comparison of the two models reveals that while soil temperature correlates strongly (R = 0.85-0.94), soil moisture (R^2 = 0.07-0.33) and water fluxes (R^2 = 0.33-0.83) differ substantially. The hydrological disparities between the models result in differences in substance residence time in the soil surface, significantly impacting susceptibility to photolysis.
We conclude that implementing a photolysis module within PEARL would likely yield PECs that differ significantly from those produced by FOCUS PELMO. Thus, both models will require calibration at the topmost soil layer similar to that performed at 1m depth. This therefore raises concern regarding the reliability of risk assessment decisions based on the current in force guidance.

3.03.P-Mo187 Modelling bromide breakthrough in railway lysimeters
***Valerian Zeender**[1], Ignaz Buerge[2], Roy Kasteel[1] and Thomas Poiger[2], (1)Agroscope, Switzerland, (2)Plant Protection Products – Impact and Assessment, Agroscope, Switzerland*
Lysimeters exposed to natural precipitation were used to study the leaching behavior of various herbicides in railway track soils. We focus here on the leaching dynamics of the commonly employed conservative tracer bromide, aiming at charactering the lysimeters in terms of effective transport volume and dispersion of solutes.
Once a year, we applied bromide to some of our ten field lysimeters (0.5 m2 x 1.45 m), which are filled with railway materials from three different locations (i.e., there are two triplicates and one quadruplicate) and analysed bromide in the leachate. Breakthrough curves (BTCs) were determined for up to five years for one and the same lysimeter, allowing us to link the BTCs to the meteorological conditions (i.e., inter-year comparisons). As data for each lysimeter are available, we can also investigate the influence of the type of the soil on the BTCs as well as differences between lysimeters filled with the same material (i.e., inter-lysimeters comparisons).
We used an analytical model to fit the bromide BTCs, assuming steady-state flow and a constant water content over depth in a homogeneous soil. The model fitted relatively well to the experimental BTCs, with calculated bromide recoveries ranging from 74% to 103%, compared to measured values of 55% to 105%. Dispersivity, a measure of how substances spread through the soil column, varied both within and between the three lysimeter materials, as well as across years. Notably, higher stone content was associated with an increased dispersivity (i.e., a lower amplitude and an extended duration of the BTC), but also an earlier onset of the BTCs. We also note that, within the same lysimeter, the effective volumetric water content that participates in bromide transport was higher during a wet year, suggesting that weather conditions play a significant role in how bromide is transported through the soil column.
Being able to model how bromide behaves in the different railway soils will greatly facilitate the interpretation of the leaching behavior of the herbicides applied to these lysimeters and their metabolites. Ultimately, the results of the study will assist railway companies in making more judicious decisions about the potential leaching risks of applied herbicides to groundwater.

3.03.P-Mo188 Assessment of Organochlorine Pesticides and Chlorpyrifos in Groundwater in the Yucatan Peninsula
***Alejandra Sanchez-Gonzalez**[1], Elsa Norena-Barroso[2], Anne Bussy[3], Gabriela Rodriguez Fuentes[4], Erick Soto-Garcia[4], Roger Pacheco-Castro[4] and Paulo Salles[4], (1)Posgrado Ciencias del Mar y Limnolog a (UNAM), Mexico, (2)Universdidad Nacional Autonoma de Mexico (UNAM), Mexico, (3)Universidad Autonoma Metropolitana (UAM-Lerma), Mexico, (4)Universidad Nacional Autonoma de Mexico (UNAM), Mexico*
Yucatan Peninsula (YP) is formed by a large limestone platform with dissolution conduits and fractures that result in a complex coastal karst system that is highly permeable and therefore vulnerable to contamination. This system transports large volumes of groundwater with significant discharge in coastal zones, representing the only source of drinking water for the population. Among the anthropogenic activities carried out in the area, agriculture has a high water consumption rate and is associated with contamination by pesticides. Despite being restricted/prohibited in Mexico, there are still reports of the use of organochlorine pesticides (OCP) in the region. Published research reports high concentrations of these compounds in groundwater (supply wells and in the ring of cenotes). OCP are highly persistent in aquatic environments and have been detected in different environmental matrices in the YP: coastal and groundwater, beach and mangrove sediments, and protected organisms such as the green turtle. The aim of this research was to assess the presence of 19 individual OCPs and the organophosphate pesticide chlorpyrifos in 16 sites (15 monitoring wells and one cenote) in the northern YP, including the states of Campeche, Yucatán and Q. Roo. Water samples (n = 29) were collected in May 2024 and spatial geographic variation and two depths (superficial and middle depth) were considered. OCP and

chlorpyrifos were determined by solid phase extraction (SPE) and gas chromatography coupled to mass spectrometry (GC-MS) in single ion monitoring (SIM) mode. Despite being a non-restricted and frequently used pesticide, chlorpyrifos was not present in the water samples; in contrast, 14 individual OCPs were detected, all below the maximum permitted limits set by the Mexican standard for drinking water. The average concentration of total pesticides was highest in the wells of Q.Roo with 127.6 ± 42.8 ng/L, while the mean levels in the wells of Yucatan and Campeche were very similar, 54.0 ± 63.9 and 53.9 ± 57.4 ng/L, respectively. The most frequently detected pesticides were endosulfan I (81.3%) and DDE (75%). Endrin and endrin ketone were the compounds detected in the highest concentration with maximum values of 82.3 and 204.0 ng/L, respectively. A general tendency to detect higher levels in surface samples is observed. The presence of these restricted pesticides in the YP groundwater is a cause for concern, since their toxic effects have been widely described.

3.03.P-Mo189 CF3-Containing Pesticides and Widespread TFA Contamination of Groundwaters: Source Evidence and Uncertainties from Luxembourgish Studies

Tom Galle[1]*, Denis Pittois*[1]*, Philippe Diderich*[2] *and Julien Farlin*[2]*, (1)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)Luxembourgish Water Management Administration, Luxembourg*

Trifluoroacetate (TFA) is currently under focus because of the widespread pollution in surface and ground waters. TFA might jeopardize the total PFAS parameter threshold in drinking water (500 ng/L). Sources of TFA are manifold ranging from ubiquitous atmospheric input, over fluorinated pesticides, manure and fluorinated pharmaceuticals contained herein as well as potential industrial sources. While the latter are not relevant for drinking water protection zones in Luxembourg, the first three sources are. The initial approach was to monitor groundwater spring and wells with a gradient of nitrate pollution that represents variable agricultural land use in the capture zones. Nitrate values spanned from 4-77 mg/L and 40 sites were sampled along the gradient. Pearson correlation coefficient turned out to be 0.61 with the intercept at 522 +/- 265 ng/L. Variability around the linear regression was substantial but residues showed normal distribution. Atmospheric wet deposition with 500 ng/L TFA concentrations have been reported throughout Europe. 28 of of 40 samples exceeded 1000 ng/L with a maximum of 5630 ng/L. A projection of average CF3 containing pesticide use statistics for Luxembourg with the assumption of 100% TFA generation showed that the regression supported pesticides, especially the largely used flufenacet as a main source. However, simultaneously run analysis of flufenacet-ESA in the samples showed no detections with an LOQ of 5 ng/L. On the other side flufenacet-ESA is regularly detected in flood waves in surface waters, as is dimethenamid-ESA, whose parent compound dimethenamid-P has been also increasingly used in the recent years. Dimethenamid-ESA is being increasingly detected in Luxembourgish groundwaters and has shown a 33% positive detection in the set of 40 samples considered here. A possible explanation would be the selective degradation of flufenacet-ESA in the aquifer with residence times of 10-20 years. The poster will present the evidence, discuss uncertainties and open questions around the stoichiometry of Flufenacet- TFA degradation pathways.

Disclaimer/Disclosure: The study is financed by the Luxembourgish Water Management Administration

3.03.P-Mo190 Landscape Level Modelling for Derivation and Contextualization of Worst-Case Surface Water Dilution Factors at Drinking Water Abstraction Locations

Mohammad Hatamjafari*, Sebastian Gebler and Tom Schroder, BASF SE, Germany*

EFSA issued a guidance document on the impact of water treatment processes on residues of active substances or their metabolites in water abstracted for the production of drinking water. The guidance contains recommendations for the Step 1 screening process, the exposure assessment of plant protection products at drinking water (DW) abstraction locations, originating either from groundwater or surface water (SW). For drinking water abstracted from surface water, the guidance proposes calculating predicted environmental concentrations (PEC) at drinking water abstraction locations (PECdw) by applying dilution factors (DF) to edge-of-field PECsw calculated according to FOCUS (FOrum for the Co-ordination of pesticide fate models and their USe). Worst-case dilution factors (DF) are to be used as the first tier; DF derived from GIS-based landscape-level assessments can be used as higher tier options. This study is an extension and continuation of a previous geospatial analysis that builds upon the Dutch DROPLET model and investigates generic dilution factors starting from edge-of-field PECsw and extending to a potential drinking water abstraction location downstream at the catchment outlet. This innovative approach incorporates agricultural land use and hydrology considerations, and utilizes a stepwise GIS-based approach at the EU level. The present study explores the significance of upstream agricultural land use, catchment hydrology, and connectivity of treated fields in relation to the proposed datasets and parameters outlined in the guidance, and beyond. Results show a significant difference when compared to the proposed worst-case dilution factors outlined in the guidance. The methodology and datasets used contribute to a more realistic Step 1 screening process. To contextualize the proposed method, the Soil and Water Assessment Tool (SWAT) is utilized as a higher tier model. By integrating detailed parameters, SWAT provides a comprehensive framework for assessing water quality and quantity within a watershed in space and time. In this study, SWAT serves as a crucial tool for evaluating the dilution factors derived from the GIS-based analysis. SWAT also offers a higher level of detail, which enables a more nuanced understanding of the interactions between agricultural practices and water quality outcomes at a catchment level.

3.03.P-Mo191 Use of Geospatial Analysis Techniques to Evaluate Potential Risks of Plant Protection Products to Drinking Water Abstraction Points in the Netherlands

Olha Khomenko *and Abdul Abu, Cambridge Environmental Assessments, United Kingdom*

In environmental risk assessment of plant protection products, geospatial analysis techniques can be used for modelling, contextualisation and vulnerability mapping, utilising surveys, monitoring data as well as satellite imagery. Spatially distributed modelling or use of monitoring data are considered higher tiers in the environmental risk assessments of active substances of plant protection products in the EU and Member States.

In this study, we applied advanced geospatial analysis techniques to evaluate the potential risks of a specific crop protection active substance to enter drinking water treatment systems (DWTP) in the Netherlands. Publicly available monitoring datasets, land use survey data, and web mapping services were combined to: (1) determine precise locations of water treatment plants, abstraction points, and water protection zones in the Dutch regions; (2) identify and map agricultural fields where the active substance was used; and (3) calculate the shortest distances between agricultural fields where the substance was used and the nearest surface water body and drinking water abstraction points.

Using Geographically Weighted Regression (GWR), we assessed how the relationship between crops cultivation and surface water concentrations of the active substance varied at the local scale around drinking water treatment plant (DWTP) abstraction points. The GWR method enabled us to capture spatial variation in the risk associated with surface water contamination more precisely, allowing for localized assessment that standard Dutch regulatory modelling approach using GeoPEARL, DROPLET or TOXSWA might overlook. Additionally, Hot Spot Analysis using the Getis-Ord Gi* technique was employed to identify agricultural areas where potato cultivation posed a statistically significant risk to the drinking water abstraction points. These tools helped identify at-risk abstraction points with much greater accuracy, while also indicating that the nearest treated field was approximately 15 km from the DWTP. The combination of GWR and Hot Spot Analysis provided a robust workflow for the identification of spatial relationships between plant protection product uses and potential contamination of surface water abstracted for drinking water in the Netherlands. These geospatial analysis techniques could allow for more precise and informed higher tier risk assessments and regulatory decision-making in the Netherlands and other EU Member States.

3.03.P-Mo192 Scoping Refinements for Surface Water Metabolites in Relation to the Drinking Water Treatment Guidance

Linda Maguire *and Wendy van Beinum, Enviresearch Ltd, United Kingdom*

The new Drinking Water Treatment guidance released by EFSA in July 2023 has led to many questions on how this will impact active substances and their metabolites in the European market. The guidance applies to both surface water and groundwater bodies, with all substances present at ?0.1 µg/L considered relevant for assessment. While active substances tend to have a large amount of data available to refine the risk assessment, the same cannot be said for metabolites. In particular metabolites only observed in the water compartment often rely on default values. Therefore, a scoping assessment has been performed to assess if defined endpoints would improve the risk assessment and eliminate the need to assess these substances further.

Several substances with metabolites triggered under the Drinking Water Treatment guidance in surface water were selected. The options were assessed according to FOCUS surface water guidance using the default parameters and then a variation of possible DT50, KOC and formation fraction values that could be generated from laboratory studies. The results were then analysed to determine the impact of the refined endpoints of these metabolites for resolving the Drinking Water Treatment guidance requirements at Step 1.

3.03.P-Mo193 Muddy Waters. Navigating the EFSA/ECHA Drinking Water Treatment Guidance for Biocidal Products: Impacts, Challenges, and Uncertainties

Helen Sneath*, TSG Consulting, United Kingdom*

The EFSA/ECHA guidance document on the impact of water treatment processes on residues in water abstracted for drinking water production applies to both active substances and products under Regulation (EU) 528/2012 from 1st April 2026. Therefore, in many cases, the biocidal product application stage will represent the first time the active substance(s) involved will be evaluated against this guidance adding additional uncertainty to the registrability of biocidal products.
The guidance can be broadly divided into three parts: environmental exposure, water treatment transformation product (tTP) testing, human health hazard assessment. Understanding the nuances of the environmental exposure assessment is key as it triggers subsequent tTP testing and human health hazard assessment, which are expected to be costly and complex to conduct.
As of July 2024, there were 294 active substance-product type combinations approved in the EU. Using the publicly available data from the active substance approvals process, an assessment of the proportion of products likely to require tTP testing is made based on the environmental risk assessments conducted for the representative products. In considering the environmental exposure pathways and models across the different product types, uncertainties come to light in the application of the guidance and consideration of further impacts on the stewardship of biocidal products through the regulatory process is made.

3.03.P-Mo194 Robust and Representative Allocation of Arable Land in Spatial Layers used for Risk Assessments
***Fabrizio Rama**[1], Gregor Spickermann[2], Sebastian Gebler[3], Nils Kehrein[4] and Raghu Vamshi[5], (1)Syngenta Ltd, United Kingdom, (2)ADAMA Agricultural Solutions Ltd, Israel, (3)BASF SE, United States, (4)Division Crop Science, Bayer AG, Research Triangle Park, United States, (5)Corteva Agriscience, United States*
The concept of arable land is a cornerstone of any regulatory activity related to agriculture in Europe. However, the identification of arable land using geodata can be still challenging. The differences in sources, versions, resolutions and accuracies of geodata become evident in spatial analyses. This work aims to demonstrate challenges and questions that may arise in defining arable land within the regulatory context using Corine Land Cover (CLC). CLC repository includes 11 agriculture classes: three annual, three permanent uses, one pasture/grass, and four heterogeneous uses. In Europe, agriculture covers more than 2.1 million pixels (~211 million ha), representing 48.8% of the land use. Majority of agricultural land is non-irrigated arable land (56.9%), followed by pasture (17.1%), and complex cultivation patterns (10.2%). However, a variable subset of those classes is used to identify arable land. All classes excluding rice and pasture are proposed in the EFSA report on SW repair, covering 82.6% of all agriculture uses that include patchy and mixed classes (e.g., agro-forestry areas). Three annual crop classes, including rice, are instead used in the latest OM map of arable land, which reduces the bias of patchy classes but also decreases the coverage (only 58.6%). A middle ground would include complex cultivation patterns and annual crops associated with permanent crops but excluding rice, thereby reducing the bias given by the most patchy classes but increasing the coverage to 74.1% of agriculture uses. Though more recent versions are available, an outdated CLC2000 is included in the EFSA spatial dataset. Input data used in the risk assessment have not been updated for 24 years, thereby resulting in many uncertainties. For example, a resampled 1-km grid map is used instead of the original map: in heterogeneous areas, the class assigned to the cell may cover only ~25% of the land uses in the grid. In comparison, the soil parameters used in the risk assessment (e.g., pH, OM, BD) are not derived in the same way and have a different origin and resolution. Thus, soil parameters derived from geodata and used for risk assessment may have forest soil biases and may not be representative of agricultural uses. This risk is reduced in less patchy areas or where the CLC class is homogenous. This work indicates the need for a broader discussion around the use of geodata in risk assessment, particularly on robustness, transparency, and consistency.

3.03.P-Mo195 Global Pesticide Application Data as Input for Assessing Ecosystem Exposure and Impacts
***Yuyue Zhang**[1], Anja Gladbach[2], Marissa B. Kosnik[3], Luke Settles[4], Ulf Norinder[5], Daniel Glas[2], Olivier Jolliet[1] and Peter Fantke[6], (1)Technical University of Denmark, Denmark, (2)Bayer AG, Crop Science Division, Germany, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (4)Bayer CropScience LP, United States, (5)Örebro University, Sweden, (6)substitute ApS, Denmark*
Agricultural pesticide applications significantly impact terrestrial and aquatic ecosystems, yet comprehensive data on actual field applications remains fragmented. We address this knowledge gap by developing the first global dataset of agricultural pesticide applications at country-crop-chemical level, incorporating detailed information on crop growth stages, application timing, and methods. This dataset aims to support the development of approaches that can predict how different application scenarios influence exposure and impact patterns across species and trophic levels in terrestrial and aquatic

ecosystems.
By synthesizing field-level application records from agricultural monitoring programs (2016-2020) and employing machine learning approaches including XGBoost and conformal prediction, we created a comprehensive dataset on pesticide application, including a spatially-explicit mapping at 5×5 arcminute resolution for each country-crop-chemical scenario. Our methodological framework integrated different datasets into a consistent format capturing application parameters, environmental conditions, and agricultural practices.
The resulting database encompasses more than 2.9 million tonnes of annual average pesticide use across 180 countries and 130 crops, involving 1077 distinct compounds. Four compounds dominate global usage: glyphosate (0.64 million tonnes), sulphur (0.17 million tonnes), mancozeb (0.16 million tonnes), and atrazine (0.1 million tonnes), with China, USA, and Brazil accounting for 46% of total mass application despite covering only 25% of global crop treated area. To address data gaps, we developed estimations for 81 nations, predominantly in sub-Saharan Africa, and supplemented missing application details for over 50% of country-crop-chemical combinations. The dataset provides compound-specific application patterns, including detailed timing and methods, exemplified by Acephate usage in US cotton and soybean production.
This comprehensive resource enables reconstruction of exposure scenarios, identification of chemical accumulation hotspots, and assessment of spatial and temporal exposure variations. The dataset uniquely supports development of targeted risk mitigation strategies and evidence-based policies for protecting biodiversity from chemical stressors, directly contributing to objectives such as the EU Zero Pollution Strategy and Biodiversity Strategy.

3.03.P-Mo196 Assessing Exposure to Pesticides with Spatially Distributed Environmental Scenarios at Field Level in Czechia

Artur Radomyski[1], *Lingtong Gai*[2], *Joao P. Nunes*[2], *Shiva Sabzevari*[1], *Joost Vlaming*[3], *Daniel M. Figueiredo*[4], *Reynold Chow*[2] *and Jakub Hofman*[1], *(1)RECETOX, Masaryk University, Czech Republic, (2)Soil Physics and Land Management Group, Wageningen University & Research, Netherlands, (3)Envista Consultancy, Netherlands, (4)Institute for Risk Assessment Sciences (IRAS), Utrecht University, Netherlands*

Biotic, abiotic and agronomic parameters are the building blocks that constitute environmental scanarios providing context for exposure modelling to chemicals. Currently used exposure modelling frameworks, e.g., FOCUS surface water 2001, provide limited view on impact of spatiotemporal variability of environmental scenarios on estimated exposure profiles of agrochemicals in environment.
We compiled data related to application regimes of three Active Substances' (AS): glyphosate, tebuconazole and acetamiprid, followed by climate, topography, soil and hydrology data at individual field level using publicly available national, European and global datasets, such as, national crop maps and Plant Protection Products use statistics (PPP), PPP authorization registers, European Soil Data Centre (ESDAC) and Food and Agriculture Organisation (FAO). Data were then aggregated as Virtual Field across georeferenced agricultural fields in Czechia. Temporal (daily for year 2021) and spatial (whole-country individual fields) aspects of collected data, in particular georeferenced AS application patterns (GeMAPs), are at the centre of this work. The GeMAPs are obtained from the AS mass applied (g) and treated area (ha) for each AS-crop combination and then matched with georeferenced agricultural fields. PECsoil and PEC surface water (sw) were determinstically modelled. AS physico-chemical properties (KOC and DT50) are used to estimate intial and time averaged PECsoil for all fields in the country. Then, using daily precipitation monitoring data, daily generated surface runoff depth (mm) and AS dissolved fraction removed from topsoil are estimated for each field within a 100m buffer area around river segments. Finally, AS concentration in surface water is obtained using AS loads from adjacent fields and basin-specific river discharge volume. Application rates and estimated regulatory variables (PECsoil and PECsw) of the three ASs show significant spatial variability among individual fields not visible when the whole-district or coarser scales are considered pointing at possible pesticide exposure hot spots/moments. Data assimilation at the field scale opens the possibility for improving decision-making by locating exposure hot spots and hot moments and introducing amendment treatments. Further steps of this work will include integration of multi-annual crop data, daily precipitation, daily river flows and AS usage for prospective exposure assessment.

Disclaimer/Disclosure: This work was supported from the European Union s Horizon 2020 research and innovation program under grant agreement No 862568 (SPRINT)

3.03.P-Mo197 Challenge Accepted – First Ultra-Trace Level Monitoring Data of Pyrethroids in Bavarian Rivers

***Sonja Krezmer**, Katharina Baudrexl, Sabine Geisthardt, Manfred Sengl and Uwe Kunkel, Bavarian Environment Agency, Germany*
Pyrethroids are widely used as insecticides, biocides and pharmaceuticals and cause adverse effects to aquatic ecosystems at very low concentrations. In addition, five pyrethroids are included in the draft of the amendment of Directive 2008/105/EC on environmental quality standards (EQS) with proposed EQS values down to the low pg/l-range. However, the detection of pyrethroids in this concentration range still represents a particular analytical challenge and thus only little monitoring data is available for adequate assessment of pyrethroids in surface waters.
Therefore, we developed a sensitive method for six common pyrethroids. Briefly the method consists of liquid-liquid extraction of 1 L surface water with 40 mL hexane and subsequent determination of pyrethroids with large-volume GC-EI-MS/MS. We reached limits of quantification (LOD) of 50 pg/l to 100 pg/l allowing a first assessment of proposed chronic EQS for most pyrethroids.
In 2022, pyrethroids were analyzed quarterly at ten major rivers across Bavaria. β-cyfluthrin and cypermethrin were not detected at all, while deltamethrin and esfenvalerate were found only very sporadically. Bifenthrin and permethrin were detected at five respectively six of the ten sampling sites with total detection frequencies of 30% and 33%. Only permethrin was determined at concentrations higher than 1000 pg/l, while the concentrations of all other pyrethroids were significantly less than 1000 pg/l.
In addition, we determined pyrethroids in 165 samples from 94 sampling sites of a project which intended to give a broad overview on the pollution status of smaller Bavarian rivers. Esfenvalerate was never detected, while β-cyhalothrin, cypermethrin and deltamethrin were detected just once. In consequence, only bifenthrin and permethrin were determined regularly above LOD at 9 respectively 33 of the 94 sampling sites with total detection frequencies of 7.8% and 34% and maximum concentrations of 1300 and 1700 pg/l.
In total, our monitoring data represents one of the first data sets that enable a preliminary assessment of pyrethroids in Bavarian surface waters. While none of the pyrethroids exceeded the proposed acute EQS values, further analytical development is required to lower the LODs for the assessment of chronic EQS values for all pyrethroids.

3.03.P-Mo198 Occurrence, Spatial Distributions, and Influencing Factors of Neonicotinoid insecticides in Soils from Agricultural Farmlands in China: A National Study

***Jie Hou** and Wenxin Liu, Key Laboratory for Earth Surface Processes, College of Urban and Environmental Sciences, Peking University, China (Mainland)*
Neonicotinoid insecticides (NEOs) are widely used in crop production in China, raising concerns about their health and ecological risks due to persistent residues in agricultural soils. Previous research has reported NEO contamination in soils of China s coastal regions, but national-scale data and information on NEO metabolites remain limited. On the other hand, both NEOs and microplastics (MPs) are commonly found in agricultural fields, but their co-occurrence characteristics under realistic fields have not been reported.
This study found that at least one NEO was detected in all soil sample. Imidacloprid was the most common parent NEO, with imidacloprid-urea as its primary metabolite. Results showed higher NEO concentrations in coastal areas at similar latitudes compared to inland regions. The extent of agricultural film cover (i.e., greenhouse, farmland with film mulching, and farmland without film mulching) and microplastics (MPs) might influence pesticide residues in soil. This study revealed an association between MPs and NEOs in realistic agricultural settings. Random forest models offered more reliable predictions than linear models and indicated that MPs, farmland type, and total nitrogen are key contributors to NEO levels.

Disclaimer/Disclosure: The authors would like to thank all responsible editors and reviewers for their helpful comments on the manuscript. This work was supported by the Natural Science Foundation Committee of China (No. 41991310).

3.03.P-Mo199 Analysis of the Contamination and Reduction of Pesticide Residues During Transition from Conventional to Organic Rice Production in the Mekong Delta of Vietnam

***Linda Klamann**[1], Björn Thiele[2], An Giang Cao Dinh[3], Khoi Chau Minh[3] and Lutz Weihermüller[2], (1)Research Center Julich GmbH, Germany, (2)Forschungszentrum Jülich GmbH, Germany, (3)Can Tho University, Viet Nam*
Rice cultivation in the Mekong Delta of Vietnam plays a critical role in both food security and the national economy. However, intensive agricultural practices, including the widespread use of pesticides and

fertilizers, have raised concerns regarding environmental sustainability and human health. This study aims to evaluate pesticide residues in the Mekong Delta, with a focus on the three provinces Vinh Long, An Giang an Dong Thap, and assess the feasibility of transitioning from conventional to organic rice farming practices. Household surveys were conducted in the three provinces to understand farmers' pesticide usage patterns. Therefore, the farmers were asked for information about which pest dominates on their farm, which pesticides are being used, on the frequency of the pesticide usage, and their application dose. Additional information about major crop, crop rotation, number of harvest per year, and farm size were also provided. The surveys revealed a diverse array of 85 different pesticide brands corresponding to 51 active ingredients, with insecticides comprising the majority, followed by fungicides and herbicides. Additionally, soil and water samples were collected for pesticide residue analysis in rice fields in each province respectively. Pesticide residues were extracted using solid-phase extraction for water samples and accelerated solvent extraction for soil samples. For the analysis of pesticides a non-target screening was carried out using LC-MS/MS and the Quanpedia data base, which contains the information of 750 widely used pesticides. The non-target screening identified 74 active compounds belonging to the categories Fungicides, Herbicides, Acaricides, Insecticides. Moving forward, ongoing farmers survey s will help to assess regional variations in pesticide usage, while targeted quantification of select compounds will provide insights into contamination levels. Ultimately, this study contributes to our understanding of pesticide pollution in rice farming regions and informs strategies for promoting sustainable agriculture and safeguarding environmental and human health in the Mekong Delta.

3.03.P-Mo200 Pesticides Contamination in the Irrigation System of Arequipa, Peru

Victor Hugo Rodriguez Uro[1], Betty Paredes[1], Cesar Ranilla[1], Mario Lopes Araujo[2], Alexandre Campos[2], Mostafa Soliman[3], Vaidotas Kisielius[4] and ***Pedro N. Carvalho****[5], (1)Universidad Nacional de San Agustin de Arequipa, Peru, (2)Interdisciplinary Centre of Marine and Environmental Research, Portugal, (3)QCAP Ministry of Agriculture and Land Reclamation, Egypt, (4)Environmental Science, Aarhus University, Aarhus, Denmark, (5)Environmental Science, Aarhus University, Denmark*

Agriculture is the second-largest economic activity in Peru, playing a significant role in the country's exports. Yet, agricultural practices in the country rely heavily on using pesticides and other chemicals to enhance and secure food production, raising public health and environmental concerns. Therefore, in this study, we aimed to detect the presence of various pesticides in the irrigation system of Arequipa, Peru. A sampling campaign was conducted in May 2022, analyzing water samples from key areas, including the Chili River, water ponds, and the Aguada Blanca and El Pañe reservoirs. Pesticide analysis involved water filtration, solid-phase extraction (C18 SPE cartridges), and a quantitative LC-MS/MS workflow. A total of 15 pesticides were analyzed in 26 samples. Results revealed the presence of 7 pesticides not approved under European regulations, although none of them are restricted by Peruvian regulation. Furthermore, Peruvian water quality standards do not include the monitoring of these pesticides, highlighting regulatory gaps. The detected pesticides included diuron, tebuconazole, propiconazole, carbendazim, azoxystrobin, and imidacloprid, confirming contamination of irrigation water bodies. This contamination suggests the existence of risks to farming workers, to consumers and to the ecosystems directly associated with the irrigation system. Further ongoing work is applying suspect screening analysis to a larger number of pesticides and other organic contaminants. The findings denote the need for stronger pesticide monitoring and regulatory measures in Peru and serve as critical evidence for governmental institutions to improve risk management and environmental protection policies.

3.03.P-Mo201 Meter-Scale Heterogeneity of Soil Properties Shapes Residual Pesticides and Potential Risk in an Agricultural Field

Yiqing Zhang*[1], Marie Uksa[1], Beate Escher[2], Qiuguo Fu[3], Mechthild Schmitt-Jansen[4], Thorsten Reemtsma[3], Hauke Harms[1] and Lukas Wick[1], (1)Helmholtz Centre for Environmental Research (UFZ), Department of Applied Microbial Ecology, Germany, (2)Helmholtz Centre for Environmental Research (UFZ), Department of Cell Toxicology, Germany, (3)Helmholtz Centre for Environmental Research (UFZ), Deptartment of Analytical Chemistry, Germany, (4)Helmholtz Centre for Environmental Research (UFZ), Department of Ecotoxicology, Germany*

Conventional agricultural management often includes field-wide, mostly homogenous application of pesticides without considering the spatial heterogeneity of soil properties. The fate and residual concentrations of pesticides, however, vastly depend on the soil properties influencing their potential risk to the environment. While the fate of pesticide residues in given soils is generally known, there is still a lack of in-situ observation on the impact of meter-scale heterogeneity effects on residual pesticide concentrations and their associated potential risk. In an agricultural field (0.37 ha) we determined the meter-scale spatial heterogeneity of soil properties and correlated the data to pesticide residues and their associated risks by chemical analysis and high-throughput cell-based in-vitro bioassays.

The soil pesticides and their transformation products were identified and quantified by LC-MS/MS upon accelerated solvent extraction. The bioassays were based on the mammalian cell-based AhR-CALUX and the freshwater algal growth inhibition assay using synchronised cultures of the green alga Scenedesmus vacuolatus. Chemical analysis and bioanalysis are combined by the bioanalytical equivalent concentration and iceberg modelling approaches.
The study field consisted of highly variable and spatially distinct soil properties. Textures ranged from loamy sand to silty clay. Chemical analysis identified 50 pesticides with total pesticide concentrations of 45 to 581 nmol kg-1 with loads in topsoil being twofold higher than in subsoil. Pesticide concentrations varied significantly between soil types, with higher levels in silty loam than in loamy sand. As for pesticide residues, the bioassays revealed a high and spatially heterogeneous distribution of toxicity effects.
While predicted mixture effects by the detected pesticides in the microalgae test adequately explained the measured mixture effects, measured pesticide concentrations were only partially able to explain the high toxicity found by the AhR-CALUX bioassay. This indicates that other compounds, such as PAHs, that were also detected in the soil extracts, may be responsible for the observed activation of the AhR receptor. Our study shows that meter-scale soil properties influence the load and fate of pesticides and other compounds. This suggests that meter-scale heterogeneity should be considered in agricultural field management to minimize risks arising from potential pesticide accumulation or runoff.

Disclaimer/Disclosure: I do not want my abstract to be published. This work has not been published.

3.03.P-Mo202 GB Stereoisomer Guidance: Experience of Applying the Guidance to an Active Substance Assessment

*Michelle Morris[1], **Emily Cumming**[2], James A. Hingston[1] and Joanna Moes[3], (1)Chemicals Regulation Division, Health and Safety Executive, United Kingdom, (2)Chemicals Regulation Division, Health & Safety Executive, United Kingdom, (3)HSE, United Kingdom*

The EU has adopted new guidance on risk assessments for active substances (a.s.) and metabolites of plant protection products that contain stereoisomers (EFSA, 2019). HSE has considered the guidance and concluded that it should be adopted for use in GB. However, HSE has also developed additional GB guidance to supplement the EFSA stereoisomer guidance. The EFSA guidance is clear in that, as a general principle, stereoisomers need to be treated as separate substances with respect to the risk assessment. However, the need to treat stereoisomers as separate substances may lead to more complex risk assessments, where each stereoisomer is taken through its own individual exposure assessment, before information on total exposure levels is considered in the risk assessment. Given the potential complexities associated with stereoisomer-specific risk assessments, HSE considers that the more complex assessment approaches should be triggered only when necessary.
This poster demonstrates experience gained from applying this GB guidance for the first time to an a.s. assessment. This a.s. assessment presents additional complexities of a chiral parent that shows isomer specific degradation, that also forms a set of chiral metabolites that similarly show isomer specific degradation. Difficulties arose when applying the stereoisomeric excess concept to metabolites using parent dosed degradation studies. Where there are shifts in metabolite ratios from parent dosed studies, and the parent also degrades preferentially, it is hard to separate out how much of the change is due to the metabolite isomers and how much is due to the parent behaviour. This aspect is not currently addressed by available guidance, but in this case, HSE put more weight on the behaviour in metabolites dosed studies. The GB guidance introduces some pragmatism and helps simplify the approach to risk assessments considering enantiomers. Individual soils might demonstrate a change in isomeric excess and therefore technically should result in a stereoisomer-specific risk assessment. However, by considering the combined data from several soils it may not be necessary to conduct a separate risk assessment for each isomer. If there are small differences in the combined data, then evaluators could consider conducting a single exposure assessment for the sum of isomers. Additional supporting evidence from isomer specific leaching assessments were used in the GB case to simplify future product assessments.

3.03.P-Mo203 Worked Examples for the Proposed Revision of the Aged-Sorption Guidance Document

*Ian Hardy[1], **Bernhard Jene**[2], Sevil Payvandi[3], Klaus Hammel[4] and Wendy van Beinum[5], (1)Battelle, United Kingdom, (2)BASF, Germany, (3)Syngenta, United Kingdom, (4)Bayer AG, Germany, (5)Enviresearch Ltd, United Kingdom*

In the EU Aged Sorption Guidance the use of field DegT50 values in combination with aged sorption parameters is only possible to a very limited extent. If the leaching assessment for a plant protection product (PPP) is based on field DegT50 values only, it is not recommended by the current guidance to

derive a DegT50equilibrium (rescaling of DegT50) for input in exposure models in combination with aged sorption parameters (fNE, kdes) as described for laboratory DegT50 values. This virtually prevents the mitigating effect of aged sorption on leaching and limits the applicability of the aged sorption guidance in combination with field DegT50 to very few cases.
Additional field studies were evaluated to show the relevance of aged sorption in the field: For evaluation of the field dissipation data, site-specific soil characterisation and daily climatic data for each trial were used to parameterise the FOCUS PEARL leaching model to allow detailed simulations of the transport of the PPP considered. These simulations using the site-specific data were used in multiple ways inverse-optimisation of DegT50equilibrium (ECPA06, 50 and 51), simulation of total residues (ECPA06, 50 and 51) and depth profile [P5-metric] analysis (ECPA06, 50 and 51). These detailed evaluations of the ECPA06, ECPA50 and ECPA51 datasets have illustrated the relevance of aged-sorption under field conditions.
Revisions to the current EU Aged Sorption Guidance fully allowing for the combination of field degradation and aged-sorption data proposed: If field and laboratory datasets are from different populations according to the EFSA DegT50 endpoint selector, then checks are made [P5-metric, Kd_app] to test if there is evidence of aged-sorption under field conditions. If there is evidence, then the geometric mean normalised field DegT50equilibrium is used in combination with the mean labaoratory aged sorption parameters, Fne and kdes, for the field soils. If there is no evidence of aged sorption under field conditions then field data and laboratory aged sorption parameters should not be used in expo sure assessments.
To illustrate the proposed changes to the aged-sorption guidance document, worked examples for calculation of the P5 metric and inverse-optimised field DegT50equilibrium are presented.

Disclaimer/Disclosure: The authors thank CropLife Europe for support in the evaluations.

3.03.P-Mo204 xCropProtection: A Spatiotemporal Component to Simulate Prospective and Retrospective PPP Applications in Real World Landscapes

*Claire Holmes[1], Sascha Bub[2], Thorsten Schad[3] and **Christopher M Holmes**[1], (1)Applied Analysis Solutions LLC, United States, (2)Rheinland-Pfalzische Technische Universitat Kaiserslautern-Landau, Germany, (3)Bayer AG, Germany*

There is currently both scientific and public discussion about chemical crop protection uses and trends. There seems to be consensus that chemical crop protection should be generally reduced or used more targeted in the future. In parallel there are requests for more realistic and holistic risk assessments of pesticides. We developed a spatiotemporally explicit component for simulating plant protection product (PPP) applications in landscapes which integrates with a larger spatiotemporal landscape model (xLandscape). This component, xCropProtection, can simulate applications at a field scale given PPP application information including target crops, spatial landscape information, and application periods. The result of running this component is a multidimensional dataset of PPP applications specific to individual fields and time steps. xCropProtection is parameterized with XML files, a file type used to store data in a hierarchical format well suited for sending and storing data. These XML files contain target crop types, PPP (or active substance) names, tank mixes, application rates (as a probability distribution function or a static value), probabilistic application windows, and mitigation measures for reducing exposure. xCropProtection functions both prospectively and retrospectively where input files can come from GAP tables in established risk assessment, can represent recommendations from plant protection advisory services, records from monitoring and field studies, or can be derived from market share grower surveys. xCropProtection is one component in the larger xLandscape framework that provides the simulation of more realistic pesticide applications for exposure, effect and risk assessments.

3.03.P-Mo205 Is a Common Environmental Risk Assessment Approach for Non-Professional Uses Possible Across Europe?

***Iker Garcia-Garizabal**[1], Christopher Bradatsch[2] and Andreas Hausler[2], (1)GAB Consulting Spain SLU, Spain, (2)GAB Consulting GmbH, Germany*

The authorisation process of plant protection products (PPP) in the EU is regulated through Regulation (EC) 1107/2009 and its implementing daughter Regulation (EU) 546/2011 (uniform principles), both designed to lay down rules for PPPs for their authorisation and placing on the market in the EU. Approaches for environmental risk assessment (ERA) developed in the frame of these Regulations predominantly address professional uses of PPPs, i.e., uniform full-area treatments of agricultural fields. Hence, the criteria for the authorisation of PPPs for non-professional uses (NPU, small scale often partial area treatments by amateurs) in the EU are based on these approaches, sometimes combined with specific exposure scenarios. In general, the authorisation of PPPs for such uses is fully relegated to information

available at the Zonal and/or National level. This results in Member States (MS) developing their own exposure scenarios and finally, different widely not harmonised approaches, as MS are ultimately responsible for approval and use of PPPs for NPU.
In this way, the absence of harmonised guidance for NPU can result in the authorisation of a certain PPP in one MS and the rejection in another, even if similar approaches were used. Additionally, the evaluation of the PPP dossiers for NPU tends to lengthen as the ERA is based on (inappropriate) evaluation criteria originally created for professional uses. This can hamper and delay the registration of PPPs for NPU, especially in case risk mitigation measures are indicated, ultimately leading to a lack of PPPs for non-professionals on the market.
This work aims to compile the current state of the art of ERA developed by EU MSs and Zonal Steering Committees for the evaluation of PPPs for NPU and to identify approaches and/or components which can contribute to a harmonised ERA for NPU in the EU. Most promising approaches currently used at MS level are (1) simplified authorisation of NPU products previously authorised for professional use, (2) restriction to 500 m2 of applied area considering correction factors if home gardens/allotments are concerned, (3) small-sized packages, and (4) tailored risk assessment in case of ready-to-use (RTU) products, spot application, or indoor/greenhouse applications. All these efforts should contribute to a sustainable use of PPPs by providing appropriate risk assessment approaches and facilitating authorisation of most suitable PPPs.

3.03.P-Mo206 A Hidden Potential of National Registers of PPP Authorizations – Generalized Application Patterns

Jakub Hofman[1]*, David Gonzales*[2]*, Evgenia Chaideftou*[3]*, Julio Yanez*[2]*, Sabela Rodriguez-Reino*[2]*, Artur Radomyski*[3] *and Shiva Sabzevari*[3]*, (1)Masaryk University, Czech Republic, (2)HOMOLOGA, Lexagri SAS A FoodChain ID company, St Julien en Genevois Cedex, France, (3)RECETOX, Masaryk University, Czech Republic*

EU has sophisticated legislation for PPP registration, but there is a lack of tools for the post-registration phase of pesticides, which is crucial to setting sustainable PPP use strategies and measuring their efficiency. Considering the goals of EU Farm to Fork , there is an urgent need for novel approaches to modelling pesticide exposures and risks at national and European scales.
Within the EU H2020 project SPRINT, we developed tools utilizing the data from national registers of PPP authorizations to model Generalized Application Patterns (GenAP) of pesticides. GenAP shows the authorized applications of each active substance on a defined crop in the defined time window, together with the application rate, BBCH range, and the maximum number of applications. The first GenAP was programmed in SQL for the relational database containing the Czech national PPP register. Many challenges were sorted out, including BBCH extraction from text notes, unit recalculation, and automated translations to English.
After an inventory across EU countries, we found that many countries have PPP registers with poor data quality, quantity, standardization, interoperability, and accessibility, hampering their use for GenAP. Thus, cooperation between the SPRINT project and the LexAgri database HOMOLOGA started. HOMOLOGA contains standardized data on registered PPP for all European countries. We developed SQL code for GenAP based on HOMOLOGA data. The benefit of this novel GenAP(H) is that it can be applied for any requested country because HOMOLOGA data are always structured the same way and use standardized ontology.
Within the SPRINT project research, GenAPs are further employed in the tools predicting the occurrence and risk of pesticides in soil, water, and air at local, regional, country and European levels. Thus, GenAP is combined with national PPP use statistics, national crop maps, and environmental variables. The benefit is that this approach is independent of monitoring results or farmers surveys. The resulting maps can identify the spatial-temporal cumulation of hazardous exposures and unacceptable risks, which is helpful in prioritizing pesticides for withdrawal and substitution.
It can be recommended that EU legally requests harmonizing the content and format of national PPP registers. If this happens, the huge potential of existing PPP-related data will be utilized for tools supporting EU efforts to reduce PPP use and risks.

3.03.P-Mo207 A Novel Approach for Large GAP Screening in View of EU Member State Authorisation – Extension for Groundwater and Drinking Water Treatment

Gunnar Kahl[1]*, Hong Zhang*[2] *and Frank Voss*[1]*, (1)knoell Germany GmbH, Germany, (2)Dr. Knoell Consult Shanghai Co. Ltd, China (Mainland)*

While the regulatory processes are largely harmonized over the three European zones, differences remain between the regulatory requirements of the EU member states (acceptance of different FOCUS-scenarios, mitigation options, required surrogate crops, application frequencies, accepted models). This makes the

evaluation of large GAP- (Good Agricultural Practice) tables (active ingredient submitted in multiple products, crops, and member states) very complex. The investigation which potential uses may pass the risk assessment and if a required mitigation is acceptable from the applicant s management and marketing perspective may become time consuming and expensive.
With the aid of the modelling software efam (environmental fate automated modeling) developed by knoell it is possible to automate model parameterisation and simulations for large GAP-tables utilising the relevant FOCUS-models and transfer the outputs to formatted tables as needed. Hence, with efam performing large sets of FOCUS runs for scouting becomes efficient and easy.
Previously we introduced a new tool deployed as an additional post-processing routine that is capable of analysing huge amounts of single PEC-values automatically for FOCUS surface water calculations. The routine scans efam result tables and groups PEC-values according to pre-defined matrices of FOCUS scenarios and mitigation options per country, as well as required surrogate crops. It adequately considers multiple/single applications, surface water bodies, and crop seasons. Finally, reliable passing rates for each modeled use with the active ingredient and multiple products are calculated via linear extrapolation for each member state and mitigation option. This allows a quick and reliable overview of potential maximum application rates in each member state.
Now an extension to FOCUS groundwater calculations and evaluation according to the EFSA Drinking Water Treatment guidance is available. For groundwater the tool is able to automatically analyse metabolic pathways implemented in FOCUS PELMO, PEARL and MACRO. It also allows for merging PEC-values from metabolites which occur in multiple PELMO pathways. For Drinking Water Treatment the evaluation is based on the time weighted average value at day 4 and considers evaluation of active substance and all relevant metabolites.

3.03.P-Mo208 FOCUS MACRO 5 Multithreading for FOCUS SW and GW Modelling

Denis Weber[1]*, Michael Brauer*[1] *and Martin Hilton*[2]*, (1)Exponent International Ltd., Switzerland, (2)Exponent International Ltd., United Kingdom*

FOCUS MACRO is used for SW and GW modelling for pesticide registration in the European Union. One single MACRO scenario simulation usually runs for 5 to 20 minutes, depending on the underlying hardware. The current official FOCUS MACRO model software package is only able run one MACRO simulation after another. If a metabolite is included, the simulation time increases by a factor of 3, taking into account the intermediate and metabolite runs.
In order to improve the user experience, a simple multithreading tool (MAMA) was developed, that allows to reduce the simulation time to a minimum. No adaptions to the MACRO model or to the input data were necessary.
By using a state-of-the-art computer, up to 12 to 24 parallel runs are usually possible. Therefore, several run combinations could be performed in parallel what would reduce the simulation time by 90%. The MACRO multithreading tool also directly transfers the MACRO surface water bin output files to m2t files, needed as input for FOCUS TOXSWA. Moreover, with the MACRO 5 multithreading tool the user is able to de-select redundant FOCUS MACRO groundwater runs, i.e., parent and intermediate runs, saving additional simulation time.
It is intended to provide the multithreading tool to the community for beta testing, likewise it was done for the MACRO multithreading functionality for the CRD Higher-tier drainflow tool.

3.03.P-Mo209 Establishing a Link Between Calendar Dates, Degree-day and BBCH Stages of Relevant Crops Across the EU

Franco Ferilli[1]*, Csaba Szentes*[2]*, Laura Padovani*[2]*, Alberto Linguadoca*[2]*, Pauline Iris Adriaanse*[3]*, Mechteld Ter Horst*[3] *and Hendrik Boogaard*[3]*, (1)European Food Safety Authority (EFSA), Parma, Italy, (2)European Food Safety Authority (EFSA), Italy, (3)Wageningen University and Research (WUR), Netherlands*

To advance the environmental risk assessment of plant protection products effectively, it is crucial to assess the relationship between crop phenology (i.e., Biologische Bundesanstalt, Bundessortenamt und CHemische Industrie, or BBCH crop growth stages), calendar dates and locations across the European Union. The project we present, and currently ongoing under a framework partnership agreement between Wageningen University and Research, and the European Food Safety Authority, focuses on linking crop development stages, expressed using the BBCH scale, with calendar dates and degree-days for selected crops (soft wheat, durum wheat, spring barley, grain maize, rye, sugar beet, potato, field beans, winter rapeseed, and sunflower) across European agricultural regions. This approach aims to improve exposure assessments by incorporating regional variability and temporal dynamics into environmental risk assessment models.
The open-source CropLife Europe Crop Development Database, C2D2, which compiles crop growth data

from efficacy trials across Europe (2000 2020), will be critically evaluated and expanded with additional phenological data. The resulting enriched database is transformed into a grid-based format that covers European Union agricultural regions. Key BBCH stages, such as emergence, flowering, and maturity, are calibrated and validated against observed data, offering detailed, spatially resolved insights into crop development patterns. This work advances the environmental risk assessment by supporting: improved estimation of pesticide application dates, better predictions of off-target exposure, including spray drift and pollinator risks, through accurate timing of crop development stages, enhanced scenario development for the European Union regulatory frameworks , such as FOCUS surface water models and bee exposure scenarios. Additionally, the results of this project could be used to update existing crop growth models, such as those used in the Joint Research Centre Monitoring Agricultural Resources project, to generate crop height as a critical parameter for spray drift assessment. By addressing the objectives, this project can provide a robust foundation for improving environmental risk assessment methodologies, supporting the regulatory processes, and promoting consistent and scientifically sound exposure assessment for pesticide use across the European Union.

3.03.P-Mo210 Improved Soil Fumigants Exposure-Related Data and Mitigation Measures Efficacy of Different Fumigation Strategy and Techniques

*Federico Ferrari[1], Georgios Fragkoulis[1], Andrea Minuto[2] and **Maura Calliera**[3], (1)Aeiforia Strada Faggiola 12 Podenzano (PC), Italy, (2)CeRSAA Centro di Sperimentazione e Assistenza Agricola, Italy, (3)Opera Research Centre Universit Cattolica Sacro Cuore Piacenza, Italy*

Pressure exerted by soil-borne plant pathogens in some area for certain high value crops is a problem of growing concerns. Several approaches have been considered for their control but the dependance on chemicals products to assure food security (and also food safety) still exist and recently, especially for root-knot nematodes and cyst nematodes, this issue is no longer confined to southern areas but is also emerging in some areas of northern Europe.

Fumigation is an activity to control such pathogens, but fumigant products may pose humans and environmental safety concerns and must be properly managed to maintain a sustainable intensification of production. This aspect must also be reconciled with the ambitious goals of the EC objectives.

To balance the importance of the contribution of chemical pesticides to food security, and social need of chemical pesticides use reduction required, sustainable and integrated nematods management strategies, taking into account the mitigation measures considered to reduce exposure risk are fundamental. Within this framework, exposure assessment is a critical component and the lack of EU soil fumigants specific guidance on exposure and risk assessment, has resulted in regulatory uncertainty.

As an example, (1) pesticides applied as soil fumigants are very volatile and FOCUS GW models are not able to simulate adequately the volatilization from the soil surface and (2) the mitigation measures, that focused on developing fumigation methods using low-permeability tarps, including totally impermeable film (TIF) or (3) contex specific application technics/strategies, as soil moisture management, that might have a relevant impact on potential exposure need to be considered during the risk assessment and decision making.

In this work improved fumigants exposure-related data and mitigation measures efficacy of different fumigation strategy and techniques are provided to support both the identification of proper models input data both the ongoing national and international strategies for a proper adoption of soil fumigation procedures that might significantly increase fumigant efficacy having potential beneficial effects on fumigant air emissions and breakdown residues, and necessary to reach the level of exposure reduction set at the EU level.

Disclaimer/Disclosure: This work was produced in the frame of Ph.d. in Agro-food system (AGRISYSTEM)-XXXVIII Cycle.

3.03.P-Mo211 Establishment of a Simultaneous Analytical Method for 370 Pesticides and Metabolites in Honey Using LC-MS/MS

***Yoon-Hee Lee**, Jae-Woon Baek, Tae-Gyu Min, Da-Geon Lee, Yong-Won Cho and Yongho Shin, Department of Applied Bioscience, Dong-A University, Republic of Korea*

Honeybees (Apis mellifera L.) can be exposed to pesticides during plant pollination, increasing the likelihood of pesticide residues in honey, thus necessitating continuous monitoring. A simultaneous multiresidue analysis method is particularly needed for neonicotinoid pesticides and their metabolites, which are suggested as potential contributors to Colony Collapse Disorder (CCD). This phenomenon was first observed in the United States and later reported in many European and Asian countries. This study optimized sample preparation using 1?g of honey by comparing combinations of two extraction solvents (acetonitrile and 0.1% formic acid in acetonitrile) and two QuEChERS salts (Original vs. EN 15662). The

Multiple Reaction Monitoring (MRM) mode of a Shimadzu LCMS-8040 was utilized, and the separation of analytes was conducted using a Cadenza CD-C18 (3 ?m, 150 × 2 mm) column. It was found that superior recovery rates were provided by the combination of 0.1% formic acid in acetonitrile with the Original QuEChERS salt. In the method validation using the established analytical method, the limit of quantitation (LOQ) was determined to be ?0.01?mg/kg for 329 of the 370 pesticides analyzed. Calibration curves showed correlation coefficients (r^2) ?0.980 for 348 analytes (94.1%). At a fortification level of 0.01?mg/kg, 266 pesticides (71.9%) showed recovery rates between 60 120% (CV ?32%); at 0.1?mg/kg, 349 (94.3%) showed recovery rates of 70 120% (CV ?22%). Matrix effects indicated that 78.1% of the analytes were within the soft range (±20%). Meanwhile, 11.6% were in the medium range (?50% to ?20% or +20% to +50%), and 10.3% were in the strong range (below ?50% or above +50%). The analysis of 14 neonicotinoids, comprising 7 pesticides (acetamiprid, clothianidin, dinotefuran, imidacloprid, nitenpyram, thiacloprid, thiamethoxam), 3 dinotefuran metabolites (-UF, -MNG, -DN), and 4 imidacloprid metabolites (-urea, -olefin, 5-hydroxy imidacloprid, 6-chloronicotinic acid), demonstrated a LOQ range of 0.0025 0.1 mg/kg. The calibration curve correlation coefficients (r^2) were ?0.980, with recovery ranges of 75.6?123.4% at 0.01 mg/kg and 26.4?120.2% at 0.1 mg/kg. The analytical method established in this study for honey is expected to facilitate the simultaneous monitoring of 370 pesticides and their metabolites.

3.03.P-Mo212 Novel Triple Quad Approaches for Sensitive Quantification of > 1000 Pesticides in Single Runs

Arnd Ingendoh[1], *Miguel Perez*[2] *and Juan Martin*[2], *(1)Bruker Daltonics GmbH & Co KG, Germany, (2)Bruker Espanola S.A., Spain*

Pesticides represent the most frequently analyzed hazardous compounds in food and feed globally. A key challenge is the analysis of a vast and ever-increasing number of diverse multi-class pesticides in single runs. The demand for higher sample throughput on top, screening techniques gain popularity, particularly for organic and pesticide-free products, to push rapid detection while still allowing for quantification of positive samples. Proposed here is a quantitative analysis method for a large number of pesticides in food using a novel triple quadrupole MS. Both throughput and the high number of target pesticides will be addressed. For the evaluation of the analytical performance, the new method was optimized in a real scenario in common matrices for more than 500 pesticides combining positive and negative ions. The aim is to evaluate in detail how the speed, number of compounds and other parameters influence the sensitivity and robustness in short- and long-term work.
An Elute 2 UHPLC was used with water (A) and methanol (B) (both (0.01% FA, 2 mM ammonium formate) at a 15-100% B gradient in 0.5-8min. Runtime was 9.2 min with subsequent 2.5 min equilibration. 2 uL sample were injected on a Bruker Intensity Solo 2.0 100x2.0 mm column at 45 ºC. An EVOQ-DART TQ+ with pulser-HESI was used in MRM Compound Based Scanning. At a scan time for each compound of 5-11 ms, the method that can accommodate >1000 pesticides in fast polarity switching with ? 2 transitions in a single run. A probe temperature program reduced the impact for thermolabile compounds eluting at the chromatogram end (Abamectin, Ivermecting, Sprimesifen). A calibration curve containing 520 mixed pesticides was prepared in pepper matrix (QuEChERS) with five calibration levels at 0.2-50 ppb. 30 real samples prepared with the same extraction method were injected afterward to quantify the potential pesticides.
The calibration curve showed R2 >0.99 for 95% of the compounds with ion ratios at < 10% deviation. For 10 consecutive injections, an RSD < 10% for most pesticides was achieved in the real matrix spiked with 2 ppb in total. Different methods have been concluded for 520 pesticides in a single run (positive/negative ionization). Due to novel electronics and the rapid polarity switching, the intensity and ion ratio remained consistent regardless of the scan speed. All these parameters indicate a robust and reliable method for screening and quantitation up to 1000 pesticides in a single run.

3.03.P-Mo213 Determination of Pyrethroids in Water Samples According to the EU Water Framework Directive Using Atmospheric Pressure Gas Chromatography Tandem Mass Spectrometry (APGC-MS/MS)

Claudia Rathmann[1], *Christian Goetz*[2] *and Andreas Wyss*[2], *(1)Waters GmbH, Eschborn, Germany, (2)Kanton Zurich Baudirektion Amt fur Abfall, Wasser, Energie und Luft, Switzerland*

Reliable and highly sensitive analytical methods are needed for detection, quantification, and identification of pyrethroids water samples. In the proposal of directive amending Directive 2000/60/EC establishing a framework for Community action in the field of water policy and Directive 2008/105/EC on environmental quality standards (EQS) in the field of water policy the EQS for cypermethrin and its isomers are more stringent and with bifenthrin, deltamethrin, and permethrin new pyrethroids were added. The assigned annual average EQS in surface water go as 1.7 µg/l x 10-6 for deltamethrin which is an analytical challenge for water testing labs.
This work describes the sample preparation and analytical method using APGC-MS/MS to be able to reliably identify and quantify pyrethroids even at the very low EQS that can be expected from the new proposal. APGC ionization is used in the application because it is considered soft when compared with techniques such as Electron Ionization, which means that less fragmentation is observed for many compounds. Reduced fragmentation simplifies pre-cursor ion selection, subsequently resulting in higher sensitivity and specificity in MS/MS analyses.

3.03.P-Mo214 QuEChERS-Based Optimization and Application of Broflanilide Analysis in Persimmon Flesh, Peel, Peduncle, and Fully Ripened Fruits for Assessing Washing Efficiency

***Jae-Woon Baek**, Tae-Gyu Min, Yoon-Hee Lee, Da-Geon Lee, Yong-Won Cho and Yongho Shin, Department of Applied Bioscience, Dong-A University, Republic of Korea*

Broflanilide is a meta-diamide pesticide that exerts a strong insecticidal effect by non-competitively acting on GABA (gamma-aminobutyric acid) receptors. These receptors function as inhibitory neurotransmitters in the central nervous system, thereby paralyzing pests. Broflanilide is widely used in persimmon farms to control the Persimmon Fruit Moth (Stathmopoda masinissa Meyrick). Many consumers wash agricultural products in various ways, such as rinsing, scrubbing, or soaking, to mitigate pesticide exposure. The effectiveness of these washing methods in reducing pesticide residues varies depending on the washing solution, technique, and the part of the produce being treated. This study optimized the analytical method for different parts of persimmons using the QuEChERS method and applied it to compare the residual levels of broflanilide across various washing methods applied to these parts. A method showing excellent sensitivity, accuracy, and precision, as well as low matrix effects was established by comparing purification conditions across persimmon flesh, peel, peduncle, and fully ripened fruits. The established method had a LOQ (limit of quantitation) of ? 0.01 mg/kg, with a correlation coefficient above 0.990 for calibration curves analyzed using matrix-matched standards. Recovery tests met acceptable criteria (70 120% recovery, relative standard deviation ? 20%), confirming its reliability. This analytical method was used to compare the residual levels of the pesticide across different washing methods and tissue types in persimmons immersed in a spray solution made with a 5% broflanilide agrochemical product (water-dispersible granule; WG). The washing methods included rinsing the persimmons under running tap water, gently rubbing under running tap water, and immersion in washing solutions containing 1.0% acetic acid, 0.2% polyethylene glycol 4000, or 10% sodium bicarbonate (NaHCO?), followed by rinsing with running water. The results were analyzed separately for each part, and the washing efficiency (%) was calculated by comparing them with the untreated control. This research provides insights into strategies for mitigating pesticide exposure and foundational data for future studies on measuring pesticide exposure through residue patterns across different parts of persimmons.

3.03.P-Mo215 Determination of Pesticide Residues in Fiber and Cottonseed in Major Cotton (*Gossypium hirsutum* L.) Production Regions of Türkiye and Assessment of Risk to Consumers

***Volkan Mehmet Cinar**[1] and Cafer Turgut[2], (1)Anadolu University, Turkiye, (2)Faculty of Agriculture, Department of Plant Protection, Aydın Adnan Menderes University, Turkiye*

Cotton is an important cash crop, mainly used in the textile industry. Cotton is cultivated on about 32.88 million ha in more than 60 countries worldwide, with an annual production of about 73.74 million tons of seed cotton. Although cotton planting covers only 2.80% of the world's agricultural area, it meets about 27% of the global textile industry demand. Many diseases, pests, and weeds damage cotton plants and can cause significant yield losses. Pesticides are used widely to control pests, diseases, and weeds. Pesticide use poses risks to the environment, biodiversity, and animal and human health via the food chain. In this study, pesticide residues were investigated in Şanlıurfa, Diyarbakır, Aydın, İzmir, Hatay, and Adana provinces, where cotton production is intensive, and pesticide residue dynamics were determined in both fiber and seed. Samples collected from each province were quickly transferred to the laboratory and stored at -20 °C until extraction and analysis. Pesticide analyses were conducted using the QuEChERS method, and pesticide residue analysis was performed using GC-MS (gas chromatography-mass spectrometry) and LC-MS/MS (liquid chromatography-mass spectrometry) instruments. Risk modeling with the 'PRIMo (Pesticide Residue Intake Model) revision 3' model of the European Food Safety Authority (EFSA) will be performed by considering the toxicity of the mixture of pesticide residues. In addition, risk classifications will be calculated based on data from Türkiye and WHO. The results of this study will be used to plan better pesticide management for more sustainable cotton production and integrated pest management. The results of the project will contribute to environmentally friendly spraying programs that support food safety.

Disclaimer/Disclosure: This study is supported by the Scientific and Technological Research Council of Türkiye (TÜBİTAK), with project number 123C296, within the scope of the "2218-National Postdoctoral Research Fellowship Program." Volkan Mehmet ÇINAR would like to thank TÜBİTAK.

3.03.P-Mo216 Fate and Transport of Microplastics and Micropollutant in Soil Environment

Ambika Selvaraj[1] *and Catherine Chakkalakkal*[2]*, (1)Faculty, Department of Civil Engineering, Indian Institute of Technology Hyderabad, Adjunct Faculty, Department of Climate Change, Indian Institute of Technology Hyderabad, Adjunct Faculty, Greenko School of Sustainability, Indian Institute of Technology, India, (2)Department of Civil Engineering, IIT Hyderabad, India*

The unique strength and resistance to water, shock, and electricity makes plastic a versatile material and has many valuable uses. As more the addiction towards minimal/single-use or disposable plastics, the environment ends up with severe consequences. Microplastics (MP), plastic size <5mm, elevates alarms about the ecological and health risks worldwide. Miserably, the massive practice of plastic goods and mismanagement of plastic waste disposal leads to the MP pollution in aquatic water bodies and their ecosystems. Similarly, the aquatic environment is contaminated with micropollutants that are sourced from industrial effluent, agricultural discharges and partially treated domestic wastewater. Even if MP doesn't cause acute fatal effects on living organisms, they can act as the carrier of these micropollutants, and cause root chronic toxicity, which is considered as a key issue in long-term exposure.
In this study, the soil sample was collected from Kandi Lake ecosystem, Kandi, Sangareddy Telangana, India and characterized for geotechnical and hydrodynamic properties. Continuous flow column experiments were conducted in one-dimensional column simulating the situation pertaining to the actual lake water infiltration and relative transport of microplastics and the selected micropollutant 2,4-dichlorophenoxy acetic acid (2,4-D) to represent their movement from the lake to sediment and soil ecosystem. The flow rate and the varieties of the MP were considered as the study factors and the results were interpreted for the fate and transport of MP from the lake to the soil ecosystem. This study enlightens the fundamental knowledge of the behavior of microplastics and micropollutant in the soil ecosystem and gives deeper insights into the vector behavior of the microplastics. This study opens a door to the possible transport and co-transport mechanism involved in the transport of microplastics and micropollutants in the natural ecosystem.

3.03.P-Mo217 Dissipation Pattern of Spirotetramat During Cultivation of Agricultural Products for Establishing Post-Harvest Residue Level in Korea

Young-Jun Lee[1]*, Seung-Hyun Yang*[1]*, Kyung-Min Na*[1]*, Hoe-Gun Kwon*[1]*, Chang-Ho Lee*[1]*, Je-Hyeong Lee*[1] *and Pyoung-Yeol Kim*[2]*, (1)Korea Testing & Research Institute, Republic of Korea, (2)Republic of Korea*

This study examined the dissipation patterns of pesticide residues in agricultural products during cultivation and proposed pre-harvest residue limits (PHRLs) based on these patterns and biological half-lives. Pesticides were applied to agricultural products in three different regions at the recommended dose. Samples for the dissipation pattern study were collected at intervals of 0, 1, 3, 5, 7, 10, and 14 days post-treatment and analyzed using LC-MS/MS. After extraction and purification of insecticide residues via the QuEChERS method, the samples underwent quantitative analysis by LC-MS/MS. The recovery rates for the tested insecticides ranged from 71.7 to 113.1%, with limits of quantification at 0.01 mg/kg and coefficients of variation below 5%. Based on first-order kinetics, the dissipation half-lives of the combined spirotetramat and spirotetramat enol were calculated as 6.3, 4.8, and 6.3 days, respectively, across the different regions. The biological half-lives of pesticides were determined for each field study. Consequently, a PHRL was recommended for 10 days before harvest to ensure safe residue levels in the agricultural products.

3.03.P-Mo218 Flood Mediated Pesticide Uptake into Riparian Plants and Phytophagous Aphids

Franziska Fiolka*, Timo Fuchs, Alexis P. Roodt, Alessandro Manfrin and Ralf Schulz, RPTU - Kaiserslautern - Landau, Germany*

Surface waters are known to be polluted with various compounds including synthetic pesticides. Pesticides are able to move between aquatic and terrestrial ecosystems, e.g., via flood mediated contaminant transport from water to land. As a bordering habitat, the riparian zone functions as a diversity hotspot for many plant and insect species. Therefore, the exposure and uptake of flood-mediated pollutants by riparian soil, riparian plants, and non-target arthropods requires evaluation. We therefore conducted a climate chamber pot experiment employing potted stinging nettle and the common nettle aphid. Each pot was artificially flooded four times within 24 days with flood water containing 31 insecticides and fungicides at an environmentally relevant concentration. We measured the concentrations of the pesticides in soil, plants, and aphids using HPLC-MS/MS. The concentrations in soil and nettle increased significantly with each flood, leading to a six-fold increase in sum pesticide concentration in soil, and a thirty-fold increase in sum pesticide concentration in nettle leaves and stems. Twelve pesticides were detected in the phytophagous aphids after four floodings, four of which were biomagnified compared to the concentrations in plant material. As aphids and nettle are a widespread food source within the riparian zone, the observed trophic transfer of contaminants might pose further risks to other arthropods such as pollinators, via honeydew, or to predators of aphids, such as spiders. Therefore, we propose to include the flood-mediated contaminant pathway as a potentially relevant exposure pathway within riparian areas, which is a habitat also experiencing exposure via various other exposure pathway routes. This is especially relevant in the light of the expected future increase in flooding intensity due to climate change.

3.03.P-Mo219 Blooming Concerns: Evaluating Exposure Toward Pollinators from Ornamental Plants

Mafalda Castro[1]*, Natalie Julia Ruddle*[2]*, Pelagia Xirogiannopoulou*[3]*, Helen Thompson*[2]*, Alexander Blakey*[2]*, Jorge Eduardo Yanez Heras*[4]*, Beatriz Anton-Garrido*[5] *and Helen Tungate*[2]*, (1)Syngenta Nordics A/S, Strandlodsvej 44, 2300 Copenhagen, Denmark, Denmark, (2)Syngenta, Jealott's Hill International Research Centre, United Kingdom, (3)Syngenta, Jealott's Hill International Research Centre, Greece, (4)Eurofins Agroscience Services EcoChem GmbH, Germany, (5)Eurofins Trialcamp S.L.U., Spain*

Ornamental plants are an extremely diverse group of plants, varying from small herbaceous plants to large ornamental trees. In addition to their diversity, their commercial cultivation is often associated with non-conventional applications of plant protection products (PPPs) and cultivation methods, thus presenting unique challenges in environmental risk assessment. In such cases, traditional approaches to assessment of exposure may not accurately reflect the potential impact on non-target organisms, particularly pollinators and arthropods. Typical pollen/nectar residue studies involve the widely used PPPs application via foliar or seed treatment. Unlike typical residue studies, this study involves the less-studied residue profiles of different ornamental plants through a soil drench application and non-soil bound cultivation, often regarded as more environmentally friendly since environmental exposure is limited. This study aims to evaluate the accuracy of conventional environmental exposure assessments for ornamentals by: (1) growing various ornamental plants in protected conditions, (2) applying a slow degrading, systemic plant protection product via soil drench (1000 g/ha), and (3) sampling pollen, nectar, and leaves during flowering. Although in pollen/nectar residues studies spatial variation is often used to obtain a certain percentile (usually 90th), given that the application in this case consists of a non-soil bound plant protection product, inter--species variation is expected to a greater than variation between test sites. This will allow exposure to be quantified from a PPP through plant matrices to pollinators and non-target arthropods. This approach aims to provide insights into how residues of PPPs are expressed in different ornamental species potentially improving risk assessment accuracy for these diverse plant types and cultivation methods. Preliminary results show very low residues of the plant protection product in the different plant matrices, even when compared to applications of the same PPP in field crops via seed treatment application.

3.03.P-Mo220 Development of Disposable Biosensors of Acetylcholinesterases from Leaf-Cutting Ants for the Detection of Potential Pesticides

Joao Batista Fernandes[1]*, Sean Araujo*[1]*, Ronaldo Faria*[1]*, Dulce Souza*[1]*, Maria Fatima da Silva*[1] *and Odair Bueno*[2]*, (1)Chemistry Department - Federal University of Sao Carlos, Brazil, (2)Centre of Social Insects Studies, UNESP, Brazil*

The application of chemical compounds such as organophosphates and carbamates as pesticides to control ants can have a negative impact on the environment and human health. In the present study, two electrochemical biosensors based on acetylcholinesterases from leaf-cutting ants were developed for the detection of insecticides in the field and potentially in plant extracts. The pests responsible for most damage and loss in agriculture are leaf-cutting ants (Atta and Acromyrmex). This insect causes damage in agricultural and forestry areas, mainly in monocultures, such as Pinus, Eucalyptus, Gmelina and Citrus. For the development of biosensors, the microelectrodes were screen-printed on polyester foil using carbon and Ag/AgCl-based inks. The acetylcholinesterase inhibition studies with organophosphate malathion reached detection limits of 9.1 nmol L-1 for AChE A and 4.7 nmol L-1 for AChE B. The extracts of Solanum lycocarpum and Ocotea sp. were applied for inhibition studies and provided different inhibitory activity profiles between themselves and for each enzyme. The extract of Solanum lycocarpum obtained

80% inhibition against AChE A, being a promising extract for future studies in the search for natural insecticides for leaf-cutting ants. In conclusion, the developed biosensors are new tools for screening extracts with potent insecticidal activities and detecting insecticide in the environment with effect to human health.

3.03.P-Mo221 Occurrence and Spatial Distribution of Neonicotinoids in South Korean Honey and Pollen Samples

*Syed Wasim Sardar, **Jun-Tae Kim** and Mina Do, Center for Climate and Carbon Cycle Research, Korea Institute of Science and Technology (KIST), Republic of Korea*

Neonicotinoids, a class of systemic insecticides can accumulate in plant tissues including nectar and pollen, and subsequently enter the food chain through pollinators such as honey bees. These residues pose potential risks not only to pollinators but also to human health. However, data on neonicotinoid contamination in honey and pollen particularly in South Korea is limited. This study investigated the occurrence and spatial distribution of neonicotinoid residues in both honey and pollen samples across various regions of South Korea. A total of 79 honey samples and 27 pollen samples were collected from agricultural, mountain, and urban areas and analyzed for 18 compounds including neonicotinoids and their metabolites using liquid chromatography coupled with mass spectrometry. All honey and pollen samples contained at least one target compounds indicating widespread contamination. Among honey samples, acetamiprid (83.5%), dinotefuran (77.2%), and flonicamid (58.2 %) were the most frequently detected compounds while pollen samples showed high detection frequencies of acetamiprid (100%) dinotefuran (96.3%) and 5-hydroxy-imidacloprid (85.2%). Honey samples collected from agricultural area demonstrated higher concentrations of flonicamid (2500 ng/g), acetamiprid (258 ng/g), and imidacloprid (133 ng/g), compared to mountain and urban samples. Pollen sample analysis revealed different distribution patterns, with mountain regions showing high concentration of acetamiprid (349 ng/g) followed by flonicamid (154 ng/g). Furthermore, the dietary risk assessment for humans suggests that consuming a certain amount of honey is unlikely to pose a health risk due to neonicotinoid intake. However, the Risk Quotient values for imidacloprid to bees was determined to be 4.0, significantly exceeding the safety threshold of 1, highlighting the elevated risk of acute toxicity to honey bees. These findings demonstrate the widespread presence of neonicotinoid residues in honey and pollen, with complex spatial patterns influenced by local agricultural practices and environmental factors. The study emphasizes the need for continued monitoring and regulation to protect pollinator and human health from potential risks associated with neonicotinoid exposure.

3.03.P-Mo222 Building Age and Seasonality Impact Levels of Pesticides in Household Dust

*Paula Marcinekova[1], Ondrej Mikes[2], Rozarka Jilkova[1], Petr Senk[1], Jakub Martinik[1] and **Lisa Melymuk**[3], (1)RECETOX, Masaryk University, Czech Republic, (2)Recetox, RECETOX, Masaryk University, ., Czech Republic, (3)Masaryk University, Brno, Czech Republic*

Pesticides are typically considered of concern in outdoor environments, but there is growing awareness of their potential contribution to exposure in indoor environments. While most pesticides are used in agriculture, domestic use is also widespread. We evaluated the exposure of the Czech children to both legacy organochlorine pesticides (OCPs) and currently used pesticides (CUPs) in their home environment, by sampling settled indoor dust, covering a diverse range of dwellings in urban, suburban, rural-agricultural and forested areas. Given the known seasonality in pesticide use and outdoor air concentrations of pesticides, we additionally sampled a subset of homes monthly over one year. Out of the 36 CUPs analyzed, 15 were detected in at least one individual dust sample, with atrazine (detection frequency = 24.1%), carbendazim (DF = 84.5%), propiconazole (DF = 49.1%) and tebuconazole (DF = 11.2%) detected more frequently. OCPs were detected in all homes. Pesticide concentrations were investigated in the context of geospatial and household variables: propiconazole, used as a biocide on building products, was found to be significantly higher in houses with adjacent gardens; while OCPs, especially DDT-related compounds, were substantially higher in homes more than 40 years old, indicating the continued presence of residues from past indoor use. Strong seasonality was also observed in the CUPs in dust, with levels in indoor dust 5-10x higher in spring in rural homes, aligned with the timing of outdoor pesticide application. The exposure estimates for various pesticides in children, under both median and high exposure scenarios, remain well below established safety thresholds, indicating minimal concern for potential adverse health effects in children for this exposure pathway.

Disclaimer/Disclosure: The study was funded by the Czech Science Foundation (GACR), project No. 22-32743S.

3.03.P-Mo223 Dissipation Patterns and Pre-Harvest Residue Limits of Pesticides in Ponytail Radishes in Korea

Jang-Hun Kim, *Won-Yeong Choi, Seong-Hwan Park and Hoon Choi, Wonkwang University, Republic of Korea*

The Republic of Korea s Ministry of Food and Drug Safety (MFDS) sets Pre-Harvest Residue Limits (PHRLs) to proactively address potential exceedances of Maximum Residue Limits (MRLs) in crops during pre-harvest steps. PHRL refers to the maximum allowable concentration of pesticides in the pre-harvest steps, by date (up to 10 days before shipment). Exceeding the PHRL during pre-harvest steps results in actions such as disposal, shipment delay, and purpose conversion. This study evaluated the dissipation patterns of pesticide residues in ponytail radishes during cultivation in greenhouse and established PHRLs based on the pesticides dissipation characteristics and biological half-lives. Pesticides and crops with a high frequency of unsuitability in the past were selected. Ponytail radishes (Raphanus sativus L.) are among the most commonly consumed vegetables in kimchi, following Korean cabbage and radish. Pesticides were applied at recommended doses following Good Agricultural Practices (GAP) across three different regions. Samples for the dissipation study were collected at 0, 1, 2, 3, 5, 7, and 10 days after treatment (DAT) to monitor residue levels over time. Residues were extracted using the QuEChERS (Quick, Easy, Cheap, Effective, Rugged, and Safe) method and analyzed by high-performance liquid chromatography or gas chromatography-mass spectrometry. The analytical method satisfied validation criteria for pesticide residues, achieving 70-110% recovery, relative standard deviations below 20%, and a limit of quantitation below 0.01 mg/kg. Following foliar application, pesticide residues in the leaves and roots of ponytail radishes decreased steadily. Biological half-lives for each pesticide were calculated using pseudo-first-order kinetics based on dissipation regression data from the three field studies. In accordance with guidelines from the MFDS in Korea, PHRLs were determined using the 95% upper confidence limit (95% UCL) of the dissipation constant (?) and MRLs for leaves and roots. Daily PHRLs for the 10 days before harvest were recommended to prevent agricultural products from exceeding MRLs at the point of harvest.

3.03.P-Mo224 Effectiveness of Home-Based Methods for Reducing Pesticide Residues on Grapes

Rozarka Jilkova[1], *Sara Honkova*[2] *and Pavlina Mrlakova*[3], *(1)RECETOX, Masaryk University, Czech Republic, (2)Faculty of Chemistry, Brno University of Technology, Czech Republic, (3)Faculty of Pharmacy, Charles University, Czech Republic*

Despite EU regulations about maximum residual levels (MRL) on vegetables and fruits, pesticide residues can still be found on many produce items, in some cases exceeding the MRL. This has led consumers to use various home-based methods to remove pesticides and reduce their exposure. This study tested the effectiveness of such methods in removing pesticide residues of tebuconazole from grapes.

Grapes were treated with a common pesticide for fruit plant treatment, tebuconazole, with the levels 0.4 mg/kg (MRL for tebuconazole is 5 mg/kg). Grapes were then subjected to eight different home-based treatments, which covered washing by cold water for 5 sec and 30 sec and hot water and soaking in water and solutions of baking soda (sodium bicarbonate), salt (sodium chloride), vinegar (acetic acid), and potassium permanganate for 10 minutes. Pesticide residues were quantified on the grapes by QuEChERS method and HPLC-MS analysis.

Every home-based method reduced the tebuconazole levels with the range 30 70 %. Our results showed that simple water-based treatments were the least effective in removing tebuconazole residue. The lowest effectivity was observed with the 5 sec wash, however, the prolongation of the rinse time to 30 sec increased the effectivity to 46 %. The highest effectiveness of 71 % was observed for two options: soaking in solution of vinegar (2 % acetic acid solution), and baking soda (1 % solution of sodium bicarbonate). While home-based methods can reduce tebuconazole residues on grapes, their effectiveness varies significantly, and they do not eliminate them completely. It is important to note that these methods may not remove all pesticide residues similarly, because of their differences in chemical structures.

3.03.P-Mo225 Geospatial Analysis as a Toolbox for Identification of Antibiotics Sources in European Surface Water Bodies at a Catchment Scale

Olha Khomenko *and Abdul Abu, Cambridge Environmental Assessments, United Kingdom*

The presence of antimicrobial drugs in the environment poses potential risk to ecosystem health due to toxicity to aquatic organisms, the potential to disrupt microbial communities, and contribute to the development of antimicrobial resistance (AMR) even at low or sub-lethal concentrations, representing a risk to human health. Antibiotics are released to the environment through wastewater treatment plants

(WWTP) and surface runoff. The European Union has added several antibiotics on the Water Framework Directive (WFD) watch list which identifies emerging pollutants that require monitoring to assess their environmental impact. This study focused on a catchment area within the UK, examining the water quality of surface waters that receive WWTP discharges. Using advanced geospatial modelling techniques, the study aimed to enhance our understanding of fluoroquinolone sources in the environment by analysing monitoring data specific to this catchment.
Discharge points of WWTP, proximities of hospitals and effluents from antibiotics manufacturing sites may correlate with elevated concentrations of antibiotics in surface water. To test this hypothesis, we combined Geographically Weighted Regression (GWR), Hotspot Analysis with Getis-Ord Gi* technique and Kriging to identify and predict potential sources and distribution of the fluoroquinolone antibiotic ofloxacin concentrations in surface water. The spatial analysis approach offers a cost-effective method for predicting spatial and temporal dynamics of antibiotics pollution. By leveraging existing monitoring data, it bypasses the need for wide-scale sampling campaigns while assisting monitoring efforts. We anticipate establishing temporal and spatial relationships between the antibiotic's concentrations and key sources, as well as generating predictive maps of the levels and distribution of pollution.
This research will contribute to improved monitoring strategies and source identification methods for antibiotic pollution. By pinpointing major contributors to the environmental occurrence of ofloxacin, and predicting concentrations in unsampled areas, our findings will inform development of targeted sampling efforts and mitigation strategies, supporting WFD objectives of combating the spread of antimicrobial resistance in aquatic ecosystems in the UK and the EU and Member States.

3.04.A Scientific Advancements in the Fate and Toxicity of Metals: Data, Models, Tools, and Their Application in Environmental Regulations

3.04.A.T-01 Measuring Bioavailable Aluminium in Natural and Laboratory Waters

William J. Adams[1], *Alexandra Duguay*[2] *and Allison Cardwell*[3], *(1)Red Cap Consulting, United States, (2)Rio Tinto, Melbourne, Australia, (3)Cardwell Consulting, United States*

Aluminium (Al) has been regarded as a difficult to test substance due to its formation of oxy-hydroxide compounds at pH values common in natural waters. The formation of gill reactive compounds occurs when acidic water (pH < 5) mixes with circumneutral pH water in natural ecosystems, or when alum is used in water treatment or in laboratory tests when a soluble Al salt is added to water. The formation of the hydroxides results in gill smothering, reduced oxygen transport and alteration of ion transport across the gill. In the laboratory, organisms often die due to oxygen deprivation. In nature, salmon smolts die when migrating to the ocean and cannot regulate the increase in salinity after exposure to Al or when sensitive organisms are exposed to mine effluents in mixing zones. Our 10-year aquatic research program has resulted in the development of a biotic ligand model (BLM) and a multiple linear regression model (MLR) to predict toxicity. The MLR model has been used by the USEPA to develop a water quality standard. Unlike other cationic metals, Al toxicity correlates with total metal in solution and not dissolved Al. Water quality guidelines in several countries require analytical measurements of total Al using a strong acid digestion. Natural water samples contain suspended solids (clays, minerals) with substantial amounts of natural Al. Thus, samples may not meet regulatory standards due to the presence of suspended solids. To alleviate this problem, we developed an analytical method that measures bioavailable Al without measuring the Al contained in suspended solids. The method was approved by ASTM in November 2024. We applied this method to samples from 10 rivers in the US. Our presentation will include details on the toxicity of Al, the MLR model and the analytical method for bioavailable Al.

3.04.A.T-02 Development and Application of a Cobalt Chronic Biotic Ligand Model

Robert C. Santore[1], *Kelly E. Croteau*[1], *William A. Stubblefield*[2] *and David Boyle*[3], *(1)Windward Environmental LLC, Seattle, United States, (2)Oregon State University, Corvalis, United States, (3)Cobalt Institute, United Kingdom*

This presentation will provide an overview of the influence of water quality parameters on the chronic toxicity of cobalt to aquatic organisms. The influence of various toxicity modifying factors (TMFs) were evaluated in an empirical testing program that used invertebrates (Brachionus calyciflorus, Ceriodaphnia dubia, *Daphnia magna*), fish (Pimephales promelas), and algae (*Pseudokirchneriella subcapitata*). Study results were used to develop a cobalt biotic ligand model (BLM). Important TMFs for explaining cobalt bioavailability and toxicity included pH, DOC, Ca, and Mg. The cations, Ca and Mg, have similar modes of action and can be addressed jointly as water hardness. Bioavailability effects were similar between taxa so a pooled model including fish, invertebrates, and plants/algae was judged to be best for guideline development. This also simplifies the normalization of a species sensitivity distribution (SSD) and could result in a critical accumulation value associated with the 5th percentile or guideline value, rather than the need for normalizing the entire SSD for each new set of conditions. The resulting model was validated by comparing its performance against measured toxicity in several natural waters, selected to represent a range of physiochemical parameters typical of European and North American surface waters. Model performance in the natural waters validation dataset was comparable to that of the calibration data. The HC5, developed from an SSD of previously published chronic toxicity data, and the cobalt BLM was used to evaluate the affect of TMFs (i.e., pH, DOC and hardness) on potential regulatory values. The results show that chemical factors have an important role in determining cobalt toxicity, and that bioavailability models such as the BLM should be used to consider these factors in order to produce accurate water quality guidelines protective of aquatic life.

3.04.A.T-03 Influence of Water Chemistry on Silver Toxicity to Freshwater Algae: Development of a Chronic Biotic Ligand Model (BLM)
***Nada Basic**[1], Karel De Schamphelaere[1] and Stephen Lofts[2], (1)GhEnToxLab - Ghent University (UGent), Belgium, (2)UK Centre for Ecology and Hydrology, United Kingdom*
Due to silver s unique properties, such as high heat and electricity conductivity, light reflectance and antimicrobial activity, it has been made indispensable in a variety of industries. With such widespread use, emissions to the environment are inevitable. This fact has positioned silver as a candidate priority contaminant under the Water Framework Directive, highlighting the need for scientifically derived environmental quality standards (EQS). EQSs for metals are often derived using bioavailability models, which are crucial because toxicity in water is influenced not only by the soluble metal concentration but also by water chemistry, which drives metal speciation and interaction with biota. While an acute biotic ligand model (BLM) already exists for silver in freshwaters, a chronic model has yet to be developed. This gap limits our ability to assess long-term risks posed by silver in freshwater environments. To address this need, we investigated chronic (72h) silver toxicity to freshwater alga *Raphidocelis subcapitata* in synthetic freshwaters, focusing on developing parameters essential for a chronic BLM. We univariately tested six water chemistry parameters, in their typical naturally occurring ranges, to determine their influence on silver toxicity. Results indicate that pH (range 6 8.7) and natural organic matter (range 0.5 22 mg DOC/L, DOC dissolved organic carbon) have a significant influence on EC10 values (silver concentration causing 10% reduction in algae growth rate), yielding differences in EC10s by factors of 4.5 and 27, respectively, across the selected ranges. A logarithmic relationship was observed between H+ and Ag+ free ion activities, suggesting the bioavailability of hydroxide complexes. Moreover, results indicate that chloride complexes are bioavailable within the range of 4 80 mg Cl/L, as toxicity was correlated with total silver concentration, rather than calculated free ion activity. This suggests that silver does not fully conform to the classical free ion activity model. Water hardness and sodium exhibited minimal or no influence on toxicity. These results offer essential parameters for establishing a chronic silver BLM for algae, making this work particularly relevant for regulatory purposes.

Disclaimer/Disclosure: The authors thank the European Precious Metal Federation (EPMF) for sponsoring this research as well as project collaborators from ARCHE Consulting and UK Centre for Ecology and Hydrology

3.04.A.T-04 Predicting Metal Toxicity in Aquatic Environments using an Innovative Toxico-Dynamic Model
***Juliette Darde**[1], Olivier Geffard[2], Nicolas Delorme[2], Laura Garnero[2], Lysiane Dherret[2], Marina Coquery[2] and Christelle Lopes[1], (1)LBBE, France, (2)INRAE, France*
Within the framework of the French national biomonitoring program under the Water Framework Directive (WFD), water agencies measure bioaccumulated concentrations of priority substances in caged gammarids as a tool for chemical monitoring of waterways. However, this approach provides information on contaminant bioavailability without accounting for their toxic effects on organisms. To address this limitation, we developed a mechanistic toxicodynamic (TD) model based on the GUTS (General Unified Threshold Model of Survival) formalism, which links bioaccumulated concentrations to lethal toxicity in adult and embryonic gammarids.
Our work focused on two metals classified as priority pollutants: zinc, an essential metal, and nickel, a non-essential metal. Laboratory experiments were conducted to generate the necessary data for model calibration. A toxicity experiment assessed adult and embryo survival rates over 21 days under various exposure concentrations. In parallel, a bioaccumulation experiment measured the dynamics of metal uptake and elimination in gammarids, allowing the calibration of a one-compartment toxicokinetic (TK) model.
The TD model was then adapted to incorporate bioaccumulated concentrations as the primary input variable, as environmental monitoring primarily provides this type of data. Results showed that embryos

are more sensitive to nickel than adults, with faster toxic effects, whereas embryos are less sensitive to zinc but experience more rapid toxicity progression than adults.
This work demonstrates the potential of integrating GUTS-based modeling into national biomonitoring frameworks to provide ecotoxicologically relevant insights. The model offers a robust approach to interpreting bioaccumulation data in terms of adult and embryonic toxicity, aiding in the assessment of metal impacts in aquatic ecosystems.

3.04.P-Th095 Cobalt Contamination Drives the Structure and the Co-occurrence Network of Freshwater Biofilms

*Marisol Goni-Urriza[1], Sarah Gourgues[1], Mathieu Milhe-Poutingon[1], Yannick Corsellis[2], Nicholas Bagger Gurieff[3], Clementine Gelber[2] and **Severine Le Faucheur**[4], (1)Universite de Pau et des Pays de l'Adour, France, (2)TotalEnergies, France, (3)Rio Tinto, Australia, (4)Iprem, Université de Pau et des Pays de l'Adour, France*

Cobalt (Co) is a key metal in the energy transition, which has led to an increase of its extraction and use over recent decades. Nevertheless, its impact on aquatic ecosystems is poorly understood. Biofilms are important biological components and indicators for river health. The present study thus examined Co impacts on the structure, interactions and functioning of prokaryotic and eukaryotic communities in growing biofilms.
Artificial substrata were placed in mesocosms (TotalEnergies facilities, Lacq, France) without (control) and with Co addition (0.1, 0.5 and 1 ?M). These substrata were then colonized by biofilms for 28 days. After the exposure period, a further 35 days without Co contamination was applied to simulate a recovery period. Water and biofilm were collected every 7 days during Co exposure. Water quality was analyzed, and biofilms were examined for Co bioaccumulation, structure and functions.
Cobalt bioaccumulation in growing biofilms was correlated with ambient free Co concentrations. Exposure at 0.5 and 1 ?M Co impacted beta-diversity of both prokaryotic and microeukaryotic communities from the earliest stages of biofilms colonization. Proportions of major prokaryotic and microeukaryotic taxa varied, highlighting sensitive and resistant taxa in both populations. Functional predictions revealed that Co exposure also influenced processes of biofilm formation (primary production and cellular processes). Finally, co-occurrence analyses indicated a reorganization of networks structure and dynamics in response to Co contamination. A loss of connectivity within microbial communities from exposed biofilms was highlighted and associated with a decreasing number and diversity of keystone OTUs. However, networks were denser with a concentration of interactions around the last central nodes, which were essential in the stress response and continued ecological function of the biofilms. Our results highlighted a new approach to assess Co impacts on biofilms considering co-occurrence patterns between microorganisms, in addition to analyses of taxonomic or functional profiles.

3.04.P-Th099 Pristine Ultramafic Waters Exhibit Baseline Chronic Ecotoxicity to *Daphnia magna*

***Davide A. L. Vignati**[1], Carole Cossu-Leguille[2], Elsa Salles[1], Celine Simon[2], Maximilien Beuret[2], Clement Bojic[1], Vincent Normant[1], Yann Sivry[3], Thi Tuyen Nguyen[3], Alexis Groleau[3], Remi Marsac[3], Yulia Erban-Kochergina[4] and Pavel Kram[4], (1)Universite de Lorraine, CNRS, LIEC, France, (2)Université de Lorraine, CNRS, LIEC, France, (3)Universite de Paris, CNRS, IPGP, France, (4)Czech Geological Survey, Division of Geochemistry and Laboratories, Czech Republic*

Ultramafic waters (UW) have naturally high concentrations of nickel (Ni), chromium (Cr) and Cobalt (Co); their relative abundances depending on the geology and mineralogy of parent rocks. Even in the absence of anthropogenic impacts, concentrations of these elements can therefore exceed the corresponding ecotoxicological standards or guidelines values for freshwaters. Because ultramafic rocks are mined for Ni, a key element for the energy transition, understanding the baseline ecotoxicity of pristine UW can assist responsible mining practices.
Water samples were collected in a pristine ultramafic catchment (Pluhuv Bor creek PLB, Czech Republic) far from anthropogenic inputs of trace elements except for atmospheric deposition. Nickel and chromium speciation was studied by filtration (0.22 µm), ultrafiltration (3 kDa) and diffusive gradients in thin films (DGTs). Previous research showed that Co levels in PLB waters were below thresholds of ecotoxicological concern. Ecotoxicity testing was performed according to OECD guideline 211 (*Daphnia magna* reproduction test) with survival, growth and reproduction as endpoints. Heartbeat rate and swimming behavior were also evaluated at the end of the test.
Filterable (147 175 µg/L) and ultrafilterable (35 40 µg/L) Ni concentrations largely exceeded the European EQS of 4 µg/L bioavailable Ni. Bioavailability corrected Ni concentrations (15 18 µg/L) were also above the EQS and were similar for filtered and ultrafilted waters. DTG-labile Ni concentrations (24 29 µg/L) compared favourably with ultrafilterable ones. Total filterable Cr concentrations (21.4 22.5 µg/L) were above the corresponding WHO guidelines: 4 µg/L for Cr(VI) and 10 µg/L for Cr(III).

However, more than 85% of total filterable Cr was associated with colloids and the corresponding ultrafilterable concentrations (2.8 3.2 µg/L) were below the most stringent guideline for Cr(VI). DGT labile Cr(VI) concentrations (1.4 1.8 µg/L) were also below the Cr(VI) guideline, while DGT-labile Cr(III) was below detection limit. Exposure to PLB waters did not affect survival and heartbeat rates of exposed daphnids. On the other hand, growth and reproduction were reduced in some samples and changes in swimming behaviour were observed in all samples. Although PLB waters caused sublethal responses in *D. magna*, further research is needed to clarify the exact causal relationships between Ni and Cr levels vs observed biological responses in *D. magna*.

Disclaimer/Disclosure: The authors thank the CNRS (projects EC2CO B-Rex-Ist et IEA GeoChemTox), LabexR21 (ANR-10-LABX-0021) and eLTER PLUS (EU Horizon 2020, grant agreement 871128) for financial support. This work was partly done with resources from the Pôle de compétences en Biologie Environnemental and Pôle de compétences en Chimie Analytique Environnementale ANATELo, LIEC laboratory, UMR 7360 CNRS Université de Lorraine.

3.04.P-Th107 Updating the Bioavailability-Based Environmental Quality Standard Derivation Approach for Compliance Assessment of Zn in Freshwaters

***Charlotte Nys**[1], Karel De Schamphelaere[1], Stephen Lofts[2], Chris Cooper[3], Frank Van Assche[4], Howard Winbow[4] and Patrick Van Sprang[1], (1)ARCHE Consulting, Belgium, (2)United Kingdom-Centre for Ecology and Hydrology, United Kingdom, (3)International Zinc Association, United States, (4)International Zinc Association, Belgium*

Many countries list Zn as a River Basin Specific Pollutant under the EU Water Framework Directive (WFD). Given the dependency of the toxicity of Zn on local water body conditions, it is essential that the derivation of Environmental Quality Standards (EQS) for Zn are bioavailability-based. In the present study, the existing bioavailability-based EQS derivation approach, which has been widely used and accepted for more than a decade; was updated by I) revising the existing ecotoxicity dataset, and updating it with recent high-quality ecotoxicity data for freshwater organisms, including species that were previously not considered and II) optimising the bioavailability models in terms of model structure and speciation software. The updated EQS derivation approach was then used to derive a bioavailable EQS for Europe, which can serve as a first-tier screening level in compliance assessments.
The updated chronic Zn freshwater ecotoxicity dataset combines high-quality data retained from the existing Zn freshwater toxicity datasets with high-quality data identified in a recent literature screening . The updated database now contains data covering 40 species and covers the minimum data requirements for species sensitivity distribution-extrapolation set out in the relevant guidance of the WFD. The existing chronic Zn bioavailability models were revised by optimizing the model structure and using the most recent version of WHAM as the underlying speciation software. Within the validation of the updated models with independent data for nine aquatic species: EC10 were generally predicted within 2-fold error for model-species and within 3-fold error for non-model species with few exceptions. Hence, the updated bioavailability models can be reliably used to accurately predict Zn toxicity across different species. The updated ecotoxicity dataset and the updated chronic bioavailability models were combined with species sensitivity distribution techniques resulting in the updated EQS derivation approach for Zn, which allows the derivation of a site-specific environmental threshold for Zn. The updated EQS derivation methodology has been used as a basis to derive a robust bioavailable EQS for Zn in European freshwaters. The bioavailable EQS in combination with the updated bioavailability normalisation approach will improve the environmental relevance of compliance assessment for Zn under the WFD.

Disclaimer/Disclosure: The authors wish to thank the International Zinc Association for funding this research.

3.04.B Scientific Advancements in the Fate and Toxicity of Metals: Data, Models, Tools, and their Application in Environmental Regulations

3.04.B.T-01 Source-Oriented Risks of Heavy Metals and their Effects on Resistance Genes in Natural Biofilms

***Xia Luo**, Yunnan University, China (Mainland)*

Heavy metal (HM) introduction from various land-use patterns can be a major source of metal resistance genes (MRGs) entering river environments. This influx can trigger the occurrence of other resistomes, such as antibiotic resistance genes (ARGs), by improving co-resistant conjugative transfer. Biofilms, which form at water solid interfaces, could serve as potential hotspots for HMs and resistance genes.

However, the enrichment of HMs from various sources within biofilms and their effect on resistomes remain undocumented. This study aims to investigate the physicochemical properties of biofilm samples collected from the Heihui River, a tributary of the Lancang River, and to analyze the concentrations of nine HMs (As, Cd, Co, Cr, Cu, Ni, Pb, V, and Zn) within these biofilms. The 16S rRNA gene and metagenomic high-throughput sequencing techniques were integrated to uncover the association between HM accumulation levels in biofilms and ecological and health risks, considering the presence of two resistance genes. Natural sources (Co, Cr), industrial (As, Cu, V), agricultural (Cd, Ni), and transportation activities (Pb, Zn) markedly contributed to HM presence within biofilms, with industrial activities posing higher noncarcinogenic and carcinogenic risks than other sources. The network correlation analyses revealed higher levels of ARG MRG coexistence in biofilms, with the ecological and health risk index of HMs in biofilms closely associated with the abundance of both resistance genes. Furthermore, the biofilm As concentration markedly affected the abundance and expression of ARGs and MRGs, with elevated As levels within biofilms significantly and positively influencing all four functional categories of MRGs. Water pH also indirectly impacted these functional types by modulating the ionic form of HMs within the biofilm matrix. Our findings underscore the significance of integrating biofilms into environmental management practices and standards for assessing environmental quality.

3.04.B.T-02 Metal Toxicity From Hydrothermal Vent Sediments and Its Impact on Deep-Sea Mining

Caio Cesar-Ribeiro[1]*, Denis Abessa*[2] *and Otto Oliveira*[3]*, (1)University of Aveiro, Brazil, (2)UNESP, Brazil, (3)UFABC, Brazil*

Deep-sea mining, aimed at extracting metal-rich sulfides containing manganese, iron, and nickel from hydrothermal vents along mid-ocean ridges, presents significant environmental risks despite its economic allure. These sulfides are formed when hot fluids from vents mix with cold seawater, causing metals to precipitate and accumulate on the seabed. From March to April 2023, the Korea Institute of Ocean Science and Technology (KIOST) conducted the MIRAE expedition in the Indian Ocean s mid-ocean ridge. Utilizing the R/V ISABU research vessel and a remotely operated vehicle (ROV), sediment and rock samples were collected from six sites, particularly focusing on black smokers and hydrothermal vents known for their metal concentrations. Toxicity tests with amphipods (Tiburonella viscana) and mussel embryos (Perna perna) revealed severe environmental hazards. Sediment toxicity tests caused 100% mortality in amphipods, indicating extreme toxicity. Aqueous toxicity tests with elutriates, solubilized extracts, and leachates exhibited variable toxic effects, with some samples showing significant impacts at low concentrations (LOEC as low as 12.5%). Using the Toxicity Identification and Evaluation (TIE) approach, EDTA and C18 filtration reduced toxicity, pointing to metals and organic contaminants as the primary toxic agents. Observed effects included high lethality in test organisms and developmental abnormalities in mussel embryos. These findings underscore the ecological risks of deep-sea mining, such as harm to fragile ecosystems, water quality degradation, and long-term environmental damage. The study highlights the urgent need for robust monitoring, stringent regulations, and thorough environmental impact assessments to reconcile the economic potential of seabed mining with the preservation of deep-sea ecosystems.

Disclaimer/Disclosure: We acknowledge the International Seabed Authority (ISA) and the Korea Institute of Ocean Science and Technology (KIOST) for their support and collaboration in facilitating this research. Their contributions were instrumental in providing the resources and expertise necessary to conduct the fieldwork and analyses.

3.04.B.T-03 Evaluating the Impacts of Nickel on Arctic Freshwater Biota, from Crustaceans to Fish

Connor B. Stewart[1]*, Emily Rogevich Garman*[2]*, Christian Schlekat*[2]*, Elizabeth Middleton*[2]*, Daniel Alessi*[3]*, Anne Cremazy*[4] *and Tamzin Blewett*[5]*, (1)Biological Sciences, University of Alberta, Edmonton, Canada, (2)NiPERA Inc, United States, (3)University of Alberta, Canada, (4)INRS, Canada, (5)Biological Sciences, University of Alberta, Canada*

Nickel (Ni) is an essential trace metal of significant economic importance, particularly in the context of transitioning to green energy. Over the past decade, global demand for Ni extraction has surged, but despite this there is limited understanding of the environmental impacts associated with this increased demand. Arctic environments are at risk of such contamination, with significant Ni mining occurring in Northern zones. Nickel toxicity is dictated by its bioavailability to organisms in the receiving environment, with many Arctic freshwaters predicted to have high Ni bioavailability due to their abiotic composition (hardness, pH, DOC). Additionally, the unique physiology of Arctic organisms may alter their responses to Ni exposure, making extrapolation of results from temperate model organisms less feasible. The work presented here focused on two crucial Arctic relevant species: Arctic char (Salvelinus alpinus), an important salmonid species at the top of many Arctic aquatic food webs, as well as Daphnia pulex, a crucial invertebrate and primary consumer. Juvenile arctic char were chronically exposed to a range of environmentally relevant Ni concentrations, finding significant growth rate reductions with a 60-day EC20 (Ni concentration causing a 20% reduction in growth rate) of 436 µg/L and significant mortality at higher concentrations, with a 28-day LC10 (Ni concentration killing 10% of exposed organisms) of only 1,111 µg/L, a concentration well within the range of Ni observed near Arctic mines. Additionally, relevant Ni concentrations caused significant alterations to the gill structure of exposed fish. Chronic Ni exposure to D. pulex showed significant reductions in survival and reproduction at concentrations orders below those observed downstream of mining operations in the Arctic in waters mimicking the ionic composition of Arctic freshwater systems. Further D. pulex experiments are currently underway to better characterize the sublethal impacts of Ni in Arctic relevant waters, with a particular focus on the toxicity modifying effects of pH in these waters. Taken together, these results provide insight into the sensitivities of Arctic relevant biota to realistic Ni exposures and help characterize the risks posed to unique Arctic ecosystems.

3.04.B.T-04 Are Physiological Responses to Exposure to an Urban Trace Metal Elements Mixture Sex-Dependent in Zebra Finches?

***Clement Parnet**[1], Axelle Robillard[1], Sylvie Massemin[1], Anne Boos[1], Pascale Ronot[1], Islah El Masoudi[1], Frederic Angelier[2], Martine Bergaentzle[1], Ludivine Valois[1] and Josefa Bleu[1], (1)Institut Pluridisciplinaire Hubert Curien - UMR 7178 Universite de Strasbourg, Centre National de la Recherche Scientifique, France, (2)Centre d Etudes Biologiques de Chize - UMR 7372 La Rochelle Universite, Centre National de la Recherche Scientifique, Institut National de Recherche pour l Agriculture, l Alimentation et l Environnement, France*

Trace metal elements and metalloids (TME) are known to affect birds physiology, like increasing physiological stress, inducing oxidative stress, lowering body mass or shortening telomere. However, little is known on the way the different sexes respond to TME contamination. Previous studies have shown sex differences in contamination which could be attributed to physiological or behavioural effects. As female and male physiology are different, we can expect TME to affect their physiology differently. The aim of this work is to investigate for evidences in sex-dependent physiological adverse effect in a passerine bird model in response to exposure to an urban relevant TME mixture. To do this, 40 zebra finches (Taeniopygia guttata) pairs were exposed through their drinking water for 60 days to a urban relevant TME mixture (350 mg.L-1 Zinc, 60 mg.L-1 Copper, 2 mg.L-1 Nickel, 0.6 mg.L-1 Cadmium, 10 mg.L-1 Lead and 2 mg.L-1 Arsenic). We focused on sublethal and non-invasive cues: Individual contamination was followed using feathers TME concentration when physiological stress was monitored using heterocytes / lympocyte ratio combined with avian stress hormone (corticosterone) feathers concentration. We used hematocrit as a general blood marker. As oxidative stress markers, we used protein carboxylation when catalase and superoxide dismutase activities and plasma carotenoid content were used as markers of oxidative defenses. The gluthathion and gluthation peroxydase activities were used as detoxification marker. We hypothesised that females and males would respond differently to all of these markers, as contamination seems to vary between male and femalle. Most of studies in controlled environment only focussed on male responses to TME or repoduction outcome whithout looking at femalle physiology. This work should enable a wider overview of the direct effects of TME on birds.

3.04.B.T-05 Aquatic Ecotoxicity of Environmentally Realistic Metal-Organic Mixtures to the Algae *Raphidocelis subcapitata*

***Maria Laura De Donno**[1], Marius Schmitt[2], Charlotte Nys[3], Karel Viaene[3], Hugo Waeterschoot[4] and Karel De Schamphelaere[5], (1)GhEnToxLab, Ghent University, Flanders, Belgium, (2)Ghent University, Belgium, (3)ARCHE Consulting, Belgium, (4)Eurometaux, Belgium, (5)Ghent University, Flanders, Belgium*

Current environmental risk assessment frameworks predominantly rely on a substance-by-substance approach. This could lead to an underestimation of the environmental risk, especially if unintended combined effects could arise even when the components of a mixture are present at concentrations below their safe levels.

This study investigates the toxicity of metal-organic mixtures by conducting 72-hour growth inhibition tests with the algae *Raphidocelis subcapitata* (OECD 201). Binary mixture tests were designed to evaluate two hypotheses: (1) that independent action (IA) provides a more accurate predictive model than concentration addition (CA) for metal-organic mixtures, and (2) that organic chemicals present at no-effect concentrations do not influence metal toxicity, and vice versa. If the second hypothesis holds, it would suggest that metals and organic chemicals could be assessed independently in regulatory mixture frameworks.

Organic substances frequently co-occurring with metals in European freshwater were prioritized using monitoring data, resulting in the selection of ten metal-organic combinations. Each experiment involved testing the individual components and their binary mixtures simultaneously, following three test rays: (1) an equitoxic ray based on EC10 values, (2) a design where the organic concentration was held constant at half its EC10, while the metal concentration was increased, and (3) a reverse design in which the metal concentration was kept at EC10/2 while the organic one increased. The results of the first three mixtures (diuron-Cu, terbuthylazine-Cd and terbuthylazine-Zn) are presented. Diuron and terbuthylazine are photosystem II inhibiting herbicides.
On average, CA was slightly more accurate than IA, with no statistically significant trend toward synergistic or antagonistic interactions relative to either model. The comparisons between the metal or organic tested individually and in the presence of low concentrations of the other revealed statistically significant effects in four out of the six cases. In three cases, the toxicity was increased by the presence of the other, while in one case it was inhibited. This suggests that PSII-inhibiting herbicides and metals should not be assessed independently in regulatory frameworks. Further testing with a broader range of metals and organics with diverse modes of action is planned to determine whether this conclusion can be generalized to the entire range of organic contaminants.

3.04.P Scientific Advancements in the Fate and Toxicity of Metals: Data, Models, Tools, and Their Application in Environmental Regulations

3.04.P-Th081 Levels of Trace Elements in Teas and Herbal Infusions Available on the Portuguese and French Markets

Ana Sousa[1]*, Rui Azevedo*[2]*, Agathe Richardeau*[3]*, Cristina Couto*[4]*, Claudia Ribeiro*[5]*, Virginia Goncalves*[5]*, Ines Padua*[5] *and Sandra Leal*[6]*, (1)Associate Laboratory i4HB - Institute for Health and Bioeconomy, University Institute of Health Sciences - CESPU, 4585-116 Gandra, Portugal. 2 UCIBIO - Applied Molecular Biosciences Unit, Toxicologic Pathology Research Laboratory, University Institute of , Portugal, (2)LAQV/REQUIMTE, Department of Chemical Sciences, Faculty of Pharmacy, University of Porto, Portugal, (3)Chemistry Department, Universite Toulouse III - Paul Sabatier, France, (4)Associate Laboratory i4HB - Institute for Health and Bioeconomy, University Institute of Health Sciences - CESPU, 4585-116 Gandra, Portugal ;UCIBIO - Applied Molecular Biosciences Unit, Translational Toxicology Research Laboratory, University Institute of, Portugal, (5)Associate Laboratory i4HB - Institute for Health and Bioeconomy, University Institute of Health Sciences - CESPU, 4585-116 Gandra, Portugal; UCIBIO - Applied Molecular Biosciences Unit, Translational Toxicology Research Laboratory, University Institute of, Portugal, (6)Associate Laboratory i4HB - Institute for Health and Bioeconomy, University Institute of Health Sciences - CESPU, 4585-116 Gandra, Portugal; UCIBIO - Applied Molecular Biosciences Unit, Toxicologic Pathology Research Laboratory, University Institute of He, Portugal*

Teas and herbal infusions (THI) are widely consumed for their recognized health benefits. However, bagged teas often contain a mixture of leaves, dust, and fannings, which can result in a higher content of trace elements (TE). TE dissolve in hot water and transfer from THI bags to the beverage. For instance, the accumulation of aluminum (Al) in tea infusions has been associated with Alzheimer's disease. Therefore, the imbalance of TE, mainly linked to anthropogenic sources, raises concerns about food safety and human health. This study aimed to determine the TE concentrations in THIs available on the Portuguese and French marketplace. THI infusions were prepared from Portuguese commercial products (n = 23) and from French commercial products (n = 9) and analysed by inductively coupled plasma mass spectrometry (ICP-MS) using an iCAP Q instrument. The TE content included Al, chromium (Cr), manganese (Mn), cobalt (Co), nickel (Ni), copper (Cu), zinc (Zn), As (arsenic), rubidium (Rb), strontium (Sr), cadmium (Cd), and mercury (Pb). Statistical data analysis was performed using jamovi 2.3.26. The TE profiles of Portuguese and French teas were similar, with most samples showing the order: Al>Mn>Rb> Zn>Sr>Cu> Cr>Co> Pb>As>Sn> Cd> Hg. Overall, Portuguese THIs had lower TE content than French samples, especially Cr, Al, and Rb. Average concentrations for Portuguese samples were 5.15 µg/L for Cr, 5856.24 µg/L for Al, and 496.39 µg/L for Rb, compared to 16.22 µg/L, 12927.04 µg/L, and 105.16 µg/L respectively for French samples.The higher TE content in French THI samples may be due to their composition, as French THI products often include flavors and blends, while Portuguese samples typically consist of a single type of tea or herb. However, tap water can introduce additional elements into THI. This study highlights the variability in trace element concentrations between Portuguese and French THIs, emphasizing the influence of product composition and potential external sources like tap water, which together underscore the need for monitoring and managing trace element exposure to ensure food safety and protect consumer health.

Disclaimer/Disclosure: The authors thank the Portuguese Foundation for Science and Technology (FCT) for funding the research project BioPlasMar (reference https://doi.org/10.54499/PTDC/CTA-AMB/0934/2021) Sandra Leal also thank CESPU Cooperativa de Ensino Superior Politécnico e Universitário for the grant ORPasTeA_GI2-CESPU-2023.

3.04.P-Th082 Evaluation of Cadmium and Lead Contamination in Wild Dandelion (*Taraxacum officinale*) from Croatia: Implications for Food Safety and Public Health

***Michaela Zeiner**[1], Nikolina Ilic[2], Iva Juranovic Cindric[2], Ivan Nemet[2] and Heidelore Fiedler[3], (1)Örebro University, School of Science and Technology, Man-Technology-Environment Research Centre, Sweden, (2)Sveuciliste u Zagrebu Prirodoslovno-matematicki fakultet, Kemijski odsjek, Croatia, (3)ChemAnalytics, Sweden*

Dandelion (*Taraxacum officinale*) often considered a weed is a highly versatile and beneficial plant that has been used in food, medicine, and as a natural remedy for centuries.

Soil pollution by potentially toxic elements is of concern since they may transfer to the edible parts of the food, especially when collecting wild plants from not cultivated, and thus not controlled soil. As examples, cadmium and lead are heavy metals that can accumulate in the body over time, leading to a range of adverse health outcomes.

The European Food Safety Authority (EFSA) stipulated maximum mass fractions of certain metals in food stuff, e.g., 0.05 mg/kg and 0.1 mg/kg for cadmium (Cd) and lead (Pb), respectively. Cadmium is primarily absorbed in the gastrointestinal tract when ingested through food. It is then distributed throughout the body, where it binds to proteins and accumulates in various tissues, particularly the kidneys, liver, and bones. Lead is absorbed into the body through the gastrointestinal tract and is distributed to the bloodstream, where it can accumulate in various tissues, including the bones, brain, and kidneys.

Dandelion and soil samples were collected at 19 different places in Croatia, divided into different parts (root, stem, leaf, flower); thus, generating a total of 95 samples. The plant parts were washed with diluted nitric acid, dried at 105 °C, and ground for homogenisation prior to acidic microwave assisted digestion. The quantification of selected potentially toxic elements in the clear digest solutions was carried out using inductively coupled plasma mass spectrometry (ICP-MS). Soil samples were air-dried and pulverized using an agate mortar prior to digestion and analysis. All plant samples had Pb mass fractions above the maximum value, the results ranging from 0.116 mg/kg to 2.39 mg/kg for the flowers, 0.272 mg/kg to 13.9 mg/kg for the leaves, 0.217 mg/kg to 3.56 mg/kg for the stem, and from 0.745 mg/kg to 40.4 mg/kg for the roots. Regarding Cd, all values except for flower and stem in two plants and four flowers exceeded the maximum mass fraction. On the contrast only five soils samples exceeded the World Health Organization (WHO) permissible limit of heavy metals in soil for Cd and only one for Pb.

The elevated levels of Cd and Pb in wild edible plants may pose a public health concern due to the exceedance of recommended limit values. In conclusion of this study, the present dandelion samples cannot be recommended for human consumption.

3.04.P-Th083 Assessing Heavy Metal Contamination from Shooting Ranges: A Case Study of the Munkatorp Shooting Range in Örebro, Sweden

***Michaela Zeiner**[1], Ramazan Naysal[2] and Katerina Prohaska[3], (1)aMan-Technology-Environment Research Centre, School of Science and Technology, Örebro University, Fakultetsgatan 1, 70182 orebro, Sweden, Sweden, (2)Man-Technology-Environment Research Centre, School of Science and Technology, Örebro University, Sweden, (3)Biotech Campus Tulln, University of Applied Sciences, Austria*

Conifer needles have been extensively studied worldwide, particularly in regions impacted by heavy metal pollution from traffic and industrial activities. These studies focus on evaluating the potential of pine needles as bioindicators of environmental contamination, due to their year-round presence. In addition to industrial pollution, shooting ranges are another significant source of heavy metal contamination.

Shooting ranges provide a controlled environment for firearm practice and training, yet the environmental impacts of these activities are often overlooked. The discharge of lead and other heavy metals from ammunition poses a serious threat to ecosystems and public health. Lead is a major contaminant, as bullets are typically composed of lead or contain lead-based components. When fired, these bullets release lead particles into the environment, contaminating soil and water. Over time, the accumulation of lead in the ecosystem can have harmful effects on plants, wildlife, and human health.

One such area of concern is the Munkatorp Shooting Range in Örebro, Sweden, which has been identified as a site of significant heavy metal pollution. Although there are plans for decontamination, no substantial actions have been taken to address the contamination so far. Within the designated area, four trees were selected for sampling: two Norway spruces (Picea abies) and two Scots pines (Pinus sylvestris). Needle samples were carefully collected and stored in plastic bags, then washed, dried, and ground into a fine powder for subsequent digestion and analysis. The metal content was quantified using inductively coupled plasma mass spectrometry (ICP-MS) after acidic digestion. The study focused not only on metals commonly associated with ammunition, specifically manganese, iron, nickel, copper, zinc, molybdenum, antimony, and lead, but also on essential elements for plants to better understand the environmental impact of the pollution in this area. Furthermore, the needles underwent analysis via Raman Spectroscopy to get information on the metabolic state of the plant material, which provides deeper inside on the soil conditions on the growing site of the conifers. The analysis of conifer needles revealed no significant contamination attributable to the shooting range. Instead, it highlighted species-specific variations in metal contents, but within the ranges reported in literature. Species-specific differences were also found using Raman Spectroscopy.

3.04.P-Th084 Analysis of the Otolith Bone for Tracing Environmental Metal Contamination in Bluegill (*Lepomis macrochirus*) and Green Sunfish (*Lepomis cyanellus*)

*Matteo Minghetti[1], Stacey Herriage[2], **Aryanna rene Carr**[2], Dan Shoup[3], Jorge Gonzalez-Estrella[3] and Jason B. Belden[2], (1)Integrative Biology, Oklahoma State University, Stillwater, United States, (2)Oklahoma State University, Stillwater, United States, (3)Oklahoma State University, United States*

Otoliths, or "ear stones," are calcareous structures in fish that aid in balance and sound detection, and their chemical composition can serve as bioindicators for aquatic environments. This study uses otolith analysis to examine the life history of metal exposure on fish from the Grand Lake and Tar Creek Superfund site in Oklahoma a historically lead- and zinc-mined area with extensive contamination. The mechanisms of metal deposition into otoliths and their link to contamination levels remain poorly understood, warranting investigation into how pollution at the Tar Creek Superfund site influences otolith biomineralization and records of historical exposure.

To evaluate whether otoliths can reflect the life history of metal exposure, Lepomis species (bluegill and green sunfish) were sampled from four sites along a contamination gradient: two reference sites (Grand Lake Honey Creek and Sycamore Creek) and two polluted sites (Tar Creek E40 and Miami, near the mine drainage). Dissolved metals concentrations in the water revealed a pronounced pollution gradient, with cadmium levels ranging from 0.10 µg/L at reference sites to over 12 µg/L at E40, and zinc levels exceeding 7,000 µg/L at E40 compared to under 2 µg/L at reference sites. Copper, lead, and iron were similarly elevated at polluted sites, reflecting persistent mining-derived contamination. Fish otoliths from toxic sites were notably lower in weight comparison (12.06 ± 3.50 mg vs. 18.03 ± 8.20 mg) but greater in length (0.477 ± 0.11 cm vs. 0.352 ± 0.09 cm) and width (0.178 ± 0.22 cm vs. 0.117 ± 0.03 cm), suggesting some effects on otolith biomineralization. Relative weight, a ratio of a fish's actual weight to its expected weight based on species and size, was lower at polluted sites (E40: 84.03/Miami: 79.42) than at reference sites (GLHC: 87.17/SYC: 84.82).

To further explore these findings, sagittal otoliths were dissected and analyzed for metal accumulation. One otolith was dissolved in nitric acid for trace metal analysis via ICP-MS, while the second will undergo laser ablation ICP-MS and X-ray fluorescence to examine spatial patterns of elemental deposition. This approach correlates environmental metal concentrations with temporal bioaccumulation in fish. By linking otolith chemistry to water quality, this study offers insights into contamination impacts on fish health and evaluates remediation efforts in the Grand Lake region.

3.04.P-Th085 Where's the Data? Updating the EU Physicochemical Freshwater Monitoring Database

*Iain Wilson[1], Graham Merrington[1], **Adam Peters**[1], Elizabeth Middleton[2], Chris Cooper[3], David Boyle[4], Stijn Baken[5], Jelle Mertens[6], Paul Marsh[7] and Kelly E Croteau[8], (1)wca environment Ltd, United Kingdom, (2)NiPERA Inc, United States, (3)International Zinc Association, Belgium, (4)Cobalt Institute, United Kingdom, (5)International Copper Association, Belgium, (6)European Precious Metals Federation, Belgium, (7)International Aluminium Institute, United Kingdom, (8)Windward Environmental LLC, Seattle, United States*

A number of metal Environmental Quality Standards (EQS) are based on the bioavailable fraction of a metal, and therefore, this needs to be accounted for during an EQS compliance assessment. However, when the guidance for using bioavailability was set there was a paucity of samples with parameters required for bioavailability correction, many existing databases were only snapshots of discrete timeframes, or of uncertain quality, which limited the ability to perform such an assessment. Launched in 2020, the EU Physicochemical Database Tool aimed to remedy this by compiling data from EU Member States (EU MS). The database is designed to assist practitioners in obtaining data for European freshwaters to allow for efficient metal EQS compliance assessments, particularly by targeting data on pH, dissolved organic carbon and calcium concentrations as well as metal exposures.

Databases, however, should not be static as data is constantly generated by environment agencies and international commissions, and the data usages rights change. Therefore, an update of the Database has

been performed. This involved contacting all EU MS, as well as select non-EU MS requesting data for a defined list of parameters (including the parameters required for bioavailability normalisation), and also covering additional parameters that were not included in the original data collection exercise, for example silver, cobalt and magnesium.
This exercise has resulted in the inclusion of 36 new datasets, containing data from 33 European countries, encompassing over 2,300,000 additional samples from more than 84,000 sampling sites. This is a significant increase from the original assessment that resulted in ~1,000,000 samples being collected from ~26,000 sites. The new data includes samples from countries that were previously available but could not be publicly shared, countries where bioavailability parameters were lacking (Portugal), and countries that were previously unavailable (Cyprus). Additionally, the spatial distribution has also increased for some countries where previously only limited data was available (e.g., Germany). All datasets collected have also been assessed using CREED for reliability and relevance for inclusion within the EU Physicochemical Database.
This poster will highlight the additional data collected, particularly the expansion in the number of parameters, the increase in spatial coverage, and general findings of the reliability and relevance assessment.

3.04.P-Th086 Simplified and Now User-Friendly! Updating Bio-Met for Better Risk Assessment
*Iain Wilson[1], Graham Merrington[1], **Adam Peters**[1], Elizabeth Middleton[2], Chris Cooper[3], David Boyle[4], Stijn Baken[5], Jasim Chowdhury[6] and Charlotte Nys[7], (1)wca environment Ltd, United Kingdom, (2)NiPERA Inc, United States, (3)International Zinc Association, United States, (4)Cobalt Institute, United Kingdom, (5)International Copper Association, Belgium, (6)International Lead Association, United States, (7)ARCHE Consulting, Belgium*
A tiered approach under the European Water Framework Directive has been developed for implementing bioavailability-based Environmental Quality Standards (EQS) for metals. Tier 2 of the approach prescribes the use of simplified tools, often based on the full and complex biotic ligand models (BLMs), to account for bioavailability. Simplified tools are designed to be less data intensive and easier to use in routine regulatory activities. bio-met is one such simplified tool that only requires pH, dissolved organic carbon and calcium concentrations to assess the potential freshwater risks and compliance with EQSbioavailable for cobalt, copper, nickel, lead and zinc. While Tier 2 provides an opportunity for the use of simplified tools it has certainly been the case in the past that simplified tools have not always been simple to use.
Feedback has been received from a number of avenues, including workshops and directly from users, regarding potential improvements to bio-met from both scientific and useability prospectives. In bio-met version 5.1, the extraction of the calculated results from the tool is difficult, and the guidance associated with results is unclear and hard to review. Additionally, if only hardness was available, a separate step converting to calcium was required prior to processing in the tool. The updates to bio-met presented in this poster focus on the usability updates applied to the tool.
A functionality has been added so that the metal(s) of interest to be assessed can be selected to focus the outputs to the user s requirements and improve processing speed. Additionally, a function to export results has been added to make reviewing of outputs simpler and clearer. All guidance, and the front-page, have been reviewed and updated with additional context while also being clear and concise. Furthermore, the reliability of results produced for samples where a parameter is outside of the model applicability domain, compared to the full BLMs outputs, has been incorporated in the updated tool. Ultimately, this means that results will only be produced if one parameter is outside of the applicability domain and the full BLM indicates the result is not likely to be under-conservative.

These updates have been designed to encourage greater use of tool, to better implement the tiered approach, and to assist in producing high-quality evidence-driven conclusions when evaluating the potential risk of metals in European waters.

3.04.P-Th087 Determination of Gallium (III) and Tin (II) Free Concentrations in Aqueous Media with the Electroanalytical Technique AGNES (Absence of Gradients and Nernstian Equilibrium Stripping)
*Adnivia Monteiro[1], Carlos Rey-Castro[2], Jaume Puy[2], Ottavia Giuffr[3], **Josep Galceran**[2] and Encarna Companys[2], (1)Departamento de Química, Física y Ciencias Ambientales y del Suelo. Universitat de Lleida, and AGROTECNIO-CERCA, Spain, (2)Departament de Qu mica, F sica i Ci ncies Ambientals i del S l. Universitat de Lleida, and AGROTECNIO-CERCA, Spain, (3)Dipartimento di Scienze Chimiche, Biologiche, Farmaceutiche ed Ambientali, Italy*
The use of gallium and tin has increased recently, especially due to their technological applications. The

potential effects of the release of these elements to the environment calls for the study of their bioavailability. The essential tenet of ecotoxicological models such as the Free Ion Activity Model (FIAM) or the Biotic Ligand Model (BLM) is that toxicity is strongly correlated to the concentration of the free metal ion. So, the development of techniques to measure these concentrations in various aqueous media is needed. The electroanalytical techniques AGNES (Absence of Gradients and Nernstian Equilibrium Stripping) has been designed to measure free metal ion concentrations. Typical analytes were Zn(II), Cd(II) and Pb(II) in a variety of matrices ranging from estuarine water to soil extracts, from ZnO nanoparticle dispersions to growth media, from wine to streams in the Pyrenees, etc. More recent analytes were Sb(OH)3 and In(III). For indium, attomole per litre concentrations were reached in dispersions of In2O3 nanoparticles in synthetic seawater. In this presentation, the implementation of AGNES to determine Ga(III) and Sn(II) will be reported. In both cases, their strong hydrolysis has led -as a first step- to the analysis in acidic conditions (up to pH 4). The electrodic irreversibility of the couple Ga0/Ga3+ on the mercury electrode implies longer deposition times than when dealing with the typical divalent cations. In the case of Sn(II), an added challenge is its easy oxidation to Sn(IV). In both cases, the free metal ion concentrations determined with AGNES are checked against those predicted by the speciation code VMINTEQ for Ga3+ complexation with phthalate and Sn2+ complexation with EDTA.

3.04.P-Th088 Possibilities and Challenges in Setting Scientifically Defensible Discharge Limits for Aluminium in the UK

Adam Peters[1]*, Mark Craig*[2]*, Jenni Hughes*[3]*, Richard Smith*[2]*, Fergus O'Brien*[4]*, Peter Sugden*[2]*, Ryan Oakley*[5]*, Jay Bullen*[6]*, Michael Brennan*[7]*, Gillian Ide*[8]*, John Bagnall*[9]*, Joanna Wishart*[10]*, Gavin Lincoln*[11]*, Adam Smart*[12]*, Simon Roe*[13]*, Curtis Howell*[14]*, Ben Bradford*[13] *and Graham Merrington*[15]*, (1)wca environment Ltd, United Kingdom, (2)Severn Trent Water, United Kingdom, (3)UKWIR, United Kingdom, (4)DWR Cymru, United Kingdom, (5)Southern Water, United Kingdom, (6)Anglian Water, United Kingdom, (7)Uisce Eireann, Ireland, (8)United Utilities, United Kingdom, (9)Wessex Water, United Kingdom, (10)Scottish Water, United Kingdom, (11)South West Water, United Kingdom, (12)Yorkshire Water, United Kingdom, (13)Environment Agency, United Kingdom, (14)Thames Water, United Kingdom, (15)wca, United Kingdom*

Aluminium is naturally occurring and abundant in the environment due to its presence in many minerals. It also has several uses including in cleaning and personal care products, industrial processes, and as a flocculant to remove nutrients from the effluent of wastewater treatment works, often in the form of aluminium sulphate (alum). Concentrations of residual aluminium may remain in wastewater effluents post treatment, resulting in potential releases to receiving waters. The assessment of potential aquatic risks from aluminium in freshwaters is complicated by the range of factors that can influence it s speciation and ecotoxicity in the water environment. This means the speciation and ecotoxicity of aluminium is not straight-forward to predict or model. Furthermore, the lack of a sufficiently practicable measurement approach that can readily distinguish between potentially toxic and non-toxic forms of aluminium from natural background sources, such as aluminosilicate minerals present in suspended particulate matter is challenging. This complexity has hindered the progress on the development of an evidence-driven limit values and standards for aluminium. This presentation considers the possibilities for the development of robust discharge consents for aluminium in freshwaters that can take account of the differences in sensitivity to aluminium between different sites.
There is a good body of evidence to support the need to take account of both the bioavailability of aluminium and its tendency to form precipitates under certain conditions in setting a standard. However, a lack of sufficient validation information for the available bioavailability models has prevented the setting of an EQS in the UK during previous reviews. This project evaluates whether field evidence based on invertebrate communities can be used to demonstrate the protectiveness of the bioavailability models and any standards that they are used as the basis for. Recommendations are made regarding the most appropriate method for setting discharge consents for aluminium containing effluents from wastewater treatment plants.

3.04.P-Th089 Free Ion Determinations to Support Silver Bioavailability Model Development

Edward Salisbury[1]*, Nada Basic*[2]*, Karel De Schamphelaere*[2]*, M. Gloria Pereira*[1]*, Katrien Arijs*[3]*, Jelle Mertens*[4] *and Stephen Lofts*[1]*, (1)UK Centre for Ecology and Hydrology, United Kingdom, (2)GhEnToxLab - Ghent University (UGent), Belgium, (3)ARCHE Consulting, Belgium, (4)European Precious Metals*

Federation, Belgium
Development of bioavailability models for metals in aquatic systems requires computation of metal speciation in the exposure medium of the ecotoxicological experiments used for model calibration. Almost always, the most import speciation model output is the activity of the free metal ion since this is almost invariably a key chemical variable within the bioavailability model. Such computations may be carried out using a speciation model, such as WHAM7 or Visual MINTEQ, if it is parameterised for the reactions of the metal of interest with solution ligands. Ligands include dissolved organic matter (DOM), if exposure waters containing DOM are to be used for model development. While the availability of a parameterised speciation model is a prerequisite for bioavailability model development, model parameters, particularly those for interaction with DOM, may not be extensively validated. Furthermore, there may be a need to gain further knowledge on the influence of variability in metal DOM binding strength on the bioavailability of the metal.
Analytical determination of free metal ion activities in the exposure waters can provide invaluable data to address both these issues. Here we present the results of ongoing research to set up and apply a system for determination of the free silver ion activity in test solutions and ecotoxicity test media for algae (Species) and *Daphnia magna*. This research is a component of a project to develop and apply chronic bioavailability models for silver to aquatic organisms. To achieve the widest possible analytical window for silver ions, we have adapted the flow cell approach used by Tait and co workers (doi.org/10.1071/EN14190) for silver, and have tested electrode linearity both in simple solutions and in solutions containing well defined synthetic organic ligands. We will present measurements of free silver ion activities in exposure media, including media containing natural DOM, over the ranges of the dissolved silver used in toxicity testing, and provide comparisons to free ion predictions made by the WHAM7 model.

Disclaimer/Disclosure: This research is funded by the European Precious Metals Federation.

3.04.P-Th090 Development of an Approach to Account for Bioavailability in the Assessment of Potential Risks of Uranium Exposures to Freshwater Ecosystems
Adam Peters[1]*, Lucy Kennelly*[1]*, Iain Wilson*[1]*, Graham Merrington*[1]*, Dean Leverett*[1]*, Stephen Lofts*[2]*, Lars Olaf Hoglund*[3]*, Magnus Sidborn*[3]*, Pernilla Boqvist*[3] *and Celia Jones*[3]*, (1)wca environment Ltd, United Kingdom, (2)CEH, United Kingdom, (3)Kemakta, Sweden*
"Water chemistry has been shown to influence the speciation and bioavailability of metals in freshwater ecosystems. Relationships have been developed to estimate the bioavailability and subsequent ecotoxicity of metals from water chemistry parameters, such as pH, dissolved organic carbon (DOC) and hardness. These relationships, developed into models such as Biotic Ligand Models (BLMs) and Multiple Linear Regressions (MLRs), once successfully validated against ecotoxicity tests in field collected waters, have been adopted by regulatory authorities around the world to provide evidence-driven assessment of potential risks. Bioavailability-based approaches are available for many metals. However, despite the recognised importance of water chemistry conditions in determining potential ecotoxicity no models, beyond simple DOC corrections, have been developed for uranium. In addition to the obvious emission sources of uranium from the global nuclear industry and mining operations, uranium occurrence is widespread as a natural component of geological matrices and bedrocks. Here we provide an outline of the approach being taken in developing an understanding of uranium bioavailability, that can provide fit for purpose assessment of uranium ecological risks in freshwaters. The key tasks in our approach are:

3.04.P-Th091 Initial Outcomes in the Development of a Bioavailability-Based Approach to Risk Assessment of Uranium in Freshwaters: Data collection and likely bioavailability relationships
Adam Peters[1]*, Lucy Kennelly*[1]*, Iain Wilson*[1]*, Graham Merrington*[1]*, Dean Leverett*[1]*, Stephen Lofts*[2]*, Lars Olaf Hoglund*[3]*, Magnus Sidborn*[3]*, Pernilla Boqvist*[3] *and Celia Jones*[3]*, (1)wca environment Ltd, United Kingdom, (2)CEH, United Kingdom, (3)Kemakta, Sweden*
Uranium may enter freshwater ecosystems through emissions from industrial activities such as mining or the generation of nuclear power. Importantly, a further source of uranium may also be from geogenic sources when underlying parent materials are disturbed by infrastructure developments or mining activities. It has long been established that water chemistry conditions may influence uranium speciation and ecotoxicity in freshwaters. However, a robust approach to account for uranium bioavailability is not yet available.
Here we describe the outcomes from the early stages in the development of an approach to account for bioavailability, that is both scientifically robust and can be practically applied by stakeholders and regulators.
A comprehensive search of the scientific literature was conducted to identify potentially relevant

ecotoxicity data for uranium. In addition, the results were cross-checked with uranium EQS dossiers published by the Netherlands and Canada. An ecotoxicity database was developed, containing nearly 400 individual datapoints covering a wide range of species and taxonomic groups. The data were assessed for their suitability for use in bioavailability modelling based on reported water chemistry parameters. Moderate quantities of chronic data representing a range of water chemistry conditions are available for several species, and efforts will be made to identify the key drivers of uranium toxicity from them. However, because these tests were not conducted with the intention of developing reliable bioavailability models for regulatory applications additional testing will be required to ensure that the models are both sufficiently reliable and cover the required range of water chemistry conditions. Various established modelling approaches (e.g., BLM, gBAM, MLR) will be taken to explain the relationship between water chemistry and uranium toxicity to aquatic organisms. Additionally, there are also more limited quantities of data available for several other species that provide an opportunity to validate the bioavailability models that are developed. The ranges of water chemistry conditions that the models need to be applicable to, and the extent to which the models developed can reliably predict uranium toxicity will also be addressed. Insights into the sensitivity of both Swedish and European surface waters to uranium toxicity will also be presented.

3.04.P-Th092 Delivering a New Framework for the Implementation of Bioavailability-Based Metal Guideline Values in Australia and New Zealand

Jennifer Stauber[1], Jenni Gadd[2], Aleicia Holland[1], Rick van Dam[3], Erin Smith[4], Adam C Ryan[5], Elizabeth Middleton[6], Graham Merrington[7], ***Adam Peters***[7] *and Iain Wilson[7], (1)La Trobe University, Australia, (2)Hydrotoxy, New Zealand, (3)WQadvice, Australia, (4)Copper Development Association, United States, (5)International Zinc Association, United States, (6)NiPERA Inc, United States, (7)wca environment Ltd, United Kingdom*

"A new framework for the derivation and implementation of bioavailability-based metal Default Guideline Values (DGVs) has been developed for Australia and New Zealand. The approach was formulated during a 2023 workshop held in Syndey and comprised of scientists and regulators from New Zealand and Australian states and territories. Specifically, the initial focus has been on copper, nickel, and zinc and has included key activities such as the:

3.04.P-Th093 Role of Medium Anionic Composition on Manganese and Zinc Cytotoxicity in Rainbow Trout Gill Cells

Grace Marie Baldwin[1]*, Victoria Rhodes[2] and Matteo Minghetti[3], (1)Oklahoma State University, United States, (2)Oklahoma State University, Stillwater, United States, (3)Integrative Biology, Oklahoma State University, Stillwater, United States*

Research has shown that the bioaccumulation of manganese (Mn) in animals can lead to neurodegenerative diseases such as Parkinsonism. Despite its potential dangers, limited data exists about the uptake mechanism and cytotoxicity of this essential metal and how the medium composition can affect bioavailability. Similarly, zinc (Zn) is another essential metal whose bioavailability and toxicity can be affected by the interaction with anions in the exposure medium. To evaluate the role of medium composition on the bioavailability and toxicity of Mn and Zn, we used a model of the rainbow trout gill cells, RTgill-W1 cell line. The RTgill-W1 cells were seeded in 24-well plates at 79,000 cells/cm2, incubated for 48 hours, and exposed to each metal separately for 24 hours in three distinct media. The role of exposure medium composition was evaluated by manipulating anionic composition to produce these media: (1) L15/ex, a phosphate-buffered medium; (2) L15/P0, a HEPES-buffered medium; and (3) L15/HCO3, a bicarbonate-buffered medium. A chemical equilibrium model, Visual MINTEQ, was used to determine the speciation of Mn and Zn in the different media. In the L15/ex medium, free Mn2+ was lowest at 79.199% but 92.567% in the L15/P0 medium, with the L15/HCO3 medium containing a value in between. Uniquely, the L15/HCO3 medium allowed the formation of the MnHCO3+ and MnCO3 (aq) species compared to L15/Ex and L15/P0. For Zn, only L15/HCO3 and L15/Ex were analyzed. In L15/HCO3, 4.075% ZnCO3 (aq), 3.311% ZnHCO3+, and 0.014% Zn(CO3)2-2 were present. In contrast, Zn in L15/Ex distinctly forms ZnHPO4 (aq). After collecting this data, multiple endpoint viability assays measuring metabolic activity, membrane integrity, and lysosome integrity were used to determine metal cytotoxicity in RTgill-W1 cells. This approach allowed for the linkage between the role of extracellular metal speciation and intracellular toxicity. The results of these assays show that the Mn EC50 value in L15/ HCO3 is 213.7µM compared to 18,918µM in L15/ex. This is especially probing because no other divalent metal has produced such a drastic effect on the RTgill-W1 cells in the L15/HCO3 medium. This finding possibly points to an unknown metal cotransporter using bicarbonate. In future research, the interactions between multiple metals in different media will be studied, which will hopefully help to fill knowledge gaps about metal toxicity.

3.04.P-Th094 Assessing the Oxidative Potential of Metals in Thoracic-Sized Fractions of Road Dust

*Sourav Das[1], Hui Peng[2] and **Clare Wiseman**[2], (1)PennState, United States, (2)University of Toronto, Canada*

Mass measurements of airborne PM have informed our current understanding of the importance of respiratory exposures for human health. It is hypothesized that documented health impacts are mediated via the generation of reactive oxygen species (ROS) leading to oxidative stress. In line with this, attention has shifted to using chemical assays to measure the oxidative potential (OP) of airborne PM to supplement traditional mass measurements to obtain a more holistic understanding of risk. Road dust is a recognized important non-exhaust source of air pollution. This includes metal-bearing particles released from asphalt and tire and brake wear, which may catalyze the generation of reactive oxygen species (ROS). In contrast to studies of airborne PM, the OP of finer road dust fractions has yet to be examined. Given this, the need to characterize its OP to better understand the potential contribution of road dust to airborne pollutant exposures is highlighted.

This study aims to measure the OP of metals in thoracic-sized road dust (<10µm) collected in Toronto, Canada. To assess the OP contribution of soluble vs. insoluble elemental fractions, samples were first treated with Gamble s to simulate the neutral, interstitial conditions in the lung. Water was also used for comparison. OP was measured using the ascorbic acid (AA) and dithiothreitol (DTT) assays (referred to as OPAA and OPDTT). For this, incubated samples were placed in UV-transmissible 96-well plates and spiked with either AA and DDT solutions to achieve final concentrations of 200µM and 100µM, respectively. Absorbance was measured over specified time intervals at 265 nm for the AA assay and 412 nm (after adding Ellman's reagent) for the DDT assay.

Soluble fractions contributed most to total OP (i.e., 90±10 % of total OPAA and 77±8 % total OPDTT). Metals accounted for most of total OPAA and OPDTT measured, with an average of 84% and 65%, respectively. Of all the elements, Cu, Mn, and Fe were determined to be responsible for most of the OP determined with the two assays (i.e., 83% for OPAA and 60% of OPDTT). The insoluble OPAA and OPDTT fractions did not correlate with their soluble counterparts, suggesting that different chemical components (e.g., organics) drive the OP in soluble vs. insoluble fractions. This study highlights the potential for finer road dust fractions to contribute to the OP of respiratory concern. The importance of transition metals, especially Cu, Mn and Fe, are emphasized.

Disclaimer/Disclosure: This study was funded by the Natural Sciences and Engineering Council of Canada (NSERC: Discovery Grants Program, RGPIN-2018 05966).

3.04.P-Th095 Cobalt Contamination Drives the Structure and the Co-occurrence Network of Freshwater Biofilms

*Marisol Goni-Urriza[1], Sarah Gourgues[1], Mathieu Milhe-Poutingon[1], Yannick Corsellis[2], Nicholas Bagger Gurieff[3], Clementine Gelber[2] and **Severine Le Faucheur**[4], (1)Universite de Pau et des Pays de l'Adour, France, (2)TotalEnergies, France, (3)Rio Tinto, Australia, (4)Iprem, Université de Pau et des Pays de l'Adour, France*

Cobalt (Co) is a key metal in the energy transition, which has led to an increase of its extraction and use over recent decades. Nevertheless, its impact on aquatic ecosystems is poorly understood. Biofilms are important biological components and indicators for river health. The present study thus examined Co impacts on the structure, interactions and functioning of prokaryotic and eukaryotic communities in growing biofilms.

Artificial substrata were placed in mesocosms (TotalEnergies facilities, Lacq, France) without (control) and with Co addition (0.1, 0.5 and 1 ?M). These substrata were then colonized by biofilms for 28 days. After the exposure period, a further 35 days without Co contamination was applied to simulate a recovery period. Water and biofilm were collected every 7 days during Co exposure. Water quality was analyzed, and biofilms were examined for Co bioaccumulation, structure and functions.

Cobalt bioaccumulation in growing biofilms was correlated with ambient free Co concentrations. Exposure at 0.5 and 1 ?M Co impacted beta-diversity of both prokaryotic and microeukaryotic communities from the earliest stages of biofilms colonization. Proportions of major prokaryotic and microeukaryotic taxa varied, highlighting sensitive and resistant taxa in both populations. Functional predictions revealed that Co exposure also influenced processes of biofilm formation (primary production and cellular processes). Finally, co-occurrence analyses indicated a reorganization of networks structure and dynamics in response to Co contamination. A loss of connectivity within microbial communities from exposed biofilms was highlighted and associated with a decreasing number and diversity of keystone OTUs. However, networks were denser with a concentration of interactions around the last central nodes, which were essential in the stress response and continued ecological function of the biofilms. Our results highlighted a new approach to assess Co impacts on biofilms considering co-occurrence patterns between microorganisms, in addition to analyses of taxonomic or functional profiles.

3.04.P-Th096 Algal Acute Toxicity of Silver Cyanide in Freshwater Environments

Jelle Mertens *and Tina Liesirova, European Precious Metals Federation, Belgium*

Silver cyanide (AgCN) is a stable silver (Ag) complex that is poorly soluble in water. The primary application of AgCN is in silver plating and electroplating processes. Cyanide (CN-) forms stable complexes with precious metals, including silver, suggesting incomplete dissociation of dissolved complexes in aquatic environments, as suggested in peer-reviewed literature and speciation modelling. Experimental evidence is however lacking to conclusively demonstrate if this distinct speciation also results in a distinct aquatic toxicity of AgCN compared to its most ecotoxic constituent, i.e., ionic silver (Ag+).

Therefore, an experimental testing program is developed to investigate this research question. Algae are identified as the most sensitive test species towards Ag+. Therefore, as a first step, an algal toxicity test with *Raphidocelis subcapitata* is conducted to compare the toxicity of AgCN with a readily soluble silver compound (AgNO3). An initial dose range finding study suggests more than 10-fold higher toxicity thresholds for AgCN compared to AgNO3, when toxicity is expressed as a function of dissolved Ag. A subsequent main algae toxicity test is currently ongoing. If this main test confirms the lower toxicity of AgCN compared to AgNO3, additional trophic levels (invertebrates and fish) will be tested to ultimately allow a substance specific hazard and risk assessment of AgCN under EU CLP and EU REACH regulations. The data of this testing program and their implications in an EU Regulatory context will be presented during the SETAC conference.

3.04.P-Th097 Response of *Scenedesmus acutus* (Chlorophyta) Microalgae to Metals Exposure

Alma Sobrino-Figueroa[1] *and Sergio Alvarez Hernandez*[2]*, (1)Alejandro Villalobos Laboratory. Autonomous Metropolitan University-Iztapalapa, Mexico, (2)Applied Phycology Laboratory. Autonomous Metropolitan University-Iztapalapa, Mexico*

Scenedesmus acutus Meyen 1829 is a microalga that was isolated from water samples collected in the Xochimilco canals, where it serves as food for copepods, cladocerans and rotifers. In this study, the toxic effect of the metals Cd, Cr, Cu, Hg, Mn, Ni, Pb, V and Zn, which are the elements found in concentrations greater than 50 mig/L in the aquatic systems of the Valley of Mexico, was determined on 4 biomarkers: biomass production, chlorophyll concentration, phenol production, and lipoperoxidation in microalgae. Bioassays lasting 72 hours were performed to determine the EC50 and in tests with a sublethal concentration (CL10), for 10 days, the effect on the biomarkers was evaluated. The toxicity of the metals based on the calculated EC50 was (from highest to lowest toxicity): Cu > Cr > Hg > Zn > Cd > Ni > Mn > Pb > V. In the sublethal bioassays with Cd, Ni, and Pb, a decrease in chlorophyll levels was observed. In the tests with Cd, Cr, Ni, Pb, and Zn, an increase in the levels of phenols and carotenes was detected. A high degree of lipoperoxidation was observed in the bioassays with Cu, Mn, and Zn. Because the EC50 values for the metals Cd, Cu, and Pb are lower than those established by NOM 001-Semarnat for discharges into aquatic systems, it is important to continue conducting research and monitoring to detect responses that indicate possible damage to the populations of this microalgae by the action of the discharges, in order to avoid irreversible deterioration of the populations in the medium and long term.

3.04.P-Th098 Nickel Ecotoxicity to *Raphidocelis subcapitata* in Standard ISO Medium vs. Ultramafic Waters

Davide A. L. Vignati[1]*, Carla Frongia*[1]*, Maximilien Beuret*[2]*, Elsa Salles*[1]*, Carole Cossu-Leguille*[2]*, Yann Sivry*[3]*, Thi Tuyen Nguyen*[3]*, Alexis Groleau*[3]*, Remi Marsac*[3]*, Charlotte Catrouillet*[3]*, Yulia Erban-Kochergina*[4] *and Pavel Kram*[4]*, (1)Universite de Lorraine, CNRS, LIEC, France, (2)Université de Lorraine, CNRS, LIEC, France, (3)Universite de Paris, CNRS, IPGP, France, (4)Czech Geological Survey, Division of Geochemistry and Laboratories, Czech Republic*

Pristine ultramafic waters (PUW) usually have Ni concentrations in excess of environmental quality standard (EQS) even in the absence of anthropogenic influence. However, PUW are also rich in colloidal carrier phases (e.g., Fe-hydroxides and natural organic matter) that can mitigate Ni ecotoxicity by reducing its bioavailability.

PUW were collected from the Pluhuv Bor creek (PLB, a small catchment in the western Czech Republic) during snowmelt and tested for their possible ecotoxicity to a model alga in relation to their high Ni content (> 100 µg/L). Ecotoxicity testing was carried using the freshwater alga *Raphidocelis subcapitata* and following the ISO norm 8692. Preliminary work established a Ni 72h-EC50 of around 30 µg/L for algal growth in ISO medium; a value 3- to 5-fold lower than concentrations measured in PLB waters (114

164 µg/L filterable Ni; 0.22 µm). However, PLB waters did not reduce algal biomass compared with control exposures. Characterization of Ni speciation using filtration/ultrafiltration showed that 70 80% of filterable Ni was associated with colloids, resulting in ultrafilterable Ni concentrations (< 3 kDa) of 30 37 µg/L. Bioavailable Ni concentrations, estimated with a user-friendly BLM tool, were 12 17 and 8 13 µg/L in filtered and ultrafiltered waters, respectively; these values being close to the Ni 72h EC10 determined in standard ISO medium. Testing of PLB waters spiked with NiCl2 (14 250 µg/L as Ni) did not result in appreciable ecotoxic effect, either. Modelled bioavailable Ni-concentrations in PLB samples spiked with 250 µg/L of soluble Ni were around 40 µg/L, i.e., above the EC50 value determined in ISO medium. Further research appears necessary to understand how the interplay between speciation and bioavailability affects the ecotoxic potential of Ni in the complex matrix of PUW.

Disclaimer/Disclosure: The authors thanks the CNRS (projects EC2CO B-Rex-Ist et IEA GeoChemTox), LabexR21 (ANR-10-LABX-0021) and eLTER PLUS (EU Horizon 2020, grant agreement 871128) for financial support. This work was partly done with resources from the Pôle de compétences en Biologie Environnemental and Pôle de compétences en Chimie Analytique Environnementale ANATELo, LIEC laboratory, UMR 7360 CNRS Université de Lorraine.

3.04.P-Th099 Pristine Ultramafic Waters Exhibit Baseline Chronic Ecotoxicity to *Daphnia magna*

***Davide A. L. Vignati*[1]**, *Carole Cossu-Leguille[2], Elsa Salles[1], Celine Simon[2], Maximilien Beuret[2], Clement Bojic[1], Vincent Normant[1], Yann Sivry[3], Thi Tuyen Nguyen[3], Alexis Groleau[3], Remi Marsac[3], Yulia Erban-Kochergina[4] and Pavel Kram[4], (1)Universite de Lorraine, CNRS, LIEC, France, (2)Université de Lorraine, CNRS, LIEC, France, (3)Universite de Paris, CNRS, IPGP, France, (4)Czech Geological Survey, Division of Geochemistry and Laboratories, Czech Republic*

Ultramafic waters (UW) have naturally high concentrations of nickel (Ni), chromium (Cr) and Cobalt (Co); their relative abundances depending on the geology and mineralogy of parent rocks. Even in the absence of anthropogenic impacts, concentrations of these elements can therefore exceed the corresponding ecotoxicological standards or guidelines values for freshwaters. Because ultramafic rocks are mined for Ni, a key element for the energy transition, understanding the baseline ecotoxicity of pristine UW can assist responsible mining practices.

Water samples were collected in a pristine ultramafic catchment (Pluhuv Bor creek PLB, Czech Republic) far from anthropogenic inputs of trace elements except for atmospheric deposition. Nickel and chromium speciation was studied by filtration (0.22 µm), ultrafiltration (3 kDa) and diffusive gradients in thin films (DGTs). Previous research showed that Co levels in PLB waters were below thresholds of ecotoxicological concern. Ecotoxicity testing was performed according to OECD guideline 211 (*Daphnia magna* reproduction test) with survival, growth and reproduction as endpoints. Heartbeat rate and swimming behavior were also evaluated at the end of the test.

Filterable (147 175 µg/L) and ultrafilterable (35 40 µg/L) Ni concentrations largely exceeded the European EQS of 4 µg/L bioavailable Ni. Bioavailability corrected Ni concentrations (15 18 µg/L) were also above the EQS and were similar for filtered and ultrafilted waters. DTG-labile Ni concentrations (24 29 µg/L) compared favourably with ultrafilterable ones. Total filterable Cr concentrations (21.4 22.5 µg/L) were above the corresponding WHO guidelines: 4 µg/L for Cr(VI) and 10 µg/L for Cr(III). However, more than 85% of total filterable Cr was associated with colloids and the corresponding ultrafilterable concentrations (2.8 3.2 µg/L) were below the most stringent guideline for Cr(VI). DGT labile Cr(VI) concentrations (1.4 1.8 µg/L) were also below the Cr(VI) guideline, while DGT-labile Cr(III) was below detection limit. Exposure to PLB waters did not affect survival and heartbeat rates of exposed daphnids. On the other hand, growth and reproduction were reduced in some samples and changes in swimming behaviour were observed in all samples. Although PLB waters caused sublethal responses in *D. magna*, further research is needed to clarify the exact causal relationships between Ni and Cr levels vs observed biological responses in *D. magna*.

Disclaimer/Disclosure: The authors thanks the CNRS (projects EC2CO B-Rex-Ist et IEA GeoChemTox), LabexR21 (ANR-10-LABX-0021) and eLTER PLUS (EU Horizon 2020, grant agreement 871128) for financial support. This work was partly done with resources from the Pôle de compétences en Biologie Environnemental and Pôle de compétences en Chimie Analytique Environnementale ANATELo, LIEC laboratory, UMR 7360 CNRS Université de Lorraine.

3.04.P-Th100 Cadmium Toxicity in *Daphnia magna* is Modified by Food Concentration

Juan Carlos Pablo-Currichi, Miriam Hernandez-Zamora and ***Fernando Martínez-Jerónimo****, Instituto Politecnico Nacional. Escuela Nacional de Ciencias Biologicas, Mexico*

Many metabolic and physiological processes in organisms are closely related to essential metals. However, non-essential metals lack identified functions in biological processes and can cause toxicity. Such is the case of cadmium (Cd), which is highly toxic and is released into the environment by natural sources and as a pollutant from anthropic activities. The demonstrated carcinogenic and teratogenic effects of Cd produce biological and ecological impacts in aquatic environments, affecting exposed organisms and the population structure of planktonic species, including both primary producers and filter-feeding consumers. This can lead to bioaccumulation processes that negatively affect higher trophic levels. In this context, the present study evaluated the toxic effect of cadmium on the cladoceran *Daphnia magna* clone F when fed with different concentrations of microalgae. For this, the median Inhibitory Concentration (IC50) 96 h for cadmium chloride (CdCl2) was determined for the microalga *Ankistrodesmus falcatus*, as well as the median Lethal Concentration (LC50) 48 h for the cladoceran *D. magna*. A 21-day chronic bioassay was then conducted, exposing *D. magna* to 6 ?g L?¹ of CdCl2, feeding with 0.5x10?, 1x10?, and 2x10? cells mL?¹ of *A. falcatus*, to evaluate the combined effects of both factors on reproductive responses. The concentrations of proteins, lipids, and carbohydrates in the cladoceran neonates were also quantified. The obtained values were IC50 = 108.02 ?g L?¹ and LC50 = 20.63 ?g L?¹ of CdCl2. The reproduction of *D. magna* was affected, showing a decrease in fecundity, the number of broods, and an increase in the age at first reproduction. The macromolecule concentration in the offspring changed according to the amount of food provided and the concentration of cadmium. These findings highlight the importance of considering the interaction between metal toxicity and food availability in studying the impact on the biological and ecological responses of aquatic biota exposed to pollutants.

3.04.P-Th101 Gadolinium and Environmental Contamination: Effects Across Trophic Levels in Aquatic Ecosystems

***Camilla Mossotto**[1], Alessandra Maganza[1], Alice Gabetti[2], Serena Anselmi[3], Francesca Provenza[3], Stefania Trevisan[3], Antonia Concetta Elia[4], Giuseppe Esposito[2], Monia Renzi[5], Marino Prearo[2] and Paolo Pastorino[2], (1)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua); Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (2)The Veterinary Medical Research Institute for Piedmont; Regional Reference Centre for the Biodiversity of Aquatic environments (BioAqua), Italy, (3)Bioscience Research Center srl, Italy, (4)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (5)Department of Life Sciences, University of Trieste, Italy*

Rare earth elements (REEs) consist of fifteen lanthanides along with scandium (Sc) and yttrium (Y). Anthropogenic activities, such as medical waste, mining, and electronics production, are key sources of REEs contamination. Their widespread use has led to environmental contamination, particularly in aquatic and soil ecosystems. Indeed, aquatic organisms have been shown to suffer from malformations, reduced reproductive success, inhibited growth, and toxicity. Among the lanthanides, gadolinium (Gd) is commonly used as a paramagnetic contrast agent for MRI, with its presence detected in rivers, drinking water, and marine environments. However, detailed studies on gadolinium s toxic effects on organisms remain limited.

This study evaluates the ecotoxicological effects of Gd on model species at different trophic levels. Ecotoxicological tests were conducted on bacteria (*Aliivibrio fischeri*, bioluminescence inhibition), algae (*Phaeodactylum tricornutum* and *Raphidocelis subcapitata*, growth inhibition), crustaceans (*Daphnia magna*, mortality), and echinoderms (*Paracentrotus lividus*, spermiotoxicity and embryotoxicity). The tested gadolinium (Gd2O3) concentrations were environmentally relevant: 0 µg/L, 0.1 µg/L, 1 µg/L, 10 µg/L, and 100 µg/L.

Results indicate that gadolinium s toxicity increases with concentration. *Aliivibrio fischeri* showed biostimulation at low concentrations but up to 98.7% bioluminescence inhibition at 100 µg/L. *Phaeodactylum tricornutum* and *Raphidocelis subcapitata* experienced growth inhibition up to 97% and 96.2% at 100 µg/L. *Daphnia magna* survival remained stable up to 1 µg/L, dropping to 75% at 100 µg/L. *Paracentrotus lividus* displayed a 70.7% reduction in embryonic development at 100 µg/L.

These findings show that gadolinium's toxicity is dose-dependent, with species varying in sensitivity, highlighting the ecological risks of Gd contamination and the need for further research.

3.04.P-Th102 Comparison of Toxicity and Bioaccumulation of Platinum Metals for Organisms of Different Trophic Levels

***Martina Buckova**, Jitka Hegrova and Vilma Jandova, Transport Research Centre, Czech Republic*

The growing use of platinum group metals (PGM) in transport and industry has increased the content of these metals in various components of the environment, especially in the aquatic ecosystem. PGM undergo changes in the environment, become bioavailable and mobile, and are therefore dangerous.

Palladium is considered the most toxic due to its high solubility and mobility, followed by platinum. The mechanism of action and fate of PGM in the environment is still not completely clear. Relatively few studies are devoted to the toxicity and at the same time bioaccumulation of PGM. These studies are mostly not done under standardized conditions, which makes it impossible to compare the results. The aim of the work was to perform both ecotoxicological tests and monitor the bioaccumulation of the most toxic and risky elements from the group of platinum metals, namely palladium (Pd) and platinum (Pt), on selected organisms (green algae Desmodesmus subspicatus, aquatic crustacean *Daphnia magna*, white mustard *Sinapis alba*). These organisms are representatives of different trophic levels and are model organisms in ecotoxicological tests. Ecotoxicological tests were carried out under standard conditions according to the relevant ISO standards. Inhibition of growth rate after 72 hours was evaluated for green algae, immobilization after 48 hours for daphnia, and inhibition of root growth after 72 hours for mustard. After performing the ecotoxicological tests, all tested organisms were washed with ultrapure water, dried and digested in a microwave digestion instrument and analyzed with ICP-MS/MS device. The results show that the least sensitive organism to Pt and Pd is mustard, for which approximately the same toxicity of Pt and Pd was found and the EC50 values were an order of magnitude higher than for algae and daphnia. Although the toxicity of both Pt and Pd to mustard was approximately comparable, mustard was found to accumulate significantly more Pt compared to Pd. Pd was more toxic than Pt to green algae, with more Pt being observed to accumulate in algal cells. On the other hand, Pt was more toxic to daphnia with a lower degree of bioaccumulation in organisms than Pd. The results of bioaccumulation studies show the different ability of individual organisms to accumulate platinum metals. The information obtained can be used for risk assessment and in the bioremediation of wastewater.

Disclaimer/Disclosure: This study was produced with the financial support of the Ministry of Transport within the programme of long-term conceptual development of research institutions.

3.04.P-Th103 Assessment of Acute Toxicity in *Daphnia magna* Exposed to Binary and Ternary Metallic Elements Mixtures of As, Cu, Zn, and Se: Experimental Investigations and Modeling Strategies

Wijdane Limouni[1]*, Valentin Dupraz*[2]*, Patrice Couture*[3]*, Eric Rosa*[4]*, Carmen Mihaela Neculita*[5] *and Vincent Cloutier*[5]*, (1)University of Quebec in Abitibi-Temiscamingue, Canada, (2)Regie de l Eau Bordeaux Metropole, Direction de la Recherche, de l Innovation et de la Transition Ecologique, France, (3)Institut National de la Recherche Scientifique (INRS)- Centre Eau Terre Environnement (ETE), Canada, (4)Research Institute on Mines and Environment (RIME) UQAT-Polytechnique, Universite du Quebec en Abitibi-Temiscamingue (UQAT), Canada, (5)Institute for Research in Mines and Environment (RIME) UQAT-Polytechnique, University of Quebec in Abitibi-Temiscamingue (UQAT), Canada*

This study investigates the impact of contaminant mixtures from mining and metallurgical effluents on *Daphnia magna*. Acute toxicity tests were conducted on metals (Cu and Zn) and metalloids (As and Se), individually, in pairs, and in ternary combinations. The results of binary mixtures revealed varying levels of toxicity: lower than expected (As-Se and As-Zn), consistent with predictions (As-Se and Zn-Se), or higher than anticipated (Cu-Zn and Cu-Se). When combined into ternary mixtures, the interactions between elements introduced additional complexity, influencing *D. magna* toxicity in different ways. The As-Cu-Zn and Cu-Zn-Se mixtures exhibited moderate to high toxicity, primarily driven by the synergistic effects of Cu-Zn and Cu-Se, while the As-Zn-Se and As-Cu-Se mixtures showed lower to moderate toxicity, potentially due to an attenuating effect of As in certain interactions. These findings underscore the importance of evaluating complex metal interactions to better understand their impact on aquatic ecosystems and to guide environmental management policies.

3.04.P-Th104 Ecotoxicity of Field-Realistic Metal-Organic Mixtures to the Freshwater Algae *Raphidocelis subcapitata*

Maria Laura De Donno[1]*, Hugo Waeterschoot*[2] *and Karel De Schamphelaere*[3]*, (1)GhEnToxLab, Ghent University, Flanders, Belgium, (2)Eurometaux, Belgium, (3)Ghent University, Flanders, Belgium*

Current environmental risk assessment frameworks predominantly rely on a substance-by-substance approach, even though chemical contamination in the environment typically occurs as complex often unknown mixtures. Regulatory agencies are increasingly recognizing the need to assess the risks associated with chemical mixtures and to systematically integrate combined exposure and effects into chemical risk assessments.

This study investigates the aquatic toxicity of real-world metal-organic mixtures. We selected four sampling sites in rivers and streams in Belgium, chosen for their proximity to wastewater discharge and industrial effluent sources to ensure the presence of both metal and organic contaminants. At each site,

samples for metal analysis (filtered at 0.45 μm) were collected and Large Volume Solid Phase Extraction was used to isolate and concentrate organic micropollutant mixtures.
We conducted 72-hour growth inhibition tests for each site with the freshwater algae *Raphidocelis subcapitata* (OECD 201). We first performed range-finding tests to estimate the toxicity of the reconstituted metal and organic mixtures by testing them at different relative enrichment factors (REF). The REF is the metric used for expressing the concentration or dilution of a mixture of contaminants relative to their environmental level, while maintaining their relative proportions always constant. A REF of 1 means that the mixture is tested at the same concentration as in the sampled body, while a REF of 10 increases all components of the mixture to 10 times their environmental concentrations. We then conducted binary mixture toxicity tests to assess the interactions between the metal and organic mixture groups.
We used a specific experimental design to test two key hypotheses: (1) that independent action provides a more accurate predictive model than concentration addition for toxicity of environmentally relevant metal-organic mixtures, and (2) that complex organic mixtures present at no-effect concentrations do not influence metal toxicity, and vice versa. If the second hypothesis holds, it would suggest that metals and organic chemicals could be assessed independently in regulatory frameworks.
We aim that this study would provide relevant experimental data to improve our understanding of the joint toxicity of environmentally and regulatory relevant metal-organic mixtures, allowing a scientifically more robust risk assessment of chemical mixtures.

3.04.P-Th105 The Impact of Metal Mixtures on Local Biodiversity – An Analysis of Flemish Freshwater Monitoring Data

***Karel Viaene*[1]*, Charlotte Nys*[1]*, Karel Vlaeminck*[1]*, Marnix Vangheluwe*[1]*, Vanessa de Almeida Moreira*[2]*, Hugo Waeterschoot*[3] *and Karel De Schamphelaere*[4]*, (1)ARCHE Consulting, Belgium, (2)Ghent University, Belgium, (3)Eurometaux, Belgium, (4)Ghent University, Flanders, Belgium*

Biodiversity loss is influenced by a complex interplay of environmental factors, yet the impact of anthropogenic chemicals in general and metals in particular on local biodiversity and how it relates to other environmental factors remains poorly understood. Additional complications are that metals in the environment occur in mixtures and their bioavailability essential to determine their toxicity varies depending on water chemistry conditions. To better understand the impact of metals on local biodiversity, we analyzed freshwater monitoring data from Flanders, including water chemistry, metal concentrations and biota (macroinvertebrates and phytobenthos). The objective of the study is to determine whether metal pressure can be used to explain local biodiversity trends and which biodiversity indices are most sensitive to metal pressure.
To quantify the expected impact of metals, metal concentrations were corrected for bioavailability and used to calculate metal mixture pressure indices based on single metal toxicity data. To quantify biodiverisity, macroinvertebrate and phytobenthos counts were used to calculate a range of biodiversity indices (e.g., Shannon-Wiener index, species richness). Additionally, trait-based indices, based on species traits such as life cycle type or feeding mechanism, were calculated. Statistic methods were used to determine whether any biodiversity indice were significantly explained by metal pressure and if there were safe mixture pressure thresholds below which no effects on biodiversity are expected. Statistical trends were further explored by subsetting the data e.g., based on water body type or location.
The findings of this study enhance the understanding of metals as potential drivers of biodiversity loss and will inform future risk assessments.

3.04.P-Th106 MEED: Progress with the Multiyear Metals Environmental Exposure Data Collection Program to Anticipate Challenges of the EU Zero Pollution Ambition Policy and the Chemicals Strategy for Sustainability

***Hugo Waeterschoot*[1]*, Marnix Vangheluwe*[2] *and Lara Van De Merckt*[3]*, (1)Eurometaux, Belgium, (2)ARCHE Consulting, Belgium, (3)AV DE TERVUEREN 168, Eurometaux, BRUXELLES, Belgium*

The Chemicals Strategy for Sustainability (CSS) is a key pillar of the EU Zero Pollution Ambition (ZPA), a main building block of the Green Deal. This policy aims for achieving good quality status of the environment by achieving exposure levels of chemicals that are no longer harmful. This challenges chemicals regulations given focused on substance specific assessments and limits. The combined effects of chemicals in the environment and assuring they do not affect biodiversity, needs therefore to be included in regulatory schemes. The EU, proposes the introduction of a Mixture Allocation Factor (MAF) to demonstrate safe use and lack of impact on ecosystems from a cocktail of chemicals exposures. This is a real scientific challenge for the EU industry, especially for metals given their increasing volume and use in Green Deal applications like electric vehicle batteries, solar cells, windmills and electronics. This challenge drove the metals sector to design a comprehensive Metals environmental exposure gathering programme (MEED), complemented by the development of scientific concepts and selective test work to assess combined exposure. All to promote we can assess progress toward the ZPA and the EU biodiversity objectives. MEED runs for 4 years up to 2025, covering 6 interlinked projects and enters its final phase. The identification of metals that contribute the most to the combined risks in EU soil and aquatic environments was a first milestone followed by an extensive investigation of today s regional background levels for metals, and an update on the STP emission contribution as a key source of consumers input. A review and reappraisal of existing knowledge on metals mixtures & metals-organics mixtures interactions allowed to define gaps and the design of a gap filling research on mixture toxicity as well as a tiered assessment system for local and regional biodiversity impact assessment. The main outcomes of this R&D are now becoming available allowing to design a science-based concept to improve the assessment of combined effects for regulatory schemes like REACH or the EU-Water Framework Directive. This poster presents the progress made and todays conclusions of the program while detailed assessment of key new milestones are presented in complementary posters. MEED is delivering a huge amount of data and relevant concepts to be used in REACH registration updates and key to assess progress with the ZPA policy of the EU in a scientific way.

3.04.P-Th107 Updating the Bioavailability-Based Environmental Quality Standard Derivation Approach for Compliance Assessment of Zn in Freshwaters

Charlotte Nys[1]*, Karel De Schamphelaere*[1]*, Stephen Lofts*[2]*, Chris Cooper*[3]*, Frank Van Assche*[4]*, Howard Winbow*[4] *and Patrick Van Sprang*[1]*, (1)ARCHE Consulting, Belgium, (2)United Kingdom-Centre for Ecology and Hydrology, United Kingdom, (3)International Zinc Association, United States, (4)International Zinc Association, Belgium*

Many countries list Zn as a River Basin Specific Pollutant under the EU Water Framework Directive (WFD). Given the dependency of the toxicity of Zn on local water body conditions, it is essential that the derivation of Environmental Quality Standards (EQS) for Zn are bioavailability-based. In the present study, the existing bioavailability-based EQS derivation approach, which has been widely used and accepted for more than a decade; was updated by I) revising the existing ecotoxicity dataset, and updating it with recent high-quality ecotoxicity data for freshwater organisms, including species that were previously not considered and II) optimising the bioavailability models in terms of model structure and speciation software. The updated EQS derivation approach was then used to derive a bioavailable EQS for Europe, which can serve as a first-tier screening level in compliance assessments.

The updated chronic Zn freshwater ecotoxicity dataset combines high-quality data retained from the existing Zn freshwater toxicity datasets with high-quality data identified in a recent literature screening. The updated database now contains data covering 40 species and covers the minimum data requirements for species sensitivity distribution-extrapolation set out in the relevant guidance of the WFD. The existing chronic Zn bioavailability models were revised by optimizing the model structure and using the most recent version of WHAM as the underlying speciation software. Within the validation of the updated models with independent data for nine aquatic species: EC10 were generally predicted within 2-fold error for model-species and within 3-fold error for non-model species with few exceptions. Hence, the updated bioavailability models can be reliably used to accurately predict Zn toxicity across different species. The updated ecotoxicity dataset and the updated chronic bioavailability models were combined with species sensitivity distribution techniques resulting in the updated EQS derivation approach for Zn, which allows the derivation of a site-specific environmental threshold for Zn. The updated EQS derivation methodology has been used as a basis to derive a robust bioavailable EQS for Zn in European freshwaters. The bioavailable EQS in combination with the updated bioavailability normalisation approach will improve the environmental relevance of compliance assessment for Zn under the WFD.

Disclaimer/Disclosure: The authors wish to thank the International Zinc Association for funding this research

3.04.P-Th108 Derivation of a Bioavailable Environmental Quality Standard for Copper

Charlotte Nys[1]*, Karel De Schamphelaere*[1]*, Stephen Lofts*[2]*, Katrien Arijs*[1]*, Stijn Baken*[3] *and Patrick Van Sprang*[1]*, (1)ARCHE Consulting, Belgium, (2)United Kingdom-Centre for Ecology and Hydrology, United Kingdom, (3)International Copper Association/VITO, United States*

The toxicity of Cu to aquatic organisms depends on local water body conditions, with dissolved organic carbon, pH, hardness and sodium as main toxicity modifying factors. Cu is a river basin specific pollutant

under the Water Framework Directive. For metals with validated bioavailability models, compliance is assessed using a tiered approach based on a bioavailable environmental quality standard (EQSbioavailable). The EQSbioavailable is set at the environmental threshold that protects 95% of the waters in the European country with the highest bioavailability conditions (or highest Cu sensitivity). The current EQSbioavailable (1.0 µg dissolved Cu/L) is based on a bioavailability-based derivation approach, which exists for more than a decade. Here, we present an updated bioavailability-based normalisation approach for Cu that incorporates recent updates in ecotoxicity data and bioavailability models, and we assess whether the current EQSbioavailable is still valid.
The proposed chronic Cu freshwater ecotoxicity dataset combines high-quality data retained from the existing Cu freshwater toxicity datasets with high-quality data identified in a recent literature screening. The updated database contains 49 species and is among the most data-rich ecotoxicity databases for metals. This dataset is combined with recent chronic Cu bioavailability models and species sensitivity distributions techniques in a dedicated, easy to use bioavailability normalisation tool, CuBioM. CuBioM calculates site-specific environmental thresholds for European surface waters, which were used as basis to derive a EQSbioavailable for Cu following the relevant guidance. Preliminary calculations suggest that the updated ecotoxicity dataset and bioavailability models confirm the validity of the current EQSbioavailable of 1.0 µg dissolved Cu/L. Next, the updated bioavailability models and ecotoxicity dataset will be included in bio-met. In practice, compliance of water bodies with the EQSbioavailable for copper is best assessed using either CuBioM or bio-met. This improves the environmental relevance of the assessment by incorporating bioavailability.

3.04.P-Th109 Compliance Assessment of Cu under the Water Framework Directive

Charlotte Nys[1]*, Karel Vlaeminck*[1]*, Karel De Schamphelaere*[1]*, Stephen Lofts*[2]*, Stijn Baken*[3] *and Patrick Van Sprang*[1]*, (1)ARCHE Consulting, Belgium, (2)United Kingdom - Centre for Ecology and Hydrology, United Kingdom, (3)International Copper Association/VITO, United States*

Cu is a river basin specific pollutant (RBSP) under the European Union (EU) Water Framework Directive (WFD). Cu has been reported by the European Environmental Agency as one of the RBSP that most frequently fails compliance against the environmental quality standards (EQS). The toxicity of Cu to aquatic organisms is dependent on local water body conditions (such as Dissolved Organ Carbon, pH, hardness and sodium), and therefore it is essential that compliance assessment of Cu is bioavailability-based. However, it is not clear whether, and to what extent bioavailability is incorporated in current compliance assessments. Therefore, the risks of Cu may be over- or underestimated.
Here, we present an EU-wide compliance assessment of Cu in freshwaters, following the tiered approach set out in the relevant WFD guidance, and based on the most recent ecotoxicity database and optimisations in Cu bioavailability models. These have been integrated in CuBioM, an easy-to-use bioavailability normalisation tool, that allows to calculate site-specific environmental thresholds for Cu, expressed as the 5% hazardous concentration. We perform a Tier 1 compliance assessment against the EQSbioavailable, and a Tier 2 bioavailability corrections based on local water chemistry conditions. While a considerable proportion of waters fail the Tier 1 assessment, the study highlights how incorporating bioavailability in Tier 2 if the compliance assessment increases the environmental relevance of compliance assessments. This suggest that a Tier 1 assessment does not really help to screen out sites for copper, and it may be more efficient for regulators to directly assess compliance against a site-specific EQS under Tier 2. In addition, the extent of Cu exceedances when incorporating bioavailability will be discussed. The bioavailability correction using CuBioM serves as a robust approach which can aid regulators to improve environmental relevance when performing local compliance assessments for Cu under the WFD. The multi-metal tool bio-met, which was developed to assess compliance of metals under the WFD, will next be updated to reflect the updated approach for copper.

3.04.P-Th110 Nickel Water Quality Guideline Updates in Canada

Kelly E Croteau[1]*, Robert C. Santore*[1]*, Andrew Burton*[2] *and Ali Azizishirazi*[3]*, (1)Windward Environmental LLC, Seattle, United States, (2)Manitoba Environment and Climate Change, Canada, (3)British Columbia Ministry of Water, Land and Resource Stewardship, Canada*

The Canadian Council of Ministers of the Environment and British Columbia Ministry of Water, Land, and Resource Stewardship have developed new sets of nickel water quality guidelines for the protection of aquatic life in freshwater and marine environments over short-term and long-term exposures. These guidelines replace an old hardness-based guideline for long-term nickel exposure in freshwater that has been the only Canadian nickel guideline since 1987. The guideline updates allowed for the consideration of bioavailability effects and new toxicity data produced since the old guideline was created. Toxicity databases were updated to form species sensitivity distributions (SSDs) for each of the four guidelines, including 29 and 34 freshwater organisms for short-term and long-term SSDs, respectively, and 31 marine organisms in each the short-term and long-term SSDs. The normalized SSDs are fit with three probability distributions (lognormal, log-logistic, and gamma), and the model average is used to calculate a best-fit 5th-percentile value as the basis for the guidelines. The new freshwater guidelines use biotic ligand model (BLM) normalization, with software providing the official guideline values as well as a conservative estimate based on fewer chemistry inputs, and lookup tables providing easier access to estimated guideline values. Three organisms in the freshwater SSDs were seen to have substantially lower nickel effect concentrations at high pH, likely due to added toxicity from bicarbonate, which lead to the decision to use a separate set of model parameters for those organisms. The freshwater guideline values generally increase with higher dissolved organic carbon and hardness, and decrease slightly with higher pH, although the relationships are very non-linear. This is because the BLM is a chemical speciation model, and two different parameter sets are used within the SSDs. The marine guidelines are based on a simple log-linear equation with salinity as the only toxicity modifying factor. Therefore, the marine guideline values increase exponentially with linearly increasing salinity and can be calculated using a simple equation. These updates to Canadian guidelines come at a time when both the United States and Europe are working to update their own nickel water quality standards, and Canada can be used as an example of how another jurisdiction is using the same data and scientific advancements to address the same environmental problem.

3.04.P-Th111 The Impact of Climate Change on the Flux and Fate of Metals in Freshwaters: Implications for Metal Bioavailability Across Different Scales
Farhan R. Khan[1], *Nicolas Bury*[2], *Chris Cooper*[3], *David Boyle*[4], *Stijn Baken*[5], *and Simon Herzog*[6], *(1)NORCE, Norway, (2)Ocean and Earth Science, University of Southampton, ., United Kingdom, (3)International Zinc Association, United States, (4)Cobalt Institute, United Kingdom, (5)International Copper Association, United States, (6)Roskilde University, Denmark*
Climate change and chemical pollution are two of the gravest environmental concerns, and it is increasingly recognised that climate change and climate variability will alter the environmental distribution and toxicity of chemical pollutants, including in the aquatic environment. Trace metals are an established contaminant group where decades of research have been able to determine causal links between environmental concentrations, water chemistry and bioavailability, and accumulation and toxic effects. In freshwaters, these relationships have been parameterised into models for some metals, most notably Biotic Ligand Models (BLMs), that have utility to normalise toxicity values to site-specific water chemistry. The assumptions that such models are predicated upon need to be tested in increasingly climate variability. Here, we assert that to fully comprehend the impact of climate change on metal bioavailability in freshwaters, three distinct scales need to be understood: (1) the global scale of metal biogeochemical cycling which will alter metal inputs into freshwaters as climate change affects soil properties, hydrological connectivity, and metal mobility; (2) the environmental scale of fluctuating water chemistry parameters, such as dissolved organic carbon inputs, that will change free ion availability; and (3) the organismal scale at which climate change will push organisms outside of their tolerance window, inducing physiological modifications that alter the bioaccumulation and toxic effects of metal exposure. By understanding the impact of climate change on metals at each of these scales, and the connection between them, it is possible to further understand the future needs for metals regulation.

Disclaimer/Disclosure: This study is funded by the Metals Environmental Research Association (MERA).

3.04.P-Th112 Impact of Diatom-Produced Extracellular Polymeric Substances on Silver Nanoparticle Behavior in Freshwater
Rocco Gasco[1], *Isabelle Worms*[1], *Arin Kantarciyan*[1] *and Vera Slaveykova*[2], *(1)University of Geneva, Switzerland, (2)University of Geneva, Switzerland*
Silver nanoparticles (nAg) are widely used across multiple fields, and they can be released into freshwater. Once into aquatic environment, their fate can be shaped by various environmental factors. Among these, extracellular polymeric substances (EPS) produced by aquatic micro-organisms represent a significant but underexamined element in the fate of nAg. This study explores how EPS derived from the diatom Cyclotella meneghiniana interact with 20 nm citrate-coated nAg, influencing their colloidal stability, surface properties, and dissolution in freshwater condition. The research employed a combination of

techniques to analyze nAg behavior when exposed to EPS. Experiments were conducted over both short (0 2 hours) and long (up to 72 hours) term in a simulated synthetic freshwater medium. Additionally, different EPS concentrations were tested to evaluate potential concentration-dependent effects on nanoparticle behavior. EPS were rich in polysaccharides and proteins, which play a key role on nAg interaction. The EPS adsorbed onto the nAg surfaces, creating a stabilizing layer that enhanced colloidal stability by inducing steric repulsion. This eco-corona formation significantly reduced homo-aggregation processes which occurred in the absence of EPS due to effect of mono and divalent ions. Interestingly, EPS also promoted slight heteroaggregation processes, with higher EPS concentrations correlating with the formation of larger aggregates, probably through a bridging effect of adsorbed polysaccharides. EPS were shown to influence the dissolution of nAg by eco-corona. This eco-corona hindered the release of silver ions, which are the primary contributors to the toxicity of nAg. Transmission Electron Microscopy imaging confirmed the formation of this eco-corona, using negative staining with uranyl acetate to highlight the interaction between EPS and nAg. Both polysaccharides and proteins were involved in the hard corona formation, with proteins more strongly implicated in ecocorona formation as demonstrated by fluorescence quenching, which indicated hydrophobic interactions between EPS and nAg. In conclusion, EPS released by C. meneghiniana play a crucial role in determining the environmental fate of silver nanoparticles. By enhancing colloidal stability, mitigating homoaggregation, and reducing dissolution rates through ecocorona formation, EPS was showed to be able to influence the behavior and potential ecological impact of nAg in freshwater environments.

3.04.P-Th113 In Vitro Biotransformation of Silver Nanoparticles by Freshwater Phytoplankton

Arin Kantarciyan[1]*, Ines Segovia-Campos*[1]*, Tingting Fu*[2]*, Isabelle Worms*[1] *and Vera Slaveykova*[1]*,*
(1)Department F.-A. Forel for Environmental and Aquatic Sciences, Environmental biogeochemistry and ecotoxicology, University of Geneva, Switzerland, (2)Department of Quantum Matter Physics, Laboratory of Advanced Technology, University of Geneva, Switzerland

Silver nanoparticles (AgNPs) are widely used due to their strong biocidal properties, leading to their inevitable release into aquatic environments. Once introduced, AgNPs can persist in the water column for extended periods, with environmental factors influencing their stability and interactions with aquatic organisms. While considerable research has focused on the toxicological effects of AgNPs on aquatic biota, the mechanisms by which phytoplankton handle and transform AgNPs remain poorly understood. This research explores the biotransformation of AgNPs by two phytoplankton species: Cyclotella meneghiniana, a diatom, and *Chlamydomonas reinhardtii*, a green alga. Biotransformation is expected to occur once AgNPs cross the biological membranes. This study focuses on the dynamics of biotransformation, including surface properties induced by bio-corona formation, and nanoparticle dissolution, through in vitro experiments up to 24 hours. Bio-corona formation was investigated using asymmetric flow field-flow fractionation coupled with ICP-MS (AF4-FluoD-ICP-MS) and bio-transformed AgNPs were analyzed by time-of-flight secondary ion mass spectrometry (TOF-SIMS). The results revealed species-specific bio-corona formation, with larger hydrodynamic sizes and altered zeta potentials of bio-transformed AgNPs. The formation of the bio-corona was confirmed by AF4 coupled with ICP-MS, where a clear colocalization of proteins with nanoparticles was observed. Finally, TOF-SIMS analysis detected protein fragments as well as Agx(CN)y species, confirming the presence of surface-bound proteins and supporting the evidence of bio-corona formation.
Furthermore, significant increases in the dissolution of AgNP was observed in both organisms extracts following the bio-corona formation, suggesting that the adsorbed biomolecules may facilitate the oxidative dissolution of AgNPs. This biomodification could enhance AgNP toxicity, as dissolved silver ions (Ag+) are known to be the primary drivers of AgNP toxicity. On the other hand, this biomodification might reduce the transfer of AgNPs through the aquatic food chain.
Overall, this study underscores the critical role of freshwater phytoplankton in the handling and biotransformation of AgNPs, providing valuable insights into their fate in the aquatic environment and their potential impact on the aquatic ecosystem.

3.04.P-Th114 Tracing Microbiome Proteins in Ecocoronas: A Case Study for Titanium Dioxide Nanoparticles

***Bregje Brinkmann**[1], Zhiling Guo[2], Martina G. Vijver[1], Willie Peijnenburg[3] and Andrew Chetwynd[4], (1)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, Netherlands, (3)Institute of Environmental Sciences (CML), Leiden University; National Institute of Public Health and the Environment (RIVM), Center for Safety of Substances and Products, Netherlands, (4)Institute of Systems, Molecular and Integrative Biology, University of Liverpool, United Kingdom*

In any internal or external environment, metal nanoparticles sequester biomolecules from their immediate surroundings through chemi- and physisorption interactions. Collectively, these biomolecules form a transient face on the particle surface, termed the biocorona or ecocorona, dynamically shaping the interactions between nanoparticles and their surroundings. Due to the transient nature of these interactions, the origin of many ecocorona proteins is unknown. We hypothesized that microbiome proteins form an important source of biomolecules for the formation of ecocoronas, given the abundance of host-associated microbes, and their activity in many host-associated processes. We set out to test this experimentally for titanium dioxide nanoparticles (nTiO2), by incubating these particles in test medium that was pre-incubated with daphnid neonates (*Daphnia magna*) and zebrafish larvae (*Danio rerio*). I will present how we combined metagenomic and proteomic data to trace up to 192 daphnid proteins, 650 zebrafish proteins, and 1405 and 822 proteins of their respective microbiomes in the acquired ecocoronas. Our study revealed that microbiome proteins occupy a large proportion of the available binding spaces on the particle surface, and exhibit distinct physico-chemical properties from host proteins. Moreover, our study showed that the binding targets that have been reported for these proteins, differ between *D. magna* and *D. rerio* ecocoronas. The results of this study exemplify how microbiome proteins can alter the surface properties of metal nanoparticles, and reveal potential implications on particle stability, adsorption and binding interactions.

3.05 Developments, Challenges and Solutions in Chemical (Bio)Degradation and Persistence Assessment

3.05.T-01 Regulatory Challenges and Needs in Degradation Testing and Persistence Assessment of Difficult to Test Substances

***Kostas Andreou**[1], Romanas Cesnaitis[2], Jane Caley[1], Doris Hirmann[3], Anu Maarit Kapanen[1] and Vincent Bonnomet[1], (1)European Chemicals Agency (ECHA), Finland, (2)Telakkakatu 6, European Chemicals Agency (ECHA), Finland, (3)European Chemicals Agency (ECHA), Helsinki, Finland*

Persistence assessment is a crucial element within the context of hazard and risk assessments under many regulatory frameworks. Data from studies that simulate various environmental compartments such as surface and marine water as well as sediments and soils are preferred. In addition, screening level tests (ready and inherent biodegradability tests) can be also employed as part of the (bio)degradation assessment strategy. Assessing persistence of difficult to test substances can be challenging due to their properties (e.g., volatility, low solubility, ionisation, complex composition etc.). Testing guidelines have limited applicability for the biodegradation testing of such substances and this hampers regulatory decision-making. Thus, there is a pressing need to provide more guidance on how to improve the quality and relevance of the data produced via the standard test methods. So far, several attempts have been made to address the issues encountered during the degradation testing for such substances (Birch, H., et al., 2023; Cefic, 2022; ECHA, 2023a; ECHA, 2023b; UBA, 2023). Further modifications to the standard test methods are needed along with the development of new approaches and methodologies. Such approaches, amongst others, could focus on specific routes for introducing the test chemical into the test system, new reference substances, bechmarking, inoculum/biomass characterisation, developing robust analytical methods, the use on non-specific testing methodologies, optimisation of test system, e.g., trapping of volatiles, development of predictive models for addressing degradation and advancing the methods for the degradation assessment of UVCB substances. From a regulatory perspective, it is critical that these modifications should focus on improving the repeatability and applicability of the test system to meet the specific objectives of the assessment. Enhanced guidance and improved testing guidelines would benefit authorities and also drive innovation toward the creation of safer and sustainable chemical products. This presentation will provide an overview of the recommendations on the degradation testing and persistence assessment of difficult to test substances included in ECHA Guidance on IR&CSA (Chapters R7b and

R.11). It will outline still existing regulatory challenges in the persistence assessment of difficult to test substances, drawing on insights from past evaluations and recent scientific literature.

3.05.T-02 Building Knowledge from Available Degradation Simulation Studies to Improve Use in Regulatory Persistence Assessments

Louise Camenzuli[1]*, Mike Earl*[2]*, Katie Endersby*[3]*, Richard Gibson*[4]*, Patricia Anna Golombek*[5]*, Jasmin Hafner*[6]*, Damian Helbling*[7]*, Christopher B Hughes*[8]*, Aurelia Lapczynski*[9]*, Sven Peter*[10]*, David MV Saunders*[11]*, Chiara Maria Vitale*[12]*, Neil Wang*[13]*, Miriam Leon Paumen*[1]*, Philippe Lemaire*[14]*, Balint Tamasi*[15]*, Johannes Tolls Dir*[16]*, Lucy Wilmot*[17] *and Marie Collard*[18]*, (1)ExxonMobil Petroleum & Chemical BV, Belgium, (2)Syngenta Ltd.,Jealott s Hill, UK, United Kingdom, (3)School of Life Sciences, Unilever, Bedford, United Kingdom, (4)Environment Agency, United Kingdom, (5)BASF SE, Germany, (6)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (7)Cornell University, United States, (8)Embark Chemical Consulting, United Kingdom, (9)RIFM, United States, (10)BASF, Germany, (11)Shell Global Solutions, Netherlands, (12)Proctor & Gamble, Belgium, (13)Syensqo, France, (14)TotalEnergies, France, (15)dsm-firmenich, Switzerland, (16)Henkel AG & Co, Germany, (17)ECETOC, Belgium, (18)DSM-Firmenich, Belgium*

Approximately 400 higher tier persistence studies are reported in REACH dossiers (eChemPortal.org). The number of regulatory requests for such information are increasing. For example, in the period 2020-2023, over 300 simulation tests were requested through the REACH dossier evaluation (DEv) process. Higher tier persistence studies, namely the OECD test guidelines (TGs) 307, 308, and 309, are technically challenging for many chemicals, costly and lengthy to perform. It is imperative that they provide usable robust and reliable data. Substances that have challenging physical chemical properties add to the complexity of performing and interpreting generated data, which must be usable for both environmental exposure and persistence assessments across different regulations. In this context, a database has been developed to capture metadata from surface water degradation simulation studies (OECD TG 309). A total of 168 substances having reliable OECD TG 309 degradation simulation studies were identified. All relevant metadata for each study was collated in a database that was designed in line with the Persistence Assessment Tool. The range of reported degradation half-lives encompassed very low values (potentially due to abiotic processes such as hydrolysis) to very high values (potentially default half-lives where little to no degradation is observed during the study). Various statistical analyses are being conducted on this dataset, and half-lives are being compared with different predictor variables such as physico-chemical properties (e.g., water solubility, volatility), structural characteristics (Ecosar classes, Biowin fragments) or test system parameters (e.g., temperature, test volume). The database allows for detailed statistical analysis to provide an understanding of test system parameters or substance physicochemical properties that significantly influence study outcomes; and will aide in the interpretation of data. Further to this, it should identify whether current practices are relevant and accurate or if they need to be updated.

3.05.T-03 Does Benchmarking Increase the Accuracy of Predicting Biodegradation Across Aquatic Ecosystems?

Run Tian[1]*, Lily Weir*[2]*, Malte Posselt*[1]*, Kathrin Fenner*[3] *and Michael McLachlan*[1]*, (1)Department of Environmental Science (ACES), Stockholm University, Sweden, (2)Queensland Alliance for Environmental Health Sciences (QAEHS), The University of Queensland, Australia, (3)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Biodegradation is often the largest source of uncertainty in assessing chemical exposure. Previous studies have reported significant spatial and temporal variability in biodegradation rates, yet no environmental factors have been identified to mechanistically explain this variability. This study compiled a comprehensive dataset of 2265 biodegradation rate constants for 97 diverse chemicals from modified OECD 309 tests in 38 European and Australian aquatic ecosystems. We evaluated three approaches for reducing/describing spatiotemporal variability in rate constants: total microbial biomass normalization (TBN); universal benchmarking (UBM), i.e., normalizing all chemicals to a single benchmark chemical; and group-specific benchmarking (GBM), i.e., normalizing chemicals within each chemical group to a single benchmark chemical selected from that group. Neither TBN nor UBM reduced the variability, while GBM reduced the variability for 87% of compounds when grouping was based on clustering of spatiotemporal patterns of rate constants. However, GBMs based on chemical features (MACCS molecular fingerprints or predicted initial biotransformation rules) had negligible effects in reducing the variability. Three chemical groups that have high structural similarity showed considerable reduction in variability using both data-driven and chemical feature-based GBMs. We conclude that chemical grouping has the potential to predict biodegradation rates across ecosystems. However, for group-specific benchmarking to become a viable predictive tool, a deeper understanding of the key chemical features associated with biodegradability is essential.

3.05.T-04 Opportunities and Limitations of Data-Driven Models to Predict Environmental Persistence

***Jose Andres Cordero Solano**[1], Jasmin Hafner[2], Heinz Singer[3], Michael McLachlan[4] and Kathrin Fenner[2], (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), University of Zurich, Switzerland, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)Department of Environmental Science, Stockholm University, Stockholm, Sweden*

Innovative methods are essential for accurate and efficient chemical exposure assessment, especially given challenges like testing numerous substances and accounting for transformation products. Current structure-activity models often lack the accuracy needed. This study explores machine learning (ML) to address these limitations, focusing on predicting two environmental persistence drivers: biotransformation half-lives (DT50) in soil and breakthrough rates in wastewater treatment plants (WWTPs). These models fill gaps in traditional testing, supporting safe-and-sustainable-by-design (SSbD) approaches for rapid chemical evaluation.

DT50 data from enviPath and breakthrough data from 44 WWTPs across three countries were processed using PEPPER, a computational workflow developed by our group and presented for the first time in this work. Six molecular representations, including PaDEL, Mordred, and RDKit-based fingerprints, were combined with 12 ML algorithms ranging from linear models to advanced methods like Random Forest and Gaussian Process Regressor.

Results showed that Gaussian Process Regressor, Support Vector Regressor, and Random Forest performed best, though accuracy remains limited by experimental variability. RMSE for breakthrough predictions was ~0.7 log units, while DT50 predictions had RMSE of ~0.8 log units. Compared to existing tools like STPWIN of the EPI Suite, our models had significantly lower RMSE, demonstrating superior capability in capturing complex processes like micropollutant removal in WWTPs.

The study also highlights the importance of confidence metrics for prediction reliability. Unlike traditional definitions of the applicability domain, we propose confidence metrics based on prediction variability, This provides more nuanced, accurate, and trustworthy insights which we believe are essential for future users. We validated this metrics and demonstrated that significantly lower errors are achieved for the predictions with the highest confidence.

This work showcases the potential of machine learning to enhance environmental persistence assessments, addressing current tool limitations and providing novel tools for reliable chemical persistence and risk evaluation.

3.05.P-We209 Polymer Biodegradability and the Link Between Abiotic and Biotic Degradation

***Christian-Sebastiano Toppi**[1], Arnaud Martel[1], Guillaume Cottin[2], Alaa Bensetra[2], Elsa Paiva[2], Xavier Schultze[2], Samia Boudah[2], Fabienne Lagarde[1] and Cyril Sweetlove[2], (1)Le Mans University, France, (2)L'Oreal Research & Innovation, France*

Polymer persistence is a growing environmental concern, and current biodegradability tests are often designed for small molecules and may not adequately capture the complexities of polymer degradation. This study evaluates the impact of hydrothermal pre-treatment on polyester biodegradability using a novel assessment method combining pre-treatment and advanced physicochemical and chemical analyses in parallel to biodegradability testing, enabling the identification and monitoring of specific degradation products.

Polyhydroxybutyrate (PHB) and polylactic acid (PLA) served as model biodegradable and non-biodegradable polymers, respectively. Hydrothermal ageing (130°C) was performed for varying durations (1-120 hours). Following hydrothermal ageing, water-soluble degradation products were analyzed directly by Liquid Chromatography-High Resolution Mass Spectrometry (LC-HRMS) to characterize the initial breakdown products. Subsequently, OECD 301F biodegradability tests were conducted on pristine and aged PHB and PLA particles, extracted water-soluble oligomers, and the corresponding monomers. To analyze the degradation products formed during these biodegradability tests, Solid Phase Extraction (SPE) cartridges were employed for efficient extraction from the complex biodegradability medium before LC-HRMS analysis.

The analysis confirmed the presence of PHB oligomers of up to 5 repetition units in hydrothermally aged samples. These same oligomers were identified at a strategically chosen 5th day of the biodegradation test. Hydrothermally aged PHB showed enhanced biodegradability (shorter lag phase, faster 60% threshold achievement), while PLA remained non-biodegradable. The contrasting responses of PHB and PLA suggest a possible correlation between the extent of hydrothermal degradation and biodegradability. This finding indicates a potential rapid screening test methodology for polyesters, which will be further investigated with additional biodegradable polymers upon solubilization/improved bioavailability such as polycaprolactone (PCL). This improved assessment approach advances our understanding of polymer environmental fate.

3.05.P-We210 Identifying Bound Compounds in Non-Extractable Residues of Pesticides in Soil by 4-Pool Kinetic Analysis

*Xiao (Michael) Huang[1], Kari Lynn[1], Steven Cryer[1], Christiaan Wijntjes[1] and **Hazel Walshaw**[2], (1)Corteva Agriscience, United States, (2)Corteva Agriscience*

Non-extractable residues (NERs) of pesticide in soil are one of the major uncertainties in pesticide risk assessment and persistence evaluation for PBT and PMT classification, because of their unknown chemical identifies. This study explores the feasibility of identifying bound compounds in non-extractable residues (NERs) of pesticides in soil by 4-pool kinetic analysis. The 4-pools refer to parent compound, metabolites, NERs, and CO2 in 14C-labeled pesticide soil degradation studies. We discovered the following two characteristic 4-pool kinetic behaviors of formation of NERs: (1) if parent compound is bound as NERs, the metabolites (m(t) in % applied radioactivity (AR)) kinetically drive the evolution of CO2 only; and (2) if a metabolite (x) in a sequential degradation pathway is bound as NERs, m(t) is split into m1(t) and m2(t) at the metabolite (x) that is bound as NERs, which kinetically drive the formation of NERs and evolution of CO2 respectively. We developed two (i.e., Parent->NER and metabolite->NER) 4-pool models to capture the kinetic behaviors respectively. By fitting the models to a set of 4-pool data, we not only determine whether NERs form from parent compound or metabolites but also identify the bound metabolite (x) by resolving the metabolites into M1(t) and M2(t) (i.e., the variables used to simulate m1(t) and m2(t)) and then matching m1(t) (i.e., the sum of bound metabolite (x) and its metabolite precursors) with M1(t). By applying the models to 14C-labeled parent compound-dosed studies and then sequentially to metabolite-dosed studies for 7 pesticides with ? 70% AR NERs, we identified the bound compounds, which have the moieties known to be responsible for NERs, are bound as NERs instantaneously when dosed into soil, and account for pH dependency of NER formation. This study demonstrated that we could identify the bound chemical species in NERs of pesticides, assess the risk/hazards of NERs at a molecular level, and thereby eliminate the uncertainties in pesticide risk and persistence assessments.

3.05.P-We219 Probabilities to Prioritize Potential Persistent Pollutants

***Sivani Baskaran**, Raoul Wolf and Hans Peter H. Arp, Norwegian Geotechnical Institute (NGI), Norway*

Chemical hazard and risk assessments often use physical-chemical properties to categorize and identify chemicals of concern. In Europe, recent legislation regarding the classification, labelling and packaging (CLP) of consumer products includes new chemical hazard categories, including persistent, mobile, and toxic (PMT) and very persistent and very mobile (vPvM). Persistency is currently assessed using ready biodegradability data and half-lives of the substance in different systems. This is additionally challenging because of the limited availability of data and information in the environment. We combine available datasets available in literature, data from OECD s eChemPortal and QSAR Toolbox and predict ready biodegradability and degradation half-lives using QSAR models such as OPERA and EPI Suite. We combine data, including availability of uncertainty data and errors, and the relative reliability of the source of data using Bayesian analysis methodologies.

In this work we assess the potential persistence of substances from the ZeroPM Global Chemical Inventory, which includes approximately 119,000 SMILES that represent 93,000 substances. We predict the probability that a substance is not persistent, persistent, or very persistent based on the available data. This data can be used as part of a weight of evidence approach when the probability of any one category is very high or to identify substances where further experimental testing and reporting is required because the probability of a substance being not persistent is near 50% and thus the results are inconclusive. We also explore the entire dataset and the cumulative probability scores, to understand how many of the chemicals registered on the global market may be considered potentially persistent or not persistent.

Disclaimer/Disclosure: This work is part of the project "ZeroPM: Zero pollution of persistent, mobile substances" which has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No 101036756.

3.05.P Developments, Challenges and Solutions in Chemical (Bio)Degradation and Persistence Assessment

3.05.P-We195 Paving the Path for A Revision of the OECD Tests on Ready Biodegradability by A Round Robin Test

Ulrich Johncke[1], *Daniel Sattler*[1], *Andrea Brunswik-Titze*[2] *and Stefan Gartiser*[2], *(1)German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)Hydrotox GmbH, Germany*

Standardised test systems offer constant test conditions as well as the possibility of generating comparable and reproducible test results. The tests of the OECD 301 series and the OECD 310 test are standardised and equally valid as screening tests on ready biodegradability. However, though standardised and the procedure used being similar, they differ from each other in important aspects. On the one hand the reason is historical: the majority were developed in the 1980s in various OECD member states, mostly independently of each other. On the other hand, their test conditions represent the technical possibilities of the time. Even the revisions of the test guidelines in 1992 did not fundamentally change the co-existence of the different variants.

All screening tests on ready biodegradability have a relatively simple test design and are inexpensive compared to simulation tests. They thus represent the first information layer on biodegradation which is important because further assessment procedure depends on the data generated here. However, observed differing and sometimes contradicting results between the different test systems is criticised. With the further development of analytical technology since 1992, but also through the preferential use of individual test systems, it should be possible to completely dispense with test systems that are now rarely used and to better standardise and adapt the framework conditions of the remaining test procedures to each other. This would also make sense as it would improve the comparability of test results between different substances.

The aim of this project is to generate data for a subsequent revision of the OECD tests for ready biodegradability. A proposal for a consolidated test design is developed and put to the test. To this end, the contractor is carrying out an international round robin test. At least ten GLP-qualified laboratories should participate and test three substances. In the course of the project, it is planned to present and discuss the results in an international workshop. The project started in September 2024.

3.05.P-We196 Consolidation of OECD Tests for Ready Biodegradability on the Example of OECD 310

Andrea Brunswik-Titze *and Stefan Gartiser, Hydrotox GmbH, Germany*

Standardized test systems ensure constant test conditions and facilitate generating comparable and reproducible test results. The OECD 301 A-F/ OECD 310 series for testing ready biodegradability are considered equally valid. The tests are routinely used both for the investigation of ready biodegradability and for the identification of non-persistent substances within the PBT-assessment. However, the guidelines have not been revised for quite some time. The last substantial revision was in 1992 for OECD 301 A-F and in 2006 for OECD 310. Revising, updating and consolidation of the current guidelines is therefore a recurring topic of discussion.

Among the different ready type tests the OECD 310 represents a broad range of boundary testing conditions: The allowed test concentration range is from 2-40 mg/L TOC (20 mg/L TOC preferred), The allowed inoculum sources are activated sludge (4-30 mg d.s./L 4 mg/L d.s. preferred), secondary effluent (up to 100 mL/L), surface water and soil. Among the points which require further clarification are:

• The inoculum concentration should result in 10^2 to 10^5 CFU/mL in the final mixture (colony-forming units), but there is no indication of the method for determining the CFU. Due to the inhomogeneous and flocculent structure of the activated sludge, CFU determination is critical.

• One validity criterium refers to the inorganic carbon allowed in the inoculum blank control which must be < 3 mg C/L at the end of the test. This criterium is only achievable when the standard concentration of 4 mg/L d.s. activated sludge is applied. The validity criterium should reflect both the test concentration and the inoculum concentration.

• The incubation temperature of the OECD 310 is 20°C ± 1°C, which is different from the incubation temperature of the OECD 301 tests (22°C ± 2°C)

Own experiences with different testing conditions reflecting the liquid/headspace ratio and the substrate/inoculum ratio are being presented. The OECD 310 provides an appropriate and variable test system allowing biodegradability testing under both ready and inherent type conditions. The version under inherent test conditions resembles the inherent test proposed by CONCAWE in 1999 (draft OECD 302D) for lubricants, but applies standard inoculum without the option to use preadapted inoculum sources which has been pre-exposed to the test substance.

3.05.P-We197 Ready Biodegradability Studies: OECD 301 or 310?

Victoria Pratt, *Fera Science Ltd, United Kingdom*

Ready biodegradability experiments are laboratory tests designed to evaluate the potential of a chemical to

undergo rapid and complete degradation by microorganisms under aerobic conditions. These tests simulate natural aquatic environments, measuring the conversion of organic carbon into CO_2, water, and biomass. They provide an early indicator of a chemical's environmental persistence and its likelihood of bioaccumulating or causing long-term harm to ecosystems.
OECD 301F and 310 are two of the internationally accepted protocols for conducting ready biodegradability experiments. While the OECD 301F study design measures the amount of oxygen consumed by microorganisms during the degradation of the test substance to calculate degradation, the OECD 310 study measures the amount of CO_2 produced.
Under the European Union s REACH (Registration, Evaluation, Authorisation, and Restriction of Chemicals) regulation, enhancements to standard biodegradability tests like OECD 301F and OECD 310 are sometimes implemented to address specific regulatory or scientific needs. These enhancements are designed to provide more environmentally realistic data or better assess challenging substances. Key modifications include larger test vessels and extended test durations.
The ready biodegradability of a compound of interest has been determined using both OECD 301F and 310 methods, with additional enhancements such of increased test vessel size and extended test duration also trialed. The results have been used to conclude compare the assessment of ready biodegradability across these two protocols, and therefore consider how interchangeably they can be used for environmental risk assessment.

3.05.P-We198 Improved Reliability of Ready Biodegradability Assessment by Omitting Ammonium Chloride from the OECD 301D Test

***Roy Geerts**[1], Pieter Blom[1], Jhonatan Alejandro Hernandez Valdes[1], Marc Geurts[1], Liesa-Kristin Beuter[2], Jens Bietz[3] and Ivana Dierdorf[3], (1)Nouryon, Netherlands, (2)Nouryon, Sweden, (3)Clariant, Germany*
The Closed Bottle test (OECD 301D) is a unique test in the OECD 301 series of ready biodegradation tests (RBTs). The low-test substance concentration used in Closed Bottle tests compared to other RBTs makes this test suitable for testing substances that are toxic to the inoculum (Gartiser et al, 2017). The Closed Bottle test is however infrequently performed due to its low potency for demonstrating biodegradability (Gartiser et al, 2023).
In RBT media, ammonium chloride is added to provide nitrogen as a macronutrient for the growth of microorganisms that degrade the test substance (OECD, 1992). Ammonium nitrogen that is not needed for growth will be oxidized to nitrate by nitrifying microorganisms, which are not involved in the actual biodegradation of the test substance. Nitrification is known to increase the probability of obtaining erroneous biodegradability data in OECD 301D tests (Richterich and Steber, 1989; Gartiser, et al, 2023). In addition, nitrification in the Closed Bottle test will increase the background respiration. The background respiration is measured in the inoculum blank bottles and is used as a validity criterion to ensure the accuracy of the test. Compared to other RBTs, the contribution of the nitrification to the maximum allowed background respiration is the highest in the OECD 301D test.
In our research, we performed OECD 301D tests with and without the prescribed addition of ammonium chloride to the test medium. The biodegradability of various test substances with and without organic nitrogen was evaluated, including some difficult to test substances (toxic to the inoculum). River water and activated sludge were used as inocula. At the end of the tests, nitrate and nitrite analyses were performed to correct the biodegradation for the nitrification.
Our research clearly demonstrates that ammonium chloride can be omitted from the OECD 301D test medium without creating a nitrogen deficiency for microbial growth and without decreasing the stringency of the test. The addition of ammonium chloride in the OECD 301D test only increases the chance of exceeding the background respiration, complicates interpretation, and increases the chance of erroneous results.
In conclusion, the reliability of the biodegradability assessment in the OECD 301D test is improved by omitting the ammonium chloride from the mineral salts medium. This modification should be included in future updates of the OECD 301D test guideline.

3.05.P-We199 Correlation of Results from Biodegradation Screening Studies with Physical Properties of the Test Substances

***Michael Essers**[1] and Ulrich Johncke[2], (1)LANXESS Deutschland GmbH, Köln, Germany, (2)German Environment Agency (UBA), Dessau-Rosslau, Germany*
This work is based on the hypothesis that results obtained from biodegradability screening studies correlate with the intrinsic physical substance properties water solubility and octanol-water partition coefficient (log Kow). Poor water solubility, high log Kow or volatility of the test substances may thwart reaching the pass level in a ready biodegradability test, while with higher solubility or lower log Kow, a higher proportion of readily degradable substances could statistically be expected. Accordingly, the

objective of this work is the statistical evaluation and assessment of such correlations.
As a source of information, the data base OECD eChemPortal was used. The datasets per endpoint as retrieved were filtered regarding several qualitative and quantitative criteria. Further subsets of above basic datasets were formed.
The statistical analysis of the datasets applying Spearman s rank correlation confirmed the initial hypothesis for biodegradation results and water solubility (?/?c = 2.41 for basic dataset, 0.07 to 4.78 for subsets) as well as for the correlation with log Kow (?/?c = -1.93 for basic dataset, 0.55 to -1.71 for subsets).
This implies that substances exhibiting poor bioavailability have a lower chance of being classified as readily biodegradable or reaching the pass level. In consequence, a substance failing the test is potentially persistent and the next level of testing, e.g., simulation testing, should be considered, or the test result is a false-negative one owing to poor bioavailability.
From the datasets investigated, the most suitable guidelines for biodegradation of poorly soluble and adsorbing substances were derived.
The results obtained suggest that it is worthwhile to aim for avoiding over-conservative or false-negative results from biodegradability screening tests by a well-devised study design, i.e., choosing the test guideline offering the best conditions for poorly soluble and/or adsorbing substances in practice, applying bioavailability improvement methods, and/or using enhancements.

3.05.P-We200 Biodegradability Screening (OECD 301: Test of Ready-Biodegradability) of Several Poorly Water-Soluble Substances

David M. V. Saunders[1]*, Alberto Martin*[2]*, Neil Wang*[3]*, Louise Camenzuli*[4] *and Delina Lyon*[5]*, (1)Shell Global Solutions, Netherlands, (2)Penman Consulting BVBA, Belgium, (3)Syensqo, France, (4)ExxonMobil Petroleum & Chemical BV, Belgium, (5)CONCAWE, ., Belgium*
Biodegradation is an important environmental process that transforms chemicals into simpler compounds and can lead to mineralization or incorporation into biomass of microorganisms. This process is essential for mitigating potential impacts of chemical pollution and supporting sustainable practices. The assessment of biodegradation under the EU REACH (Registration, Evaluation, Authorization and Restriction of Chemicals) regulation typically begins with a stringent screening test for ready biodegradability, using the OECD 301 test guidelines. These tests screen for the potential for rapid mineralisation of substances across various environmental compartments including water, soil, and sediment. However, as the OECD 301 test is an aquatic system, poorly soluble chemicals may be difficult to dose into the water phase, which can lead to misleading results regarding the chemical s inherent biodegradability. The biodegradation of poorly soluble substances is likely hindered due to their limited bioavailability to microorganisms in the aquatic media, as high test concentrations are required (in general, 3-100 mg/L).
There are several bioavailability improvement methods that can increase the chemical-microorganism interaction, such as using solvents and solid substrates, listed in the ISO guideline ISO 10634. In this study we tested seven poorly water-soluble substances to understand their biodegradability in the OECD 301F test using five different bioavailability improvements: specifically ultrasonic dispersion, adsorption onto silica gel, silicone oil and heating with direct addition. Additional guidance from ISO 10634 and the ECHA endpoint specific guidance document Chapter R.7b (Version 4, 2017), led to the inclusion of five additional control groups for poorly soluble substances. This project showed that several of the poorly soluble substances were readily biodegradable (>60% mineralization in 28 days) when appropriate bioavailability improvements were used compared to direct addition. It was also observed that efficacies of bioavailability improvements can differ even for substances with similar structures. Results from this study highlight several issues in biodegradation testing of insoluble substances such as the choice of appropriate bioavailability improvement, the number and performance of control groups required under regulatory guidance, and the most appropriate strategies moving forward.

3.05.P-We201 Improved Interpretation of Ready Biodegradability Tests for Tire-Derived Chemicals: Insights into Microbial Community Structure and Biodegradation Profiles

Göksu Celik[1]*, Claire Lamb*[2]*, Camille van den Langenberg*[1]*, Alexander Loy*[2] *and Thilo Hofmann*[1]*, (1)University of Vienna, Centre for Microbiology and Environmental Systems Science, Division of Environmental Geosciences, Austria, (2)University of Vienna, Centre for Microbiology and Environmental Systems Science, Division of Microbial Ecology, Austria*
Tires are a significant source of environmental contaminants, releasing complex chemical mixtures into ecosystems via physical abrasion and chemical leaching. Despite their widespread presence across environmental matrices, including freshwater and wastewater treatment plants (WWTPs), the environmental fate and persistence of tire-derived chemicals remain poorly understood. Ready

biodegradability tests (RBTs) serve as critical screening tools to evaluate whether these chemicals are rapidly removed or potentially persistent in the environment. However, RBTs often exhibit high variability across replicates, test conditions, and facilities, which is in parts influenced by the microbiota in the environmental inoculum. The presence, abundance, and activity of microorganisms with biodegradation potential can affect both lag phases and biodegradation kinetics. The environmental microbial community involved in these tests often remain as a black box, despite its central role in biodegradation outcomes. This study aims to enhance the interpretation of RBTs by investigating the biodegradability of 11 representative tire-derived chemicals, including 6PPD, diphenylguanidine, benzothiazoles, and benzotriazoles, while simultaneously characterizing microbial community composition via 16S rRNA gene amplicon sequencing. Key variables explored include (1) test concentration, (2) inoculum source (freshwater and WWTP), (3) inoculum toxicity, and (4) structure-biodegradability relationships. Initial findings revealed that none of the tire chemicals tested were readily biodegradable; however, five were classified as ultimately or inherently biodegradable. Notably, the widely used and highly toxic antioxidant 6PPD demonstrated mineralization in some replicates at high exposure levels (15 mg/L). In contrast, no biodegradation was observed for benzothiazole, hydroxybenzothiazole, and mercaptobenzothiazole at similar concentrations, but reducing the concentration fourfold shortened lag phases and increased biodegradation rates. Our results underline the importance of microbial community monitoring in understanding biodegradation profiles of tire-derived chemicals. These insights are critical to advancing the information output of RBTs and supporting environmental risk assessments of tire-related contaminants.

3.05.P-We202 Overcoming Challenges and Advancing (Bio)degradation Guidelines: OECD TG 309 Revisited

Louise Camenzuli[1], *Megan D'Souza*[2], *Dieter Hennecke*[3], *Christopher B. Hughes*[4], *Delina Lyon*[5], *Michael McLachlan*[6], *Amelie Ott*[7], *Katherine Santizo*[8], *Christian Schlechtriem*[9] *and Blanca Serrano*[2], *(1)ExxonMobil Petroleum & Chemical, Belgium, (2)ECETOC, Belgium, (3)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Embark Chemical Consulting, Belgium, (5)CONCAWE, ., Belgium, (6)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (7)ICCS, Belgium, (8)Cefic, Belgium, (9)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

In Europe, if a chemical is non-readily biodegradable, and is manufactured or imported in quantities of 100 tonnes or more, biodegradation simulation testing is required under the REACH regulation. Simulation testing may also be requested for lower tonnage substances, if a concern for PBT/vPvB properties has been flagged. The OECD 309 Test Guideline (Aerobic Mineralisation in Surface Water), which was last updated in April 2004, hence plays a pivotal role in assessing the environmental fate of chemicals globally. Over the last 20 years, the state of science has evolved, and updates to the OECD 309 Test Guideline are anticipated. ECETOC organized a 2-day workshop in January in Brussels, bringing together participants from regulatory bodies, academia, industry and environmental non-governmental organisations (NGO), having expertise in biodegradation testing and persistence assessment. The objectives of the workshop included to (1) discuss and address current challenges and limitations in conducting and interpreting degradation simulation studies, (2) define/align on the key updates needed for the OECD 309 test guideline, (3) define a roadmap to ensure that the prioritised updates flagged would be addressed in time for the OECD 309 test guideline update, and (4) identify research needs and potential methodological advancements to improve the guideline's relevance and applicability, with possible implementation in other test guidelines. This was coordinated in multiple break out discussions focussing on robustness, interpretation and relevance. The outcomes of the workshop presented in this poster highlight further research needs that the community can address to improve biodegradation and persistence assessment.

3.05.P-We203 Results of Ring Testing for the Selection Reference Substances for Improving Chemical Persistence Assessment in Higher Tier OECD 309 Simulation Test

Kate Schofield[1], *Christopher B. Hughes*[1], *Dirk Scheerbaum*[2], *Christian Maess*[3], *David Brown*[1], ***Megan Griffiths***[1] *and Sigrid Hakvaag*[4], *(1)Ricardo, United Kingdom, (2)Noack Laboratorien GmbH, Germany, (3)NOACK Laboratorien GmbH, Germany, (4)Sintef Ocean, Norway*

The OECD 309 test guideline is a crucial tool for assessing the biodegradation and persistence of organic contaminants in surface water. However, variability in test parameters and inoculum characteristics can lead to inconsistencies in observed degradation kinetics. The inclusion of substances with varying

biodegradation profiles will provide a more comprehensive benchmark for assessing inoculum activity and overall test performance.
A ring trial has been performed, focusing on two selected candidate reference substances: caffeine and 2,4-D. These substances were chosen from an initial pool of 32 candidates, which was narrowed down to eight based on relevant properties, and availability of radiolabelled forms of the compounds. Further screening using a modified OECD 301D study led to the final selection of caffeine and 2,4-D, alongside the existing reference substance aniline. Caffeine, known for its ready biodegradability with a lag phase, and 2,4-D, characterized by slow or incomplete biodegradation, were subjected to rigorous simulation testing. The tests were conducted under various conditions, including two temperatures (12°C and 20°C), two concentrations (1 and 10 µg/L), and using inoculum from two water sampling locations. This comprehensive approach aimed to capture each substance's biodegradation profiles and assess their performance under diverse environmental conditions.
The interlaboratory ring trial aimed to assess the suitability of the selected candidate reference substances and to evaluate test validity across different laboratories. Nine laboratories from different parts of Europe participated in the test. Involving multiple laboratories enabled the assessment of reproducibility and consistency of OECD 309 test results when using the proposed new reference substances. This collaborative effort sought to enhance the reliability of OECD 309 testing by providing a more comprehensive benchmark for assessing inoculum activity and overall test performance. The inclusion of substances with varying biodegradation profiles aimed to capture a broader range of degradation behaviours, potentially improving the test's ability to assess the persistence of diverse organic contaminants.
By conducting this extensive interlaboratory study, the project has aimed to strengthen the foundation of OECD 309 testing, ultimately supporting more accurate and consistent persistence assessments for regulatory purposes in environmental risk evaluations.

3.05.P-We204 OECD 309-Aerobic Mineralisation in Surface Water-Results from a Laboratory Participating in the CEFIC-LRI ECO55 Ring Trial

*Avril Crowe[1], Sarah Button[1], Adele Jones[1], Victoria Remnant[1], Simon Tate[1], Nitesh Panchal[2], **Robert Unsworth**[1] and Stephen Brewin[1], (1)Labcorp, United Kingdom, (2)Metabolism, Labcorp, United Kingdom*

The OECD 309 guideline is the aerobic mineralisation in surface water simulation biodegradation test. The purpose of the test is to assess the biodegradation and mineralisation of test items in natural water at low concentrations. These studies are usually conducted with radiolabeled test items at test concentrations between 1 and 100 µg/L. The use of radiolabeled test item allows primary degradation and mineralisation to be assessed and mass balances to be measured. The identity of primary degradates can also be investigated.
As part of the test a reference substance is used to ensure that the natural water contains an active microbial population. Historically either aniline or sodium benzoate have been used and it is expected that they will be substantially degraded within two weeks.

Under the European Chemicals Agency s (ECHA) regulations for the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH), the OECD 309 test has become the favoured test to assess persistence in the environment for industrial chemicals at 12°C (freshwater).
It is considered that aniline and sodium benzoate do not provide a sufficiently robust assessment of the viability of the natural water as they are too easily mineralised to carbon dioxide. Therefore, as part of the CEFIC LRI funded project, ECO55, investigating the parameters around the OECD 309 test, the use of alternative reference substances was proposed. The alternative reference substances investigated in this interlaboratory ring trial are caffeine and 2,4-dichlorophenoxyacetic acid.
The objective of the ring trial is to identify a reference substance which will better assess the viability of the test water and therefore lead to an improved assessment of persistence. The overall aim of the project is to update the guideline to provide a more consistent and robust measure of persistence for chemicals in the environment.
The poster will present the data generated in tests conducted, using each of the reference substances, in our laboratory and compare the results we obtained to those for aniline and sodium benzoate.

3.05.P-We205 Investigation into Reference Substance Degradation Rates in OECD 309 Tests

***Desmond Kelly** and Daniel T Evans, Smithers ERS, United Kingdom*

Simulation tests performed using a radiolabelled molecule are important in determining the primary and ultimate degradation of a chemical and evaluating its potential to persist in the environment. The surface water mineralisation test performed according to OECD test guideline 309 incorporates a reference substance as a positive control to demonstrate that the water contains an active microbial population. The

test guideline suggests aniline or sodium benzoate as the reference substance and that the expected time interval for degradation is usually less than two weeks.
The current work was undertaken to understand the expected rate of degradation of these reference substances when incubated under varying conditions. Surface water with suspended solids in the range 10 20 mg dry weight/L was freshly collected and treated with 14C-aniline or 14C-sodium benzoate at a rate of 10 µg/L. The treated samples were then incubated under aerobic conditions at 12 and 20°C, and the rate of mineralisation to 14CO2 was monitored at regular intervals throughout the incubation period. Further investigations were performed using surface water from different sources. In addition the impact of different amounts of suspended solids was assessed.
The results of the work are discussed in this presentation.

3.05.P-We206 Will Carbon Capture Plants Contaminate Drinking Water? Biodegradation Potential of Nitramines in Lake Water

***Aina Charlotte Wennberg**[1], Cathrine Brecke Gundersen[1], Alexander Eiler[2], Merete Grung[1] and Malcolm Reid[1], (1)Norwegian Institute for Water Research (NIVA), Norway, (2)University of Oslo, Faculty of Mathematics and Natural Sciences, Norway*

There is a potential risk associated with (potentially) carcinogenic nitrosamines (NSAs) and nitramines (NAs) that can form in the air from amines escaping amine-based carbon capture plants (CCP). These are very soluble molecules that can end up in drinking water sources such as lakes and groundwater basins. In Norway, a drinking water threshold of 4 ng/L has been set for the sum of NSAs and NAs. A dynamic modelling tool is under development to guide the industry and regulators to ensure that the safety limit will not be exceeded. In the model, the major removal mechanism for NSAs is photodegradation, while biodegradation is the dominant removal mechanisms for NAs. Thus, reliable biodegradation rates for NAs are needed to realistically simulate future levels in the water compartment.
A modified OECD 309 simulation test for biodegradation in surface water was used to assess biodegradation rates of three representative nitramines. Caffein was used as positive reference control. The study site was a drinking water lake located in the vicinity of a planned CO2 capture plant. Water and sediment were collected at different seasons, and the tests were performed with and without added sediment. The three nitramines were added either separately or together to the test bottles, and primary degradation was measured by LC-MS/MS compared to the abiotic control. The biodegradation rates varied between experiments. However, the difference in degradation rates was consistent with (monoethanol)-nitramine (MEA) being the most rapidly degradable, 2-methyl-2-(nitramine)-1-propanol (AMP) being moderately degradable and N-nitropiperazine (NIPZ) having limited degradation after 60 days. Adding sediment to the surface water increased biodegradation rates. The effect of different modifications of the test set up (with/without sediment and single vs mixture of test substance) will be presented and discussed.

Disclaimer/Disclosure: This work was funded by The Research Council of Norway grant number 342612 and 336357.

3.05.P-We207 The Influence of Spike Timing and Inoculum Stability on the Biodegradation of Organic Compounds in a Water-Sediment Test System

***Joeselle Serrana**[1], Kozo Watanabe[2] and Malte Posselt[3], (1)Stockholm University Center for Circular and Sustainable Systems (SUCCeSS), Stockholm University, Sweden, (2)Ehime University, Japan, (3)Department of Environmental Science, Stockholm University, Sweden*

The OECD 309 test is a widely accepted method for determining the biodegradation rates of organic substances utilizing batch incubations with pelagic or suspended sediments. While it is a highly recommended biodegradation test, it faces challenges from inconsistencies and variable results, which require further investigation. Also, our understanding of the inoculum, specifically the microbial community dynamics in environmental samples during simulated tests, remains limited. This includes evaluating microbial stability and examining critical aspects of batch incubation experiments, e.g., test compound spiking, which may influence microbial diversity and community composition. In particular, the period between contaminant spiking can influence whether microbial communities acclimate to the contaminant, potentially increasing the degradation rate in subsequent exposures. Spike timing refers to the point at which test substances (i.e., contaminant mixtures) are introduced to the test system, and it is crucial as it determines the inoculum's exposure to the substance, influencing the observed biodegradation rates. These insights could be instrumental in advancing the standardization of simulated biodegradation testing. Here, we profiled the diversity and composition of the batch incubation microbiome at different spiking times and linked this to the biodegradation capacity of the inoculum against 129 test compounds. In particular, we sampled a wastewater-impacted river segment, followed the OECD 309 test guidelines for sediment-water collection and preparation, and spiked the samples at different time points, i.e., 0 hr, after 24 hrs, 2 days, and 3 days. We used 16S rRNA amplicon sequencing to profile the microbial communities' taxonomic and putative functional information. Our observations will be useful in improving our knowledge of the microbial community dynamics in biodegradation tests. This will also provide insights into the environmental relevance of sediment microbiome samples used for standard simulation tests.

3.05.P-We208 Challenges and Successes in Radiolabeling and Characterizing Polymers for Environmental Simulation Studies

*Jennifer Menzies[1], Ashley Wilcox[1], Maura Hall[1], Nigel Yates[1] and **Kathleen McDonough**[2], (1)Procter & Gamble, United States, (2)Procter & Gamble, Mason, United States*

The ability to quantify the rate and extent of chemical biodegradation using laboratory simulation studies that mimic real world conditions is important for an accurate evaluation of environmental fate. Simulating environmental conditions requires tests to be conducted in complex environmental matrices under realistic test concentrations which makes analytical sensitivity a challenge. Radiolabeled test materials are a well-accepted solution. Synthesis of radiolabeled polymers and analytical characterization of the parent and degradation metabolites provide new technical challenges as the methods traditionally employed for small molecules are not all applicable to polymers due to their typically higher molecular weight and complex multi-component structures. In this poster we will discuss a variety of isotopes (3H, 14C) and synthesis methods (specific, general, and uniform) currently employed to generate radiolabeled polymers. Further, analytical approaches (thin layer chromatography, gel permeation chromatography, nuclear magnetic resonance, and molecular weight cut off filters) used for the characterization of radiolabeled polymers and metabolites will be discussed. The data presented will support the assertion that both biobased and synthetic polymers can be radiolabeled and characterized while highlighting technical watch outs and challenges.

3.05.P-We209 Polymer Biodegradability and the Link Between Abiotic and Biotic Degradation

***Christian-Sebastiano Toppi**[1], Arnaud Martel[1], Guillaume Cottin[2], Alaa Bensetra[2], Elsa Paiva[2], Xavier Schultze[2], Samia Boudah[2], Fabienne Lagarde[1] and Cyril Sweetlove[2], (1)Le Mans University, France, (2)L'Oreal Research & Innovation, France*

Polymer persistence is a growing environmental concern, and current biodegradability tests are often designed for small molecules and may not adequately capture the complexities of polymer degradation. This study evaluates the impact of hydrothermal pre-treatment on polyester biodegradability using a novel assessment method combining pre-treatment and advanced physicochemical and chemical analyses in parallel to biodegradability testing, enabling the identification and monitoring of specific degradation products.

Polyhydroxybutyrate (PHB) and polylactic acid (PLA) served as model biodegradable and non-biodegradable polymers, respectively. Hydrothermal ageing (130°C) was performed for varying durations (1-120 hours). Following hydrothermal ageing, water-soluble degradation products were analyzed directly by Liquid Chromatography-High Resolution Mass Spectrometry (LC-HRMS) to characterize the initial breakdown products. Subsequently, OECD 301F biodegradability tests were conducted on pristine and aged PHB and PLA particles, extracted water-soluble oligomers, and the corresponding monomers. To analyze the degradation products formed during these biodegradability tests, Solid Phase Extraction (SPE) cartridges were employed for efficient extraction from the complex biodegradability medium before LC-HRMS analysis.

The analysis confirmed the presence of PHB oligomers of up to 5 repetition units in hydrothermally aged samples. These same oligomers were identified at a strategically chosen 5th day of the biodegradation test. Hydrothermally aged PHB showed enhanced biodegradability (shorter lag phase, faster 60% threshold achievement), while PLA remained non-biodegradable. The contrasting responses of PHB and PLA suggest a possible correlation between the extent of hydrothermal degradation and biodegradability. This finding indicates a potential rapid screening test methodology for polyesters, which will be further investigated with additional biodegradable polymers upon solubilization/improved bioavailability such as polycaprolactone (PCL). This improved assessment approach advances our understanding of polymer environmental fate.

3.05.P-We210 Identifying Bound Compounds in Non-Extractable Residues of Pesticides in Soil by 4-Pool Kinetic Analysis

*Xiao (Michael) Huang[1], Kari Lynn[1], Steven Cryer[1], Christiaan Wijntjes[1] and **Hazel Walshaw**[2], (1)Corteva Agriscience, United States, (2)Corteva Agriscience*

Non-extractable residues (NERs) of pesticide in soil are one of the major uncertainties in pesticide risk assessment and persistence evaluation for PBT and PMT classification, because of their unknown chemical identifies. This study explores the feasibility of identifying bound compounds in non-extractable residues (NERs) of pesticides in soil by 4-pool kinetic analysis. The 4-pools refer to parent compound, metabolites, NERs, and CO2 in 14C-labeled pesticide soil degradation studies. We discovered the following two characteristic 4-pool kinetic behaviors of formation of NERs: (1) if parent compound is bound as NERs, the metabolites (m(t) in % applied radioactivity (AR)) kinetically drive the evolution of CO2 only; and (2) if a metabolite (x) in a sequential degradation pathway is bound as NERs, m(t) is split into m1(t) and m2(t) at the metabolite (x) that is bound as NERs, which kinetically drive the formation of NERs and evolution of CO2 respectively. We developed two (i.e., Parent->NER and metabolite->NER) 4-pool models to capture the kinetic behaviors respectively. By fitting the models to a set of 4-pool data, we not only determine whether NERs form from parent compound or metabolites but also identify the bound metabolite (x) by resolving the metabolites into M1(t) and M2(t) (i.e., the variables used to simulate m1(t) and m2(t)) and then matching m1(t) (i.e., the sum of bound metabolite (x) and its metabolite precursors) with M1(t). By applying the models to 14C-labeled parent compound-dosed studies and then sequentially to metabolite-dosed studies for 7 pesticides with ? 70% AR NERs, we identified the bound compounds, which have the moieties known to be responsible for NERs, are bound as NERs instantaneously when dosed into soil, and account for pH dependency of NER formation. This study demonstrated that we could identify the bound chemical species in NERs of pesticides, assess the risk/hazards of NERs at a molecular level, and thereby eliminate the uncertainties in pesticide risk and persistence assessments.

3.05.P-We211 Developing Principles for Read-Across of Biodegradation Simulation Test Endpoints

Christopher B. Hughes[1], *Louise Camenzuli*[2], *Marie Collard*[3], *David M. V. Saunders*[4] *and Lucy Wilmot*[5], *(1)Embark Chemical Consulting, United Kingdom, (2)ExxonMobil Petroleum & Chemical BV, Belgium, (3)DSM-Firmenich, Belgium, (4)Shell Global Solutions, Netherlands, (5)ECETOC, Belgium*

Biodegradation simulation tests are a standard information requirement under the EU REACH regulation and aim to provide information on the degradation rate of substances and the formation of transformation products under realistic environmental conditions. These tests are complex and costly and carry important implications for the evaluation and risk management of substances. In practice, few substances registered under REACH currently have simulation testing data available. In the absence of data, it is possible to address standard information requirements using adaptations. One such adaptation is read-across, whereby data for one or more substances (source substance(s)) are used to support the data requirements of other substance(s) (target substance(s)). This can be advantageous for reducing the costs of meeting information requirements, and for increasing the efficiency of the evaluation process.

Read-across is an established approach for (eco)toxicity endpoints. However, the application of read-across to degradation endpoints has so far received little attention. In this poster, the concept and principles of read-across will be explored and applied to the specific information requirements of biodegradation simulation tests. The regulatory requirements for justification of read-across will be discussed, including the ECHA read-across assessment framework (RAAF) and how this might apply to biodegradation simulation test endpoints.

Simulation tests can produce information on both the degradation half-life of the substance and the identity of transformation products. Read-across approaches could consider one, or both, of these aspects, and each may need to be justified separately. For example, two substances may have a similar degradation half-life but different transformation products, or vice versa. Potential considerations related to assessing the suitability of read-across for both aspects will be discussed (such as considering the behaviour of source and target substances with respect to non-extractable residue (NER) formation). Further, the potential use of a data matrix, as discussed in RAAF, to support a category approach for reading across simulation test endpoints will be presented.

3.05.P-We212 Biochemical Oxygen Demand as a Proxy for Micropollutant Biodegradation

Arild Gustafsson, *Joeselle Serrana, Run Tian, Michael McLachlan and Malte Posselt, Department of Environmental Science, Stockholm University, Sweden*

The biodegradation rate of organic micropollutants in the environment is highly variable, presenting a challenge when assessing their risks and the exposure of humans and ecosystems. Simultaneously, measuring these biodegradation rates for a given site using established methods such as the OECD 309 is both time consuming and expensive, limiting the information available to researchers and regulators. It would therefore be useful to develop a faster and more affordable test which provides an indication of environmental biodegradation rates, allowing a large number of sites to be screened using less time and resources. In this study, we assessed if a modified three-day Biochemical Oxygen Demand (BOD3) test could serve this purpose. This was done by applying a modified BOD3 test in parallel with a modified OECD 309 test to water and sediment samples, simultaneously assessing BOD3 and the first order attenuation rate constant for 47 spiked micropollutants. Water and sediment samples were collected at 10 sites in the Fyris river and its tributaries in Uppsala, Sweden. Attenuation rate constants for at least three sites were obtained for 22 spiked compounds, allowing the relation between the two metrics to be assessed using linear least squares regression. There was a strong positive correlation ($r2 > 0.8$) between site BOD3 and attenuation rate for 12 of the 22 compounds, and a moderate correlation ($r2 > 0.5$) for a further 5 compounds. For the last 5 compounds there was no clear correlation between attenuation rate and BOD3. The results reveal that a modified BOD test could have the potential to serve as a screening tool for the micropollutant biodegradation capacity of aquatic systems. Before broad application, it is however necessary to test the relationship between the two metrics for samples from different river systems.

Disclaimer/Disclosure: The authors thank Formas for funding this study (grant 2021-02059).

3.05.P-We213 Towards Streamlined Environmental Persistence Assays for Trace Organic Contaminants: Findings from High-Throughput Method Optimization and Biodegradation Testing

Chiel Kaal[1]*, Sarah Partanen*[1]*, Nicolas Mueller*[2] *and Kathrin Fenner*[1]*, (1)University of Zurich, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

The 2022 European Commission framework entitled Safe and Sustainable by Design chemicals and materials emphasizes the need for early assessment of the hazardous properties of chemicals during their design. One such property is environmental persistence, which is currently evaluated using outdated, time-intensive, and resource-heavy methods. To address this, we developed a high-throughput method for evaluating chemical persistence using activated sludge as a microbial inoculum source. Performing the assay in activated sludge allows for a rapid (48 hour) assessment of pollutant biodegradation, while avoiding the microbial lottery and still allowing for extrapolation of the results to environmental compartments such as soil. Our approach combines a 24-well plate format with an eight-minute reverse-phase liquid chromatography runtime and high-resolution mass spectrometry for the high-throughput detection of micropollutants. The method was developed based on a test set of 40 compounds, primarily pesticides, and demonstrated comparable half-lives between the 24-well plate and traditional large-volume biotransformation experiments. To further assess the method's throughput and applicability domain, we applied it to a mixture of 200 compounds including pharmaceuticals and agrochemicals and analysed their degradation and adsorption behaviour in the miniaturized setup compared to large volume reference data. The presented results will include comparisons of persistence between the large-volume and miniaturized formats for the 200 compounds, as well as an investigation into the impact of chemical mixtures and dissolved organic carbon (DOC) content on degradation behavior. We hypothesize that minimal mixture effects will be observed due to the environmentally relevant spike concentrations and based on preliminary experiments with the initial test set of 40 compounds. However, the DOC introduced by the solvent used to dissolve the standards may influence biotransformation rates, as these spikes significantly elevate the carbon content in the samples and provide an easily accessible carbon source for microorganisms. By developing a high-throughput screening method for measuring primary biotransformation, a first-tier assessment can be made on the persistence of chemicals, which is especially useful for early-stage chemical development pipelines.

3.05.P-We214 Persistence Directed Testing of potential PMT Chemicals in Mixtures

Heidi Birch[1]*, Rune Hjorth*[1]*, Michael Neumann*[2] *and Philipp Mayer*[1]*, (1)Technical University of Denmark, Denmark, (2)Umweltbundesamt, Germany*

Environmental persistence is the critical property of organic pollutants that makes them remain in the environment for extended periods of time and notoriously difficult to remove again. The current persistence assessment strategy is based on the biodegradation testing of individual chemicals with the implicit aim to demonstrate biodegradability rather than persistence. This biodegradation directed testing of each chemical is time consuming, and many chemicals have consequently not yet been tested. Persistent chemicals that are still untested and therefore remain unregulated might cause severe and long-lasting pollution problems. Therefore, there is a need to turn the test strategy upside down and focus on finding and managing the most persistent chemicals.

We propose persistence directed aquatic testing of chemicals conducted in mixtures, where the persistence of each chemical is assessed based on substrate depletion in biotic test systems (incubated with surface water) relative to abiotic controls (i.e., absence of primary degradation). The approach can speed up biodegradation testing, since one test can yield biodegradation data for e.g., 20-50 chemicals and is particularly suited to uncover the most persistent chemicals in the mixture. In the current project we will adjust and apply this approach to develop a time-efficient and reliable persistence directed testing strategy to investigate suspected PMT and vPvM chemicals.

This project poster introduces a novel tournament test strategy to narrow a larger number of potentially persistent chemicals down to a smaller number of confirmed persistent chemicals through three rounds of persistence testing. The absence of primary degradation in all rounds will be used as sound evidence of persistence (P and vP). At least 3 inoculums will be used to maximize the reliability of the conclusions. A small number of test chemicals will be included in all mixtures and serve as reference substances and benchmark substances. Final biodegradation tests will be conducted with single substances to increase regulatory acceptability.

3.05.P-We215 Assessing Persistence in Aquatic and Aquatic Sediment Systems using Static and Semi-Continuous Biodegradation Test Systems

Jason Snape, *University of York, United Kingdom*

The persistence of chemicals in the environment is now the most critical parameter in regulatory frameworks for environmental hazard assessment. The extension of the hazard criteria from persistent, bioaccumulative and toxic substances (PBT) to include persistent, mobile and toxic substances (PMT); and their very persistent and very bioaccumulative (vPvB), and very persistent and very mobile (vPvM) categories of increased concern, coupled with stakeholder concerns about the continued presence of chemicals in the environment make persistence the key property of concern in hazard assessment. Scientific innovations to capture environmental realism and relevance in chemical persistence assessments are lagging the regulatory frameworks aimed at restricting the use of hazardous chemicals. There is an overreliance on biodegradability assessments that have limited microbial ecological and functional relevance due to their limited biomass concentrations, biomass preconditioning regimes, the batch nature of the study, limited test volumes and limited test durations. There is also a mis-placed perception that persistence is an intrinsic substance property amongst some communities; whilst some chemical structures will be inherently more persistent than others this premise fails to allow for microorganisms to adapt and evolve new catabolic capabilities over time. These dated and misplaced perceptions are leading to the over-classification of chemical persistence and hindering chemical innovation. Within this presentation we will demonstrate that lag periods and adaptation times often exceed the test duration of many standard biodegradation test guideline studies (e.g., OECD 301 and 309) before the onset of rapid biodegradation for chemicals widely considered to be non-persistent (e.g., nitrophenols, anilines and chloro-anilines). The presentation will also demonstrate that (1) the presence of settled or suspended sediment within the test system can reduce lag periods, and (2) that or semi-continuous operation demonstrates reductions in lag periods overtime with increased biodegradation rates as microbial communities adapt.

Disclaimer/Disclosure: This work was co-funded by UKRI-BBSRC, CEFIC-LRI and the Defra.

3.05.P-We216 Biodegradation Testing Strategies in the Framework of REACH and CLP Regulations

Emilie Bigorgne-Vizade[1], *Steven Andrews*[2], *Liam Burns*[2], *Craig Anderson*[2] *and Pauline Remuzat*[1],
(1)Blue Frog Scientific EURL, France, (2)Blue Frog Scientific Limited, United Kingdom

Biodegradation assessment of chemicals plays a key role to protect human health and ecosystems in EU regulations (REACH regulation EC n°1907/2006 and CLP regulation EC n°1272/2008), especially with the recent implementation of the latest Persistent, Bioaccumulable, Toxic (PBT)/very Persistent and very Bioaccumulable (vPvB) and Persistent, Mobile, Toxic (PMT)/very Persistent and very Mobile (vPvM) hazard classes in CLP regulation.

Based on current biodegradation tests, a chemical substance can be considered as readily biodegradable (with or without the 10-day window), inherently biodegradable (fulfilling or not specific criteria) or not biodegradable in a REACH registration dossier.

The aim of this work is to show how different results of biodegradation tests can have an impact on testing strategies for REACH requirements and for CLP regulation depending on the registration tonnage band. Based on comparison of stepwise approach developed by ECHA to assess biodegradation/persistence and recent ECHA reviews of REACH dossiers, a flowchart has been created to identify the requirement(s) depending on the result(s) of biodegradation tests.

Only chemical substances considered as readily biodegradable or inherently biodegradable are not classified persistent according to PBT/vPvB assessment. Despite the fact that a substance is not classified as persistent , further tests on the degradation of the substance can be required to meet the requirements of the REACH regulation and refine the Soil Hazard Category of a substance.

A substance not biodegradable is considered as persistent in different assessment of REACH and CLP (PBT/vPvB, REACH requirements, Soil Hazard Category).

Overall, the results indicate that different interpretations of persistence can be made for the same substance depending on the EU regulation. Interpretation of biodegradation results for persistence assessment among ECHA guidances should be harmonised in the context of the future one substance-one assessment approach in Europe.

3.05.P-We217 The Persistence Assessment Tool (PAT): Implementing a Methodology for Data Quality Evaluation and Weight of Evidence in Persistence Assessments

Megan Griffiths[1]*, Christopher B. Hughes*[1]*, Simon Cook*[1]*, Amelie Ott*[2]*, Blanca Serrano*[3]*, Katherine Santizo*[4]*, Dik van de Meent*[5]*, John Parsons*[5] *and Delina Lyon*[6]*, (1)Ricardo, United Kingdom, (2)International Collaboration on Cosmetics Safety (ICCS), New York, United States, (3)ECETOC, Belgium, (4)Cefic-LRI, Belgium, (5)Association of Retired Environmental Scientists (ARES), Netherlands, (6)CONCAWE, ., Belgium*

Interest in chemical persistence has increased significantly in recent years, with Persistent, Mobile, and Toxic (PMT) and very Persistent, very Mobile (vPvM) now hazard classes under the CLP Regulation. Regulatory persistence assessments require building a weight-of-evidence (WoE) to compare chemical degradation half-lives to set criteria for different environmental compartments, using all relevant lines of evidence (LoE) e.g., biodegradation screening tests, field data, etc. Implementation challenges remain in persistence assessments, particularly relating to guidance around data quality evaluation and the WoE determination. In addition, there are issues for substances whose properties render them difficult to evaluate using standard methods.

To address these challenges, the freely available Persistence Assessment Tool (PAT) was developed to support the evaluation of persistence and released on the Ricardo website. To develop the PAT, available persistence assessment guidance was extracted and converted into rules and logical tests to be coded into a stepwise methodology. First, the quality of individual studies are evaluated, which are then combined within the same LoE to draw conclusions at the LoE level. Information from different LoEs are then weighted and integrated into single persistence assessment conclusions. This software tool provides clear guidance and structure to evaluate data quality, and a quantitative WoE methodology to process the information and calculate persistence conclusions in line with regulatory guidance. The PAT provides specific features to account for difficult and complex substances and includes various options for customisation to specific regulatory frameworks. In addition, a multimedia fate model, SimpleRisk4PAT, is included to optionally calculate overall persistence (Pov).

Since the PAT is mentioned as a WoE tool in the new Guidance on the Application of the CLP Critera, it is important to continually upgrade and improve it. Input from users and stakeholders thus far has lead to an update of the PAT, which includes allowing more flexibility in study input parameters and treatment of half-lives, fixing software issues, and including free text fields for assessors to add comments. The PAT aims to support robust, consistent, and transparent decision-making for persistence assessments. Further stakeholder input is needed to support consensus-building and uptake of the methodology.

3.05.P-We218 Can an In Silico Model Predict Ready Biodegradability Results While Enhancing Understanding of Degradation Mechanisms?

Floriane Larras[1]*, Paul Thomas*[2] *and Emel Ay-Albrecht*[1]*, (1)KREATiS, France, (2)KREATiS, ., France*

Aerobic microbial biodegradation of chemicals is a key environmental process resulting ultimately in the transformation of organic compounds into water and carbon dioxide. The assessment of chemical biodegradation is crucial to limit the release of compounds that may persist in ecosystems. To experimentally determine if a chemical is readily biodegradable, the OECD 301/310 Guidelines set out specific criteria that must be met. The test is not rapid (28-60 days). In the area of the Safe and Sustainable by Design approach, quick and robust ready-biodegradable property predictions is increasingly important. In many applications the risk of persistence of a substance may limit its commercial potential. Thus, limiting the time and cost while providing, in addition, a mechanistic interpretation and uncertainty of the result is advantageous. We developed a Structure Activity Relationship (SAR) model based on machine learning approaches compliant with the five OECD principles for (Q)SAR method validation. First, numerous data performed according to OECD 301/310 Guidelines were retrieved from the literature in order to cover a wide structural chemical space. To maximise reliability, an in depth curation of the database was performed removing studies that were not OECD compliant or dealing with compounds such as multi-constituents, salts, organo-metallics and stereoisomers. Also, substances for which more than one study was available were manually assessed based on expert judgement. Then, data splitting was performed using a clustering algorithm to ensure structural diversity and a balanced distribution across the training, validation, and test sets, while also considering the response variable to achieve better representativity of the target properties. Following the data split, various machine learning modelling approaches were explored such as a support vector machine, random forest and artificial neural network among others. Different strategies for setting up the descriptors were tested, including generating numerous atomic descriptors and incorporating specific variables identified in the literature that influence biodegradation. This model represents the first version of KREATiS biodegradation model based on machine learning. Future versions will be dedicated to specific OECD 301 (B,C, D, & F) and 310 methods, include salts and organometallic compounds, as well as integrating microbial ecological data to enhance the model's environmental reliability.

3.05.P-We219 Probabilities to Prioritize Potential Persistent Pollutants
***Sivani Baskaran**, Raoul Wolf and Hans Peter H. Arp, Norwegian Geotechnical Institute (NGI), Norway*
Chemical hazard and risk assessments often use physical-chemical properties to categorize and identify chemicals of concern. In Europe, recent legislation regarding the classification, labelling and packaging (CLP) of consumer products includes new chemical hazard categories, including persistent, mobile, and toxic (PMT) and very persistent and very mobile (vPvM). Persistency is currently assessed using ready biodegradability data and half-lives of the substance in different systems. This is additionally challenging because of the limited availability of data and information in the environment. We combine available datasets available in literature, data from OECD s eChemPortal and QSAR Toolbox and predict ready biodegradability and degradation half-lives using QSAR models such as OPERA and EPI Suite. We combine data, including availability of uncertainty data and errors, and the relative reliability of the source of data using Bayesian analysis methodologies.
In this work we assess the potential persistence of substances from the ZeroPM Global Chemical Inventory, which includes approximately 119,000 SMILES that represent 93,000 substances. We predict the probability that a substance is not persistent, persistent, or very persistent based on the available data. This data can be used as part of a weight of evidence approach when the probability of any one category is very high or to identify substances where further experimental testing and reporting is required because the probability of a substance being not persistent is near 50% and thus the results are inconclusive. We also explore the entire dataset and the cumulative probability scores, to understand how many of the chemicals registered on the global market may be considered potentially persistent or not persistent.

Disclaimer/Disclosure: This work is part of the project "ZeroPM: Zero pollution of persistent, mobile substances" which has received funding from the European Union s Horizon 2020 research and innovation programme under grant agreement No 101036756.

3.05.P-We220 Screening Assessment of the Fate of Naturals Constituents: A Review of Data and Analysis in the Context of More than One Constituent Substances (MOCS)
***Kevin Bonnot**[1], Sylvia Gimeno[1], Floriane Larras[2], Paul Thomas[3], Mylene Leger[4] and Cyril Durou[4], (1)dsm-firmenich, Belgium, (2)KREATiS, France, (3)KREATiS, France, (4)CEHTRA, France*
Natural Complex Substances (NCS), such as essential oils, are substances of natural origin with a complex chemical composition. They are distinguished by their heterogeneous nature, resulting from biological, geological or physical processes without significant chemical modification. The revision of the CLP regulation, part of the EU Green Deal s Chemical Strategy for Sustainability (CSS), aims to ensure a toxic-free environment by updating classification rules for complex substances referred to as More than One Constituent Substances (MOCS). The Parliament and the Council agreed on a specific derogation for plant extracts not chemically modified, including essential oils, with a 5-year review of scientific evidence by the Commission. Last year, the update of the CLP, regulation (EU) 2023/707, introduced PMT/vPvM and PBT/vPvB as new hazard class and criteria.
For this scientific challenge within the framework of NCS, it is essential, first of all, to assess the environmental fate (Persistence, Bioaccumulation, Mobility) and environmental Toxicity (PMBT) potential of the major constituents present in commercial essential oils.
Starting from a list of essential oils in the market and their composition, we have analysed over 1,000 constituents. A screening PBMT assessment has been conducted using the outcome of various QSAR models (e.g., BIOWIN and CATALOGIC for biodegradation/persistence, KOWIN, BCFBAFWIN and CATALOGIC for bioaccumulation, KOCWIN for mobility, ECOSAR and iSafeRat for ecotoxicity) and when available experimental data. These later were extracted from the QSAR ToolBox v.4.7 and from the Research Institute Fragrance Materials database. This allows us to compare the predictivity potential of the various models. In a second phase, the analysis will focus on the high-impact constituents, i.e., less than 100 constituents representing around 99% of the total volumes of constituents.

This study offers a unique perspective on the environmental fate and ecotoxicity of a large number of natural constituents present in essential oils. Focusing on the available experimental data and supplementing it with our reliable predictions from models will highlight the datagaps for those constituents. This analysis provides an initial information on constituents that will support discussion about the application of the MOCS rule to plant extracts that have been chemically modified.

3.05.P-We221 Lost in Complexity: Limitations of the Current REACH Guidance in Assessing UVCB Persistence

Anne Diez[1]*, Markus Junker*[2]*, Angelika Langsch*[3] *and Beate Fast*[4]*, (1)Abteilung GBP/RA, BASF SE, Germany, (2)GBP/RA, BASF SE, Germany, (3)Regulatory Affairs and Advocacy, Industrial Petrochemicals Europe, BASF SE, Germany, (4)BASF SE, Germany*

The REACH regulation encounters significant challenges when assessing complex substances like UVCBs. These mixtures are characterized by intricate compositions, often consisting of hundreds of isomers, many of which may be unknown or unidentified. This complexity poses substantial difficulties in evaluating their persistence in the environment.

One primary issue is the impossibility to analytically determine a main component within these mixtures. The diversity of isomers makes isolating a single compound for targeted testing nearly impossible. Consequently, methodologies such as radioactive labeling, which could facilitate degradation studies through simulations, become unfeasible. Without a clear understanding of specific components, traditional persistence testing methods may yield unreliable or misleading results.

Moreover, the current ECHA Guidance is often too generic and vague to effectively address the unique challenges posed by UVCBs. Established protocols typically overlook the complexity of these substances, leading to a one-size-fits-all approach that fails to capture their intricacies. This limitation is further exemplified by the use of QSAR modeling. While QSAR can be a powerful tool for predicting the behavior of chemicals, applying it to individual isomers of UVCBs can be of little value under certain circumstances. The uncertainty of these modeled structures in the UVCB means that any predictive outcomes may not accurately reflect reality.

In our specific case, a screening study of the entire UVCB resulted in >97% degradation, providing the most informative assessment of the biodegradation behavior of this specific UVCB. While this approach may lack the precision of more focused analytical methods, it generates a holistic understanding of the environmental fate of the substance, considering interactions among its various isomers. However, this method may not be universally applicable to all UVCBs, as each substance presents unique challenges that require tailored assessment strategies.

In conclusion, the existing REACH guidance is inadequate for assessing the persistence of complex UVCBs. The multitude of isomers, the challenges in identifying a main component, and the limitations of standard methodologies highlight the need for more tailored strategies. As the understanding of UVCBs continues to evolve, regulatory frameworks must adapt to develop specific guidance that addresses the complexities of these substances more effectively.

3.05.P-We222 Higher Tier Biodegradation Assessments of Industrial UVCBs: Which Alternative Approaches are Acceptable?

Michiel Claessens[1]*, Laura Lef vre*[1]*, Sandy Jacobs*[1]*,* ***Nele Deleebeeck***[2] *and Bart Kerre*[1]*, (1)Arcadis Belgium, Belgium, (2)Arcadis, Belgium*

A case study is presented in which the (environmental) degradation products of a complex industrial UVCB compound were predicted using the online rule-based model EAWAG-BBD Pathway Prediction System, as performing higher tier experimental biodegradation testing was deemed technically infeasible. The aim was to obtain a list of predicted (bio)degradation products (PBPs) that may form in the environment and then determine their persistency, bioaccumulation and toxicity (PBT/vPvB) profile. The parent compound consisted of 3 different main constituents, each constituent itself present as a mixture of structures varying in length. However, the substance's complexity and the conservative nature of the computer model caused unexpected issues for the alternative approach as well, as a list of roughly 80,000 unique PBPs was generated. This occurred despite that the substance's constituents were deemed to fall within the model's domain of applicability. Attempts to group the PBPs were abandoned due to too much overlap and the need to justify the use of groups/categories. Hence, the PBT/vPvB characteristics of all the predicted PBPs were determined using different models of EPI Suite (US EPA).

The results of the PBT/vPvB assessment indicated that whereas a majority of the PBPs was predicted to be not readily biodegradable, none of them should be considered as potential PBT/vPvB substances. No potential for bioaccumulation was observed and the estimated toxicity for aquatic organisms was predicted to be low. In addition, only minor issues with model domain applicability were observed for a minority of the PBPs, none of which were deemed to impact the final conclusion of the assessment.

Still, despite that using experimental studies is often technically not possible for substances like this, regulatory acceptance of alternative approaches, regardless of how conservative their results might be, remains of concern. This is due to the apparent expectation of the regulator that alternative approaches should provide the exact same type of information as the experimental studies they replace. As such alternative approaches are currently lacking, there is currently not enough clarity on how to approach the biodegradation assessment of industrial UVCBs such as the one used in this case study. This presentation aims to open and contribute to this discussion.

3.05.P-We223 Navigating the Complexities of Biodegradation Testing for UVCBs: Challenges, Approaches, and Case-study Insights

Fola Ogungbemi[1]*, Michael Huben*[2]*, Jan Wolff*[1] *and Yvonne Zielezny*[3]*, (1)Currenta GmbH & Co. OHG, Product Compliance Department, Germany, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Covestro Deutschland AG, Germany*

Substances of Unknown or Variable Composition, Complex Reaction Products, or Biological Materials (UVCBs) represent a significant challenge in environmental risk assessment due to their structural and compositional complexity. This study highlights the methodological approaches, challenges and potential solutions in assessing the persistence of UVCBs, using a case study to demonstrate practical insights. There are 3 main approaches recommended to test UVCBS, including the known constituent approach, block profiling, and the whole substance approach. Each strategy offers advantages depending on the availability of constituent-specific data and analytical feasibility. In a case study, the biodegradation of a UVCB substance was investigated using the known constituent approach. A representative component (the test item) was selected from the UVCB substance, followed by radiosynthesis and biodegradation testing in surface water according to OECD 309 test guideline. Results indicated significant degradation differences between low (10 µg/L) and high (100 µg/L) concentrations, with maximal biodegradation reaching 56 % and 0.4 %, respectively, after 60 days incubation. Apart from significant difference in the observed degradation rate for high and low concentrations, differences were also observed in the biodegradation variability between replicates at later time points, pointing to potential differences in microbial diversity and density.

Key challenges for biodegradation testing were identified based on the results including divergent degradation rates across replicates, concentration-dependent discrepancies, and radioactivity losses during sample processing. Addressing these challenges require enhanced microbial monitoring, better reference substances, and the integration of new approach methodologies (NAMs) and QSAR models.

This study underscores the importance of tailored testing approaches, the integration of microbial insights, and methodological refinement to advance our understanding of UVCB biodegradation. Furthermore, the study demonstrates that for UVCB-Substances, such method is very expensive and becomes economically unsustainable when multiple components of the UVCB-substance need to be examined.

3.05.P-We224 Organic Micropollutant Biodegradation Capacity of Dutch Drinking Water Aquifers

Merel Nederend*, Silvana Quiton-Tapia and Nora B. Sutton, Environmental Technology, Wageningen University & Research (WUR), Netherlands*

Water quality in Dutch drinking water aquifers is threatened by the increasing presence of organic micropollutants (OMPs) such as pharmaceuticals, pesticides and household chemicals. Aquifers are oligotrophic and anaerobic environments where the ability of indigenous microbial communities to biodegrade OMPs is limited. Supplying oxygen and a biodegradable carbon source harvests the OMP biodegradation capacity present in aquifers. Biodegradation capacity is shaped by the geochemical characteristics of aquifers, leading to variations in biodegradation rate and removal efficiency of specific OMPs. This variation indicates that assessing the potential of Dutch drinking water aquifers to support OMP biodegradation requires further investigation. This research aims to survey conditions determining the OMP biodegradation capacity of Dutch drinking water aquifers and clarify the role of biodegradable dissolved organic carbon (DOC) in this process. The biodegradation capacity of more than 20 OMPs was tested at environmental concentrations (1 ug/L) during aerobic batch bottle experiments inoculated with indigenous microbial communities from 15 different drinking water aquifers. Microbial activity and OMP removal were monitored over a period of 80 days, with OMP biodegradation normalized to the biomass content of the different waters. The biodegradability of bulk DOC in each aquifer was analyzed using excitation emission matrix (EEM) to characterize the DOC fractions. We hypothesized that microbial activity and richness as well as availability of biodegradable DOC are important parameters determining OMP biodegradation capacity. With our findings, drinking water companies can more effectively harness the potential of the indigenous microbial community, increasing the viability of nature based solutions to remove OMPs.

3.05.P-We225 Innovative Strategies for Removal of Organochlorine Contaminants: Selection of the Best Tools for Synergistic Abiotic-Biotic Breakdown

Marcela Tlc kova[1]*, Lubomir Jurkovic*[1] *and* ***Hana Horvathova***[2]*, (1)Comenius University in Bratislava,*

Faculty of Natural Sciences, Department of Geochemistry, Slovakia, (2)Comenius University Bratislava, Slovakia
Organochlorine substances (PCBs, chlorinated hydrocarbons, pesticides, e.g.,) are among the most common environmental pollutants. Their diverse properties as chemical stability, low water solubility, and volatility are outlining their environmental fate. Generally, they are toxic, hardly biodegradable, and persistent. The molecular complexity of several substances of this kind, mainly aromatics and alicyclics driving forward the research of the complementary technologies consisting of individual steps, resulting in the effective degradation of contaminant molecule. One of such approaches is nanobiodegradation. First, iron-based nanoparticles dechlorinate the pollutant molecule, and in the second step specialized bacteria cleave the remaining structure. In our study, the iron bionanoparticles (Fe-BNPs) synthetized from the waste-based plant materials were applied and compared with synthetic nZVI nanoparticles. The bacteria were isolated directly from the contaminated matrix by enrichment method using the increasing selection pressure of contaminant. The research was focused on obtaining of the degrading bacterial culture and optimization of the Fe-BNP synthesis so that they are compatible and provide the highest possible efficiency. The results show that plant waste from food industry (peels, seeds, pomace) are a valuable source of bioactive substances which can mediate the formation of Fe-BNPs, yielding high especially when (a) nitrogen atmosphere was maintained during whole process of synthesis, (b) plant extract was combined with low concentration of synthetic reducing agent and (c) pH was adjusted to slightly alkaline values. It was also possible to obtain bacterial culture capable of significant reduction of organochlorines. As the abiotic and biotic processes differs in the oxygen requirements, the further steps are aimed to construct the microcosm setup for sequential nanobiodegradation of organochlorines with potential for latter scale-up to pilot unit, where biodegradation could proceed anoxically and biodegradation in oxic atmosphere. It will relate also to determining of the toxicity of Fe-BNPs to bacterial culture, as well as with searching of the appropriate way for deactivation of Fe-BNPs before biodegradation step. Nanobiodegradation exploits the potential of natural sources as adapted bacteria and gives the added value to the material originally considered waste, thus appears to be an economically and ecologically friendly approach.

The expressed opinions and views are those of the authors and do not necessarily reflect the requirements of the European Union. The European Union is not responsible for them.

3.05.P-We226 Natural Degradation of Plastic Surfaces in Lake Geneva: Analyzing Depth-Dependent Changes and Microbial Influences

***Laureen Mori-Bazzano**[1], Nhung Nguyen[2], Alena Sevcu[3], Bastiaan Ibelings[4] and Vera Slaveykova[5], (1)Switzerland, (2)researcher, Czech Republic, (3)Technical University of Liberec, Czech Republic, (4)University of Geneva, Switzerland, (5)University of Geneva, ., Switzerland*
Plastic degradation in aquatic ecosystems involves abiotic processes, such as photooxidation, and biotic processes driven by biofilm microorganisms producing polymer-degrading enzymes. However, the long-term impact of the natural plastic degradation in freshwater ecosystems remains understudied. This project aims to (1) characterize the biofilm community on low-density polyethylene (LDPE), polyethylene terephthalate (PET), and glass in Lake Geneva, and (2) examine plastic degradation at different depths under reduced light conditions. Samples were incubated for 10 months at 2, 30, and 100 meters, with environmental parameters monitored via the LéXPLORE platform. Biofilm DNA is extracted for Next-Generation Sequencing (NGS) to identify bacteria, algae, and fungi. Quantitative PCR (qPCR) is performed to investigate the biodegradation potential targeting the alkane hydrolase genes (alkB). After biofilm removal, plastic surfaces were analyzed using Fourier Transform Infrared spectroscopy (FTIR) to detect chemical changes, contact angle measurements for hydrophobicity, and Scanning Electron Microscopy (SEM) for surface morphology. The results from NGS indicate that depth and time gradient influences strongly biofilm composition: at 2 meters, a dense biofilm of bacteria, fungi, and algae fluctuates seasonally; at 30 meters, bacteria and fungi dominate with constant growth; and at 100 meters, only a few bacteria persist. Hydrophobicity reduction was most significant at 2 meters, likely due to photooxidation or biotic factors. At 30 meters, PET s hydrophobicity remains stable, while LDPE s surfaces showed a significant decrease in hydrophobicity compared to virgin LDPE. FTIR spectra revealed a strong decrease in CH bonds (methyl group) and the appearance of new carbonyl peaks (1715 cm-1 1649 cm-1) on LDPE at 30 meters only, suggesting chemical changes on the surface. Noticeable porous cavities are observed with SEM imaging at 30 meters, confirming a possible plastic degradation after 8 months of incubation. Additionally, the abundance of alkB increased significantly on LDPE,

whereas it decreased on PET. Heterotrophic bacteria, such as Sphingomonas, and saprotrophic fungi, like Cladosporium, were identified in biofilms and are promising candidates for plastic degradation. The chemical properties of LDPE, with its aliphatic hydrocarbon structure and lower crystallinity, make it more susceptible to both abiotic and biotic degradation processes than PET.

3.05.P-We227 Biodegradation of Food-Related Plastic Materials by Penicillium Brevicompactum

Joao Pinto da Costa[1], *Ana Maria Paço*[2], *Armando Duarte*[1], *Artur Alves*[3] *and Teresa Rocha-Santos*[1], *(1)University of Aveiro, Portugal, (2)Chemistry, University of Aveiro, Aveiro, Portugal, (3)University of Aveiro, Aveiro, Portugal*

The pervasive use of plastic polymers, particularly in the food industry, has steadily increased in recent decades, presently posing a problem of urgent environmental concern. These materials, while beneficial for extending the shelf life of various food products, significantly contribute to plastic waste, much of which eventually reaches and contaminates natural environments. Consequently, developing effective and environmental friendly solutions for plastic waste management is of paramount importance.
Herein, we explored a promising approach to mitigating this environmental crisis through the biological degradation of plastic waste. The research focused on the fungus Penicillium brevicompactum and its ability to degrade polyethylene (PE), a common type of plastic widely used in the food industry. Two types of PE were selected: high-density polyethylene (HDPE), sourced from a yogurt bottle, and low-density polyethylene (LDPE) obtained from a food storage plastic bag. These materials were chosen due to their prevalence in everyday consumer products and their substantial contribution to plastic pollution.
Experimental results revealed that P. brevicompactum was capable of colonizing both types of PE, demonstrating its potential as a biological agent for plastic degradation. Although complete degradation of these materials was not achieved, approximately 20% of HDPE and 40% of LDPE were degraded. These findings highlight the potential of fungi in reducing plastic waste through biodegradation.
By harnessing biological mechanisms, such as the action of fungi, more sustainable and eco-friendly practices for managing plastic waste may be developed. The study underscores the importance of continued research in the field of bioremediation and the need for interdisciplinary efforts to combat the growing problem of plastic pollution. Furthermore, results constitute a promising avenue for the application of green chemistry principles in addressing one of the most pressing environmental issues of our time. By leveraging natural processes for the degradation of plastic waste, we can move towards a more sustainable and environmentally responsible future.

3.06.A Can Biodegradable Polymers Serve as a Safe and Sustainable Solution to Environmental Accumulation of Polymers?

3.06.A.T-01 A Conceptual Model to Overview Microplastic Persistence and Environmental Impact of Biodegradable and Non-Biodegradable Polymers

Miriam Weber *and Christian Lott, HYDRA Marine Sciences, Germany*

Reducing plastic pollution is at the top of the Green Deal agenda. We are looking at plastic applications that, after reduction, redesign, reuse and recycling, still have an input to and thus an impact on the environment. Biodegradable materials can be a solution, but questions remain: Where do they make sense? Do they offer benefit over non-biodegradable plastics? And how do you find the right polymer or material? Full biodegradation leads to a reduction in pollution, which is cited as an advantage in the EU policy framework for bio-based, biodegradable and compostable plastics. The document clarifies that materials and products claiming to be biodegradable should be verified against existing standards and certificates that they are biodegradable and how long it actually takes for them to biodegrade. However, before such verification or even certification can take place, the manufacturer is faced with the question of which material to choose or what biodegradation times are required or should be achieved. We present a novel conceptual model to move forward in these two situations. It combines materials, processes, environmental behavior and effects with the lifetimes of different plastic polymers. We discuss the model which provides a promising baseline for selecting a polymer/material that combines the required functionality with the minimum possible impact, and the reduction of accumulation in the environment.

3.06.A.T-02 Analysis of (Micro)Plastic Biodegradation at Single-Cell Level by Stable Isotope Raman Microspectroscopy

*Kara Muller[1], Martin Elsner[2] and **Natalia P. Ivleva**[2], (1)Institute of Hydrochemistry, Chair of Analytical Chemistry and Water Chemistry, Technical University of Munich, Garching, Germany, (2)Chair of Analytical Chemistry and Water Chemistry, Technical University of Munich, Germany*

The ubiquitous use of plastics demands thoughtfulness about their fate in the environment. Biodegradability is, therefore, a prerequisite for sustainable future applications in cases where plastics cannot be efficiently retrieved, e.g., in agriculture. Here, complete mineralization of the plastic into water, CO2 and biomass is desired. To this end, the biodegradation process must be systematically studied to reliably classify biodegradable polymers and to design new ones. Conventional methods either analyze the change of polymer properties during degradation (e.g., mass loss or fragmentation) or microbial activity in terms of O2 consumption or CO2 production. However, those methods lack a direct relation between plastics and microorganisms, to see which species are responsible for the degradation and to determine the finale fate of plastics. Stable isotope techniques can close this gap by tracing plastics to their ultimate degradation products. Here, we bring forward stable isotope Raman microspectroscopy at the single-cell level to broaden the mechanistic understanding of microbial degradation of (micro)plastics in natural systems. We selected perdeuterated D-polylactic acid (dPLA) as model plastic and traced Deuterium label during incubation experiments into microbial biomass using C-D vibrations (appear in the Raman-silent region of undeuterated biomass, 2050 2300 cm-1). The use of deuterated, instead of 13C-labeled polymers, turned out to be a very suitable alternative (i.e., availability, price, and pronounced red-shift in Raman spectra). The 2068 cm-1 C-D band was indicative of strongly deuterated lipids, enabling the detection of metabolic differences during incubation with dPLA (i.e., stronger lipid and weaker protein deuteration) compared to glucose-d12 and D2O as alternative D sources. Single-cell analysis was the key to detecting phenotypic heterogeneity and classifying cells of the naturally occurring bacterium Sphingomonas koreensis in two clusters: one showed a significantly stronger deuteration level than the Escherichia coli control, whereas the other was non-labeled. The Deuterium label could even be detected in the strong resonance Raman signal of carotenoids, highlighting the potential for high throughput technologies like imaging and cell sorting. To demonstrate the transferability to environmental samples, experiments were conducted with soil bacteria isolates and D uptake from dPLA into microbial biomass was observed after two weeks.

3.06.A.T-03 Biodegradable Mulch Films in Agricultural Soils: The Effect of Temperature on Biodegradation Dynamics

***Flora Wille**, Juliana Laszakovits, Kristopher McNeill and Michael Sander, ETH Zurich, Switzerland*

Mulch films play a crucial role in modern agriculture to increase crop yields, e.g., by extending growing seasons, controlling weeds, and saving irrigation water. Biodegradable mulch films (BDMFs) are a viable alternative to conventional, environmentally persistent polyethylene films by offering the benefit of biodegrading in soils after use. When assessing biodegradability of BDMFs in field soils, understanding the effect of temperature on biodegradation dynamics is essential. Yet research in this area remains limited. This study investigates the effect of incubation temperature on the biodegradation dynamics of BDMFs containing the biodegradable polyesters poly(butylene adipate-co-terephthalate) (PBAT) and poly(lactic acid) (PLA). To this end, laboratory soil incubations were run at four environmentally relevant temperatures (i.e., 5, 15, 25 and 35°C) in three soils over a period of two years. Biodegradation was followed by quantifying residual PBAT and PLA at five timepoints over the incubation period by Soxhlet extraction of residual polymer coupled to quantitation by proton nuclear magnetic resonance spectroscopy (1H-NMR). This analytical methodology enabled the independent tracking of PBAT and PLA biodegradation. The biodegradation rates and extents of both PBAT and PLA varied between soils but, independent of the soil, were strongly temperature dependent with a general expected increase in biodegradation rates with increasing temperature. Kinetic modeling of the data allowed for the estimation of biodegradation rate constants and activation energies. The 1H-NMR analysis also allowed assessing changes in the monomeric composition of PBAT and revealed an increase in the aromatic diacid (i.e., terephthalate) content with increased biodegradation extent. Modeling efforts, including predictions based on in situ field temperature data, aim to use the laboratory incubation results to predict biodegradation half-lives for the BDMF polymers in the field. The applicability of rate-temperature relationships (e.g., the Arrhenius rate law) will be critically assessed. This work represents a first step toward predicting in situ field biodegradation rates from laboratory incubations conducted at 20 28°C, as specified by the European (EN 17033:2018) and international (ISO 23517:2021) BDMF biodegradability standards.

Disclaimer/Disclosure: The authors acknowledge funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowsla-Curie Actions grant agreement No 955334.

3.06.A.T-04 Case Studies that Show the Predictive Modelling of Microplastic Accumulation in the Natural Environment

***Marieke Brouwer**, Despoina Barouta, Wouter Post, Maarten van der Zee, Rob Reilink, Remko Boom and Evelien Maaskant, Wageningen University and Research (WUR), Netherlands*

The use of plastics inevitably leads to (micro-)plastics entering and accumulating in the natural environment, affecting biodiversity, food security and human health. Biodegradable polymers have emerged as a potential solution to mitigate plastic pollution and the environmental accumulation of polymers, offering stable performance during use while leading to shorter residence times in natural environments. But do we know the effect of these novel polymers on microplastic accumulation in the natural environment?

We developed a comprehensive and universally applicable method to quantify microplastic accumulation in the natural environment. This method includes an integrated biodegradation model that provides the possibility to examine and compare the microplastic formation and accumulation of different polymer types in diverse natural environments. The model uses experimental mineralisation curves of polymers to predict the microplastics accumulation. The model fits the mineralisation curves to a state-space model and therewith generates a mass balance of substances formed during the biodegradation process. This polymer-environment specific mass balance is used to predict the concentrations and residence times of microplastics in the natural environment. The modelling results can be used directly to assess and compare the accumulation of different polymers, and could be used as input for sustainability studies such as a life cycle analysis (LCA). Ultimately, the proposed methodology identifies the required biodegradation behaviour to prevent the microplastic accumulation of specific plastic products in the natural environment. This will facilitate the transition to a system in which products are designed based on their intended functionality and anticipated end-of-life scenario.

For this presentation, the model is applied in different case studies to study the possible benefits of the use of biodegradable polymers as a solution to environmental accumulation of polymers. These case studies are focused on different applications of biodegradable polymers, in different environments. The preliminary results of modelled case studies show that replacing non-biodegradable polymers with biodegradable polymers can be effective in the prevention of environmental microplastic accumulation, even in case of higher littering ratios or the application in agricultural products that are not retrieved from the land.

Disclaimer/Disclosure: This work was supported by the Netherlands Ministry of Infrastructure and Water under subsidy case number 5000005762 and the Wageningen University & Research Knowledge Base Programme KB34 Circular & Climate Neutral Society (KB-34-003-006) that is supported by financing from the Dutch Ministry of Agriculture, Fisheries, Food security and Nature.

3.06.P-We244 Degradation of Biodegradable Plastics

***Sevil Vafadar Afshar**[1], Alessio Boldrin[2], Thomas F. Astrup[3], Thomas H. Christensen[1], Anders E. Daugaard[1], Beatrice Rosso[4], Fabiana Corami[4] and Nanna B. Hartmann[1], (1)Technical University of Denmark, Denmark, (2)Quantis, Switzerland, (3)Rambool, Denmark, (4)Ca Foscari University of Venice, Italy*

Decades of extensive production and use of conventional plastics have led to their accumulation in the environment. Bioplastics (bio-based and/or biodegradable) have been promoted as a more sustainable alternative. However, the literature reveals conflicting conclusions regarding their suitability and environmental impact. A primary area of dispute concerns their biodegradability and the conditions necessary for proper degradation. In real-world settings, biodegradable plastics may not degrade as rapidly or efficiently as laboratory tests indicate. Here, we describe three activities that were conducted to address these issues: (1) a systematic literature review to explore the current level of knowledge, (2) a degradation test on consumer products made from biodegradable plastics was conducted based on an identified knowledge gap in the current literature, and (3) development of a novel oil-based method for extracting aged bio-microplastics from compost matrices. The review covered the degradation of biodegradable plastic in waste management environments (e.g., compost, sludge, or landfill) and the open environment (e.g., seawater, freshwater, or soil). The results highlight challenges in comparing and quantitatively analyzing data on plastic degradation due to methodological variations, including differences in testing methods, materials, and quantification strategies. Moreover, several research gaps and limitations exist. Notably, there is a need to intensify research on polyhydroxyalkanoates (PHAs), polybutylene adipate terephthalate (PBAT), and polybutylene succinate (PBS) to match the level of polylactic acid (PLA) and starch-based plastics. A degradation test was carried out on commercially available biodegradable plastics under simulated industrial composting conditions according to ISO 20200. The results indicated disintegration degrees between 75-100 % for all tested biodegradable plastic products, with five of ten reaching complete disintegration within 90 days. Finally, a method was developed to extract microplastics from these compost samples using oleoextraction. The outcomes of these studies offer valuable insights, particularly in guiding discussions about the prospective role of biodegradable plastics within society. Based on our findings, essential knowledge and data gaps will be highlighted, and suggestions will be provided regarding the direction of future research to assess their role as alternatives to conventional plastics.

3.06.P-We245 Toward Standardization in Microplastics Research: Development of an Extraction Protocol from Compost for ISO

Dean Velikov[1], *Frank Von der Kammer*[1], *Patrizia Pfohl*[2] *and Thilo Hofmann*[1], *(1)University of Vienna, Austria, (2)BASF SE, Germany*

The current economic model is producing plastics in large quantities, and despite our best efforts to recycle and reuse them, some still end up in the environment. With the potential to have negative impacts on flora and fauna, with the potential to be harmful to humans as well. These plastics age and fragment over time, generating microplastics, which vary in color, shape, and physicochemical properties. These differences in properties between different particles challenge their treatment as only one type of contaminant. Besides that, despite knowing that microplastics are present everywhere, there is still no standard method for their extraction and characterization from environmentally complex matrices. This is why we are in the process to standardize a method for the extraction and characterization of microplastics from compost, with a plan to have it finalized by 2027 or earlier. This standard will allow for reproducible and homogenized results, allowing the comparison of findings between different studies and laboratories. The developed extraction protocol consists of deagglomeration, organic matter removal, and density separation. The organic matter removal is done by Fenton oxidation, and the density separation employs calcium chloride. Not only would it target the extraction of fossil fuel-based non-degradable microplastics, but also fragments from biodegradable polymers. Fragments from biodegradable plastics could be present during the initial stages of the composting process but are not expected to be found in final composting products. To achieve the extraction of microplastics, the extraction protocol, under standardization, does not apply harsh conditions. Current results show that the herein developed method has high recovery efficiencies for PBAT microparticles without affecting non-degradable plastics and has negligible effect on the size of biodegradable ones. For the characterization of the particles, we are using a micro-Raman system that employs a 785 nm laser and a particle finder/analyzer software to automate the process. Currently, an interlaboratory study is ongoing to test and validate the presented extraction protocol. Furthermore, we aim to sample final compost products from industrial composting plants in Austria and Germany, comparing plants serving small and large communities.

3.06.P-We251 The Impact of Fossil and Biobased Microplastics on Human Cells

Miguel Oliveira[1], *Monica Almeida*[1], *Miguel Tamayo-Belda*[2], *Carolina Frazao*[1] *and Francisca Fernandez-Pinas*[2], *(1)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (2)Universidad Autonoma de Madrid (UAM) Ciudad Universitaria de Cantoblanco, Spain*

Plastic pollution is one of the most significant environmental challenges of the twenty-first century, with microparticles now found in virtually all ecosystems. Humans are exposed to these particles through three primary routes: ingestion, absorption, and inhalation, and the potential effects largely depend on the composition, shape, and size of the particles. While most research on micro- and nanoplastics focuses on spherical or rod-shaped particles, with polystyrene (PS) being the most commonly studied polymer, the most widely produced plastics are polypropylene (PP) and low-density polyethylene (LDPE). Additionally, there has been a rise in the production of biobased polymers, which degrade faster than traditional fossil-based plastics in an effort to mitigate the harmful effects of conventional plastics. However, the impacts of these newer materials remain largely unknown.

To better understand the effects of micro- and nanoparticles on human health, five types of plastic three from fossil sources (LDPE, PS, and PP) and two from biological sources (PLA and PHB) were mechanically degraded and separated by size using stainless steel mesh filtration and the fraction below 1.6 ?m was chosen. Human cell lines from the liver (HepG2) and intestine (HCT116) were used as biological models and exposed to eight different concentrations of each plastic type and size range, starting from 1.28 μg/L to 100 mg/L. Cellular viability was assessed at three time points (24, 48, and 72 hours) using the MTT assay. In general, HCT116 cells showed greater sensitivity to the plastics than

HepG2 cells, with toxicity being similar between fossil-based micro- and nanoplastics, but biobased present a higher impact than biobased microplastics. Our findings highlight the importance of further investigating the impact of novel biobased and biodegradable polymers on human health.

3.06.B Can Biodegradable Polymers Serve as a Safe and Sustainable Solution to Environmental Accumulation of Polymers?

3.06.B.T-01 Polymer Biodegradability 2.0: A Holistic View on Polymer Biodegradation in Natural and Engineered Environments for a Reliable Product Development

Andreas Kuenkel, *Research Biopolymers, BASF SE, Germany*

Biodegradable polymers are an important part of the solution toolbox to achieve circularity (biological cycle). Therefore reliable biodegradable polymers need to achieve not only an appropriate performance level in applications e.g., home and personal care to fulfill their function during the use phase but also on a biodegradation performance level after use. The biodegradation performance is tailored to the application and the receiving environment of the polymer product after use, which can be both engineered systems (e.g., wastewater treatment plants) and natural systems (e.g., soils, freshwater, or marine environments). This presentation addresses key aspects of polymer biodegradability and biodegradation in both natural and engineered systems with the goal to advance a more holistic view on the topic and, thereby, provide guidance for all stakeholders working on developing, testing, and regulating biodegradable polymers. These aspects include definitions of biodegradability and biodegradation, elucidating polymer- and environmental factors that control the biodegradation process, a discussion of the analytical chemistry of polymer biodegradation, polymer biodegradability testing and certification, the contribution of digital tools like predictive modelling, as well as a brief overview of research needs. In addition, Biodegradability 2.0 includes a joint approach of academia, industry, associations and political decision makers to enable the development of new high performing reliable biodegradable polymers in respective applications e.g., for home and personal in the future.

3.06.B.T-02 Relationships Between Structure and Soil Biodegradability for Synthetic Polyesters: Tracking Carbon using Stable-Isotope Labelling

Taylor F. Nelson, *University of Konstanz, Germany*

Replacing conventional plastics in some applications with those designd to be biodegradable is one key strategy to reduce well-documented accumulation of plastic pollutants in the open environment. The application of biodegradable polymers necessitates an in-depth understanding of the controlling factors on their biodegradability under environmental conditions.
Here, our goal is to understand structure-biodegradability relationships for different, novel, synthetic polyesters. To this end, we synthesize stable carbon isotope (13C)-labelled polyesters, and investigate their soil biodegradability in controlled laboratory incubations. We utilize isotope-selective analytics to track polyester carbon to CO2 and to close mass balances on polyester carbon during aerobic biodegradation. By quantifying residual polyesters in the soil, we can infer their assimilation into microbial biomass, comprehensively understanding their microbial utilization.
In our studies, we have looked into different polyester classes of emerging interest, with varying structures. One class is aliphatic-aromatic copolyesters based on polybutylene adipate-co-terephthalate (PBAT), with changes to the aliphatic monomer identity (sebacate (Se) vs. adipate (A)), and changes to the ratio of aliphatic to aromatic monomer units. Another type is long-chain aliphatic polyesters, such as polyester-2.18 (PE-2.18), which have polyetyhylene-like solid-state structures and tunable properties based on changes in the chain length of the long-chain aliphatic monomers.
Overall, we find strong dependence of soil biodegradation of synthetic polyesters, including mineralization and assimilation into microbial biomass, on their monomer structures. These relationships, together with related structure-property relationships for key materials properties, are key to inform the design of biodegradable polymers for environmental applications.

3.06.B.T-03 Review of Experimental Approaches and Analytical Methods for Biodegradability and Persistence Assessment of Water-Soluble Polymers

Christopher B. Hughes[1], *Dieter Hennecke*[2], *Elaine Jennings*[3], *Boris Meisterjahn*[4], *Julia Marie Peters*[4], *Michael Sander*[5] *and Michael Zumstein*[6], *(1)Embark Chemical Consulting, United Kingdom, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ricardo, Spain, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)ETH Zurich, Switzerland, (6)University of Vienna, Austria*

Water-soluble polymers (WSP) are important and diverse classes of macromolecules that are used in a wide variety of applications, including home and personal care and agricultural formulations. There is a need to better understand the biodegradation, and broader fate, of WSPs in engineered and natural systems that receive these polymers after their use, and to develop robust methods to evaluate this process. Polymers of high molecular weight are not directly available for uptake into microbial cells, preventing these polymers from direct intracellular metabolic processing. These polymers therefore often require initial extracellular breakdown into smaller chemicals. Due to diverse chemical structures and molecular weights of WSPs, a number of physicochemical properties may affect their biodegradation. The interpretation of biodegradation data can be challenging due to the complex composition of WSPs. Finally, complete biodegradation requires many transformation steps which individually may be difficult to detect. Taken together, these WSP-specific considerations challenge the applicability of current biodegradability and persistence assessment frameworks developed for low molecular weight organic chemicals. There is a need to critically assess the transferability of these frameworks to WSPs and, if needed, propose scientifically-founded yet practical frameworks for biodegradability assessment of WSPs. To address this need, we conducted a comprehensive review of available methods and policy frameworks for assessing the biodegradation and environmental persistence of WSPs. The aims of this work were to (1) investigate the applicability of current biodegradability and persistence frameworks to WSP; (2) review available standard and experimental methods, addressing their applicability to the assessment of WSP biodegradation; (3) develop recommendations for future research and advancements in these areas. Scientific studies on this emerging topic remain scarce, highlighting the need for further research. Various promising experimental approaches for assessing WSP biodegradation have been identified and we considered these in the context of applicable regulatory frameworks and possible shortcomings identified therein. Existing and emerging policies suggest that assessing WSP biodegradation will be increasingly required.

Disclaimer/Disclosure: This work was funded by the International Collaboration on Cosmetics Safety (ICCS). The research team maintained full independence and discretion to decide on the content of expert assessment.

3.06.B.T-04 Photochemical Chain Scissions Enhance Polyethylene Glycol Biodegradability: From Probabilistic Modelling to Experimental Demonstration

Kevin Kleemann *and Michael Sander, ETH Zurich, Switzerland*

Polyethylene glycols (PEGs), a prominent group of water-soluble polymers (WSPs), are extensively used across multiple sectors, leading to potential environmental release. This study investigates the interaction of PEGs with photochemically generated hydroxyl radicals (OH), a highly reactive oxidant found in natural environments, and examines how the resulting molecular weight (MW) reduction influences PEG biodegradability in soil and sediment. A probabilistic kinetic model was developed to simulate the production of low-MW PEG fragments through OH-driven chain scissions, revealing that MW drops significantly with only a few scission events per original chain. To validate the model, experimental reactions were conducted using 13C-labeled PEGs (initial average MW = 6200 Da) exposed to OH, which showed a strong decrease in MW, closely matching the model predictions. Subsequent 150-day soil and sediment incubations of both untreated and OH-treated PEGs revealed that lower MWs, achieved via OH reaction, led to faster and more extensive mineralization to 13CO2. This research highlights the importance of considering full MW distributions and their transformation through biotic and abiotic chain scissions, as illustrated by PEGs reaction with photochemically generated OH, for a comprehensive understanding of WSP biodegradability in various environmental settings.

3.06.P-We233 Developing a High-Throughput Biodegradation Test to Investigate the Influence of Microbial Inocula on Biodegradation Outcome in Polymers

Edward Mitchell[1]*, Jennifer Menzies*[2]*, Russell Davenport*[3] *and Kathleen McDonough*[4]*, (1)Environmental Engineering, Newcastle University, United Kingdom, (2)Procter & Gamble, United States, (3)Newcastle University, United Kingdom, (4)Procter & Gamble, Mason, United States*

Polymers are key components in many homecare products, from pharmaceuticals and cosmetics to detergents and sun cream. However, the range of methods available to determine the fate of these polymers in the environment after their disposal is limited, with most being designed for smaller, low-molecular weight compounds. Additionally, existing biodegradation tests are resource-intensive and low-throughput, often only providing a few replicates over 28 days. To address this research gap, we have developed a quick, simple and high-throughput biodegradation test method for water-soluble polymers. This utilises a cresol red-based gel in a 96-well plate setup to measure CO2 released by microbial inocula as the polymer is degraded. The plates are inoculated with an environmentally relevant microbial inoculum with the polymer and then clamped to a second plate with the detection gel to form a gas-tight environment. The gel s colour change can be measured with a spectrophotometer and used to calculate a mass of CO2 produced. With CO2 as the analytical endpoint and a 96-well plate format, hundreds of replicates for a given polymer can be produced in the same time that a standard test could produce just a few. The method is being tested with the polymers pullulan and dextran against a range of inocula including activated sludge from wastewater treatment. Our primary aim is to determine if the method can detect clear differences in biodegradation outcome of a given polymer when exposed to differing concentrations of inoculum. This would provide validation of the method s effectiveness. We further hypothesise that significant differences will be found in the biodegradation of a given polymer depending on the inoculum type it is exposed to such as activated sludge versus river water communities. This new high-throughput biodegradation test could increase our capacity to rapidly assess the wide range of new polymers currently in development. Therefore, paving the way for more biodegradable products and better protection for the environment post-disposal as well as allowing us to study the factors affecting biodegradability in greater detail.

3.06.P-We235 Polyquaternium Polymers in the Aquatic Environment: Analytical Method Development and First Occurrence Data

Daniel Zahn[1]*, Anna Scheller*[1]*, Eva-Maria Burkhardt*[2]*, Gabriele Treu*[2] *and Thorsten Reemtsma*[1]*, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)German Environment Agency (UBA), Germany*

Polyquaternium (PQ) compounds are a highly variable sub-class of water-soluble polymers (WSPs) that share a quaternary ammonium substructure as their common structural element. Due to their h igh production volumes, wide-spread use, first evidence of ecotoxicity, and assumed persistence in the environment information on their occurrence and environmental concentrations is essential to assess the risk these chemicals may pose and if regulatory action is required. However, typical trace-analytical methods cannot be applied for PQ-compounds since the total intensity of the polymer in electrospray-ionization mass spectrometry is spread out over countless signals. These originate from the polymer s polydispersity, charge states, and adduct formation and are nearly indistinguishable from background noise even in high concentrations and pure standards. To enable the detection of four selected PQs (PQ-2, PQ-6, PQ-7, and PQ-10) in environmental matrices in-source fragmentation was provoked, converting polymers of different chain lengths, charge states, and adducts to diagnostic fragments of higher intensity than any individual polymer signal.

The developed method was used to screen for these four PQs in 15 surface water samples, which led to the widespread detection of PQ-2 (13/15 samples) after direct injection and the detection of PQ-7 and PQ-10 in samples with a strong urban impact after freeze drying (20-fold enrichment). PQs where shown to interact strongly with humic acids, hampering their analysis and combined with the lack of well-characterized standards this prevents accurate quantification with the current iteration of the method. Nevertheless, PQ-concentrations were estimated in the tens to hundreds of µg/L for many of the investigated samples and reached up to a 1 mg/L for the most contaminated sample. These estimated concentrations seem remarkably high and thus require confirmation with orthogonal methods and, if confirmed, a regulatory follow-up.

Disclaimer/Disclosure: The study was funded by the German Federal Ministry for the Environment, Nature Conservation, Nuclear Safety and Consumer Protection.

3.06.P-We252 Screening of the Environmental Safety of a Novel Biomaterial for Use as Alternative for Plastics

Lara Pinheiro[1]*, Charlene Smith*[2]*, Pilar Bolumburu*[2]*, Alysia Garmulewicz*[2]*, Liz Corbin*[2]*, Ceri Lewis*[1] *and Tamara Susan Galloway*[1]*, (1)Faculty of Health and Life Sciences, University of Exeter, United Kingdom, (2)Materiom, United Kingdom*

Bioplastics are products with enhanced biodegradability and/or of biobased source whose growing production has the potential to replace conventional petroleum-based plastics. Natural biopolymers such as chitosan and cellulose are the most abundant on the planet and can be used for bioplastic production. Here, a newly developed chitosan-methylcellulose bioplastic was investigated for its environmental safety in terms of its disposal after use in terrestrial environments as compost. For this, ecotoxicological tests using three higher plant species exposed to different concentrations of the tested bioplastic were ran. Bioplastics were mixed in standard soil at 0.1, 1, and 10% (w/w) concentrations, and parameters of seed emergence, root growth and shoot growth were measured after 3 and 6 days after seed incubation in dark at 25±1°C. The value for effective concentration to observe 50% of effect (EC50) was also estimated. There was a significant decrease in seed germination in seeds exposed to the 10% bioplastic treatment (avg. 8.3%) when compared to the control (avg. 98.89%). Previous studies have shown that plant seeds exposed to conventional plastic particles can have delayed seed emergence, but this could not be verified here as experiment was terminated at day 6. We hypothesize that delays in seed emergence might be related to reduced water availability caused by the bioplastic hygroscopic nature, and this is being currently tested. Root growth and shoot growth followed a similar pattern as seed emergence, with many zero values for root/shoot length at the 10% bioplastics treatment. EC50 values varied among species, and the dose-response curves highlight the datapoint gaps between treatments of 1%-10% bioplastics which calls for further experiments with a refined range of concentrations. In summary, the tested chitosan-methylcellulose bioplastic material showed no significant effects on seed emergence, root length, or shoot length in tested plant species at concentrations up to 1% bioplastic in soil (w/w). There appears to be a transient effect at a 10% concentration that can be related to changes in water availability caused by the bioplastic addition, and further tests are underway to confirm this. This study adds to the potential for using biobased materials to replace persistent, toxic plastics and for safely disposing the tested bioplastic in terrestrial environments as compost.

3.06.P Can Biodegradable Polymers Serve as a Safe and Sustainable Solution to Environmental Accumulation of Polymers?

3.06.P-We228 Biodegradation of Water-Soluble Polymers – Reviewing In-Silico Methods

***Dimitrios Alexander Skodras*[1]** *and Michael Huben[2], (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Polymers have been in long-term, broad use by various industries. Evaluating their environmental impact is essential, especially within the framework of the European Green Deal and the Chemicals Strategy for Sustainability. While polymers have been exempt from mandatory environmental fate scrutiny under REACH (EC 1107/2009), this exemption is going to be revised. A critical component of this evaluation is the assessment of degradability and persistence of functional polymers, such as those used in cosmetic formulations.

Biodegradation modelling for polymers can employ most notably Quantitative Structure-Activity Relationship (QSAR) models or molecular modelling simulations representing statistical and deterministic approaches. However, common QSAR models for biodegradability, such as BIOWIN in EPI Suite, cannot be extended to polymers due to their stochastic structures. While QSAR tools like Polymer Genome exist for deriving polymer properties, biodegradability prediction has not yet been implemented in any of them. Molecular modelling, although computationally demanding, is capable of estimating polymer properties but still needs to be adapted for biodegradability predictions.

This poster explores the current landscape of in silico methods for assessing polymer degradation. It argues that teaching polymer-specific models to predict biodegradability is more feasible than modifying existing biodegradability tools (including pathway prediction systems) to handle polymers. In an underlying database, biodegradability would be considered as a property. Polymer databases, however, have to capture their stochastic nature. The need for advancing these methodologies is highlighted, with suggestions for refining in silico approaches to improve the understanding of polymer environmental fate.

Disclaimer/Disclosure: We thank ICCS for funding this project.

3.06.P-We229 Applicability and Improvements of OECD (Bio)degradation Testing for Water-Soluble Polymers

***Boris Meisterjahn*[1]**, *Glauco Battagliarin[2], Megan Griffiths[3], Stefan Hahn[4], Dieter Hennecke[5] and Christopher B. Hughes[6], (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Research Biopolymers, BASF SE, Germany, (3)Ricardo, United Kingdom, (4)Fraunhofer Institute for Toxicology and Experimental Medicine ITEM, Germany, (5)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)Embark Chemical Consulting, United Kingdom*

Biodegradation screening testing and more complex biodegradation simulation studies are requested under regulatory frameworks such as REACh for persistency assessment of low molecular weight (small) molecules. While polymers and polymeric substances were initially exempted from REACh, this will change in the near future, and implementation of polymer-specific modifications of the respective ordinances and guidance are necessary. In this context, the question arises whether standard test guidelines used for the determination of small molecules degradability are appropriate for polymers. These guidelines

might need modifications to obtain meaningful data on the biodegradation of polymers in environmental compartments. Possible modifications are not limited to the test setup and technical aspects, but are concerned more with degradation endpoints, which will have to be different compared to small molecules (e.g., changes of the molecular weight distribution, definition of primary degradation). While there is much attention paid to degradation of plastics due to the microplastic restriction, so far studies on water-soluble polymers such as e.g., PEGs or PVOHs are largely missing, especially with regard to higher-tier biodegradation simulation studies.
The CEFIC LRI ECO64 project makes a start to close these gaps. In a first step 14C-radioactive labelled water-soluble polymers will be synthesized, e.g., PVOH and/or CMC. With these compounds available, their biodegradation in the four most important biodegradation simulation tests (soil, sediment, surface water and WWTP-simulation) should be investigated. In parallel these compounds will also be applied to standard screening tests for comparison reasons. In addition to the aforementioned substances, also a radiolabelled biocidal polymer will be tested in soil, water/sediment and WWTP simulation tests. Using the specificity of the radioactive labelling, endpoints possibly relevant for polymer biodegradation beyond the parameter mineralisation will be investigated. Based on the results of the biodegradation simulation and screening tests, recommendations for polymer testing and also appropriate reference substances should be derived.

3.06.P-We230 Scientific and Regulatory Challenges for Assessing the Biodegradability Testing of Fragrance Encapsulates

Arturo Mendoza[1]*, Thomas Dutriez*[1]*, Georg Kreutzer*[1] *and Heike Laue*[2]*, (1)Givaudan Suisse SA, Switzerland, (2)Givaudan International SA, Switzerland*

The rising demand for sustainable solutions in the fragrance industry, coupled with the EU's restriction on synthetic polymer microparticles, has driven the development of biodegradable fragrance encapsulates that meet OECD tests, such as OECD 301B or OECD 301F. Internal and external studies confirm these encapsulates achieve >60% biodegradation, ensuring their global applicability.
To tackle biodegradation testing challenges, we have applied standard test conditions while enhancing testing volume and duration. However, we still investigate issues related to low inoculum concentrations in typical settings (usually 30 mg/L) compared to the significantly higher suspended solids concentrations in wastewater treatment plants. We are exploring inoculum from sources like activated sludge or soil and other modifications to improve biodegradability assessments. Additionally, we are testing raw materials for their biodegradability to increase the likelihood that the final polymer is also biodegradable.
Understanding the biodegradation pathways and kinetics of polymers is also a challenge. Due to their non-soluble nature, analytical methods such as LC-HRMS, used for identifying metabolites in the case of low molecular weight chemicals, are of limited use for solid polymers. Furthermore, physicochemical analyses, e.g., partition coefficients, pose significant challenges due to the intricate nature of polymer compared to traditional fragrance assessments. To address these issues, we investigate employing techniques such as Fourier Transform Infrared Spectroscopy (FTIR), Thermogravimetric Analysis (TGA), Pyrolysis-GC-MS, electronic microscopy, and Total Organic Carbon (TOC) measurements. However, the isolation of the intermediates from organic matter remains a difficult task, as does the interpretation of the analytical result in case of analysis of samples in present of the inoculum as matrix. Another regulatory hurdle is the varying regulatory standards across regions, for example, the necessity to conduct biodegradability tests in e.g., Japan (OECD 301C or OECD 301F), where test performed outside the country are not recognized.
In conclusion, our findings not only advance the understanding of biodegradable fragrance encapsulates but also help overcome some regulatory and experimental challenges in the fragrance industry. By ensuring compliance with inter-national standards, we pave the way for more sustainable practices that align with global environmental goals.

3.06.P-We231 Water-Soluble Polymers Going Down the Drain: Assessing Biodegradation by Wastewater and Freshwater Microbiomes and Adsorption to Activated Sludge

Anika Mikes*, Aaron Kintzi and Michael Zumstein, University of Vienna, Centre for Microbiology and Environmental Systems Science, Division of Environmental Geosciences, Austria*

Water-soluble polymers (WSPs) are essential components in many consumer products, such as household cleaners and personal care items. After use, WSPs used in these products are often discharged into wastewater systems, where various processes such as biodegradation and adsorption to sewage sludge determine to what extent WSPs are removed from wastewater or released into the natural aquatic environment. For a better understanding and prediction of the fate of WSPs during wastewater treatment processes and in natural aquatic environments, it is important to study the biodegradation of WSPs by microbiomes in these systems and the adsorption of WSPs to activated sludge and how these processes are affected by the properties of a WSP (e.g., charge state). In this study we conducted biodegradation and adsorption experiments with three selected WSPs with varying charge states (i.e., polyethylene glycol (PEG), poly(lysine) (PLL), charged carboxymethyl-dextran (CM-DEX)). Biodegradation experiments were conducted using freshly collected activated sludge from a municipal WWTP, as well as river water sampled upstream and downstream of the WWTP, following a protocol adapted from the OECD 301F guidelines. Sludge adsorption experiments were performed using fluorescently labeled (FITC-tagged) WSPs, with adsorption monitored via fluorescence measurements using a microplate reader. All polymers exhibited promising biodegradation dynamics by wastewater microbiomes. PEG and PLL showed distinct lag phases over several days, followed by rapid biodegradation before reaching a plateau. In contrast, CM-dextran showed an immediate onset in biodegradation but afterwards displayed a more gradual biodegradation process. WSPs were also biodegraded in river water, but with high inter-experimental and inter-replicate variabilities. No significant differences were observed between upstream and downstream river inocula. Adsorption experiments revealed concentration-dependent results for PEG supporting the usefulness of the chosen assay. For the other tested WSPs, the tested assay came with challenges and has to be optimized. Together, this study presents insights into how to conduct environmental fate experiments of WSPs going down the drain at their end of life.

Disclaimer/Disclosure: We thank the wastewater treatment plant operators for providing sampling access. AK and MZ acknowledge BASF SE for financial support.

3.06.P-We232 Enzymatic Hydrolyzability of Biobased and Biodegradable Polyesters: Towards Structure-Reactivity Relationships

Thijs Vangeel *and Michael Sander, ETH Zurich, Switzerland*

Biodegradable polymers can play an important role in achieving a circular plastic economy, particularly in cases where collecting and recycling used plastic is challenging (e.g., soil-biodegradable mulch films, compostable biowaste bags). While biodegradable, many of these polymers are still (partly) fossil-based. Transitioning to fully bio-based polymers could reduce greenhouse gas emissions and dependency on fossil resources.

Poly(butylene adipate-co-terephthalate) (PBAT), a widely used biodegradable aromatic-aliphatic copolyester, is typically fossil-based. Replacing PBAT's fossil-derived monomers (terephthalic acid and adipic acid) with bio-based alternatives such as the promising 2,5-furandicarboxylic acid is therefore desirable.

In this study, fully bio-based aromatic-aliphatic copolyesters were synthesized using combinations of bio-based diols, aliphatic diacids, and an aromatic diacid (2,5-furandicarboxylic acid). By varying the ratio of aliphatic-to-aromatic diacid for each combination, a total of 28 unique copolyesters were prepared. Thin films of these copolyesters were then produced via solvent casting.

To evaluate biodegradability, the enzymatic hydrolysis of these copolyester films was assessed using two microbial carboxylesterases: Rhizopus oryzae Lipase (RoL) and Humicola insolens Cutinase (HiC). Hydrolysis was monitored by measuring dissolved organic carbon, while 1H-NMR was used to identify hydrolysis products and characterize the residual polyester structures.

The results highlighted three key findings. First, enzymatic hydrolysis strongly depended on the ratio of aliphatic-to-aromatic diacid. Higher aromatic diacid fractions led to reduced hydrolytic activity for both enzymes, emphasizing the importance of this ratio in determining biodegradability. Second, HiC exhibited significantly higher hydrolytic activity compared to RoL, efficiently hydrolyzing most copolyesters within five days. In contrast, RoL showed limited activity, particularly for copolyesters with aromatic diacid fractions of 50% or more. Third, replacing (fossil-based) terephthalic acid with 2,5-furandicarboxylic acid markedly improved hydrolyzability, suggesting enhanced biodegradability with this bio-based aromatic component.

In conclusion, this study establishes clear relationships between copolyester molecular structure and enzymatic hydrolyzability, providing a framework for designing fully bio-based, biodegradable aromatic-aliphatic copolyesters.

3.06.P-We233 Developing a High-Throughput Biodegradation Test to Investigate the Influence of Microbial Inocula on Biodegradation Outcome in Polymers

Edward Mitchell[1]*, Jennifer Menzies*[2]*, Russell Davenport*[3] *and Kathleen McDonough*[4]*, (1)Environmental Engineering, Newcastle University, United Kingdom, (2)Procter & Gamble, United States, (3)Newcastle University, United Kingdom, (4)Procter & Gamble, Mason, United States*
Polymers are key components in many homecare products, from pharmaceuticals and cosmetics to detergents and sun cream. However, the range of methods available to determine the fate of these polymers in the environment after their disposal is limited, with most being designed for smaller, low-molecular weight compounds. Additionally, existing biodegradation tests are resource-intensive and low-throughput, often only providing a few replicates over 28 days. To address this research gap, we have developed a quick, simple and high-throughput biodegradation test method for water-soluble polymers. This utilises a cresol red-based gel in a 96-well plate setup to measure CO2 released by microbial inocula as the polymer is degraded. The plates are inoculated with an environmentally relevant microbial inoculum with the polymer and then clamped to a second plate with the detection gel to form a gas-tight environment. The gel s colour change can be measured with a spectrophotometer and used to calculate a mass of CO2 produced. With CO2 as the analytical endpoint and a 96-well plate format, hundreds of replicates for a given polymer can be produced in the same time that a standard test could produce just a few. The method is being tested with the polymers pullulan and dextran against a range of inocula including activated sludge from wastewater treatment. Our primary aim is to determine if the method can detect clear differences in biodegradation outcome of a given polymer when exposed to differing concentrations of inoculum. This would provide validation of the method s effectiveness. We further hypothesise that significant differences will be found in the biodegradation of a given polymer depending on the inoculum type it is exposed to such as activated sludge versus river water communities. This new high-throughput biodegradation test could increase our capacity to rapidly assess the wide range of new polymers currently in development. Therefore, paving the way for more biodegradable products and better protection for the environment post-disposal as well as allowing us to study the factors affecting biodegradability in greater detail.

3.06.P-We234 Assessing the Biodegradation of Polymers Under Realistic Environmental Conditions
Ashley Wilcox[1]*, Maura Hall*[1]*, Jennifer Menzies*[1]*, Nigel Yates*[1] *and* ***Kathleen McDonough***[2]*, (1)Procter & Gamble, United States, (2)Procter & Gamble, Mason, United States*
As focus on sustainable-by-design biodegradable polymers increases, research is needed to evaluate methods to accurately assess polymer biodegradation. Limited research has been conducted on methods to access the biodegradation of polymers under realistic environmental conditions (i.e., simulating real world test chemical concentrations and inoculum levels). This poster will discuss recent research on radiolabeled polysaccharides ([14C-Carboxyl] Dextrans, [3H] Carboxymethyl Dextran, and [3H] Carboxymethyl Cellulose) under laboratory simulated realistic environmental conditions using activated sludge as the receiving compartment. Primary biodegradation, ultimate biodegradation, and transformation intermediates (formed during biodegradation) were quantified using liquid scintillation counting, and as applicable, thin layer chromatography (Rad-TLC) or gel permeation chromatography (Rad-GPC) coupled with a MicroBeta2® microplate counter. Additionally, variability in activated sludge from multiple wastewater treatment plants (WWTPs) as well as river water as the receiving compartment will be explored.

3.06.P-We235 Polyquaternium Polymers in the Aquatic Environment: Analytical Method Development and First Occurrence Data
Daniel Zahn[1]*, Anna Scheller*[1]*, Eva-Maria Burkhardt*[2]*, Gabriele Treu*[2] *and Thorsten Reemtsma*[1]*, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)German Environment Agency (UBA), Germany*
Polyquaternium (PQ) compounds are a highly variable sub-class of water-soluble polymers (WSPs) that share a quaternary ammonium substructure as their common structural element. Due to their high production volumes, wide-spread use, first evidence of ecotoxicity, and assumed persistence in the environment information on their occurrence and environmental concentrations is essential to assess the risk these chemicals may pose and if regulatory action is required. However, typical trace-analytical methods cannot be applied for PQ-compounds since the total intensity of the polymer in electrospray-ionization mass spectrometry is spread out over countless signals. These originate from the polymer s polydispersity, charge states, and adduct formation and are nearly indistinguishable from background noise even in high concentrations and pure standards. To enable the detection of four selected PQs (PQ-2, PQ-6, PQ-7, and PQ-10) in environmental matrices in-source fragmentation was provoked, converting polymers of different chain lengths, charge states, and adducts to diagnostic fragments of higher intensity than any individual polymer signal.
The developed method was used to screen for these four PQs in 15 surface water samples, which led to the

widespread detection of PQ-2 (13/15 samples) after direct injection and the detection of PQ-7 and PQ-10 in samples with a strong urban impact after freeze drying (20-fold enrichment). PQs where shown to interact strongly with humic acids, hampering their analysis and combined with the lack of well-characterized standards this prevents accurate quantification with the current iteration of the method. Nevertheless, PQ-concentrations were estimated in the tens to hundreds of µg/L for many of the investigated samples and reached up to a 1 mg/L for the most contaminated sample. These estimated concentrations seem remarkably high and thus require confirmation with orthogonal methods and, if confirmed, a regulatory follow-up.

3.06.P-We236 Eco-Friendly or Ecologically Disruptive? Investigating Biodegradable Wipe Breakdown and Their Effects on Freshwater Microbial Communities

***Daniel Jolly**[1], Dannielle S. Green[2], Eoin O'Gorman[3], Adil Bakir[4], Richard Cooper[1] and Trevor Tolhurst[1], (1)University of East Anglia, United Kingdom, (2)Life Sciences, Anglia Ruskin University, United Kingdom, (3)University of Essex, United Kingdom, (4)Cefas, United Kingdom*

Wet wipes are a prominent source of plastic pollution, entering freshwater environments via wastewater treatment systems, where they may be discharged through raw sewage, or shed microfibres that can bypass stringent treatment procedures. Plastic microfibres have been observed to persist in the environment and elicit negative ecological and ecotoxicological impacts. Therefore, biodegradable wipe alternatives are increasingly sought after and assumed to have little environmental impact. However, the degradation behaviour of wipe products in natural systems, or their ecological impacts, are relatively unknown beyond controlled condition investigations. Therefore, it is not currently possible to guarantee their sustainability or environmental safety. This study aims to assess how different plastic and biodegradable wipe products behave aquatic environments. This was achieved by carrying out a field experiment in a natural river system, placing wipe products in the environment for a period of 8 weeks. Every 2 weeks, wipe degradation was analysed utilising scanning electron microscopy and infrared spectroscopy. At experiment termination, eDNA samples of wipe biofilms were collected, and 16S sequencing performed to assess the potential changes to microbial communities that colonise and decompose the materials. The results of this field experiment will then be compared to controlled condition degradation experiments, such as the ISO 4892-2 method, utilising enhanced temperatures and irradiance to represent accelerated ageing under solar radiation. This will allow the separation and comparison of physical and biological factors during degradation. We hypothesise that biodegradable alternatives will show considerable degradation compared to their plastic counterparts in both field and laboratory experiments. Their microbial communities may differ, with expected greater abundance and diversity on biodegradable materials. However, the addition of chemical additives to commercial wipe products may influence microbial community composition and diversity, which may have implications for their degradation and potential ecological impact. Gaining a deeper understanding of how biodegradable wipe alternatives behave in natural systems, their residency, and their potential ecological impacts, is paramount to ensure their adoption is a more sustainable and less environmentally impactful decision than their plastic counterparts.

Disclaimer/Disclosure: This project is UKRI, Natural Environment Research Council funded through the ARIES Doctoral Training Programme, University of East Anglia and Centre for Environment, Fisheries and Aquaculture Science.

3.06.P-We237 Degradation of Bioplastics and Related Compounds in a Conventional WWTP Process by Activated Sludge

***David Alcaide**[1], Eloy Torres[1], Marinella Farre[2] and Marta Llorca-Casamayor[1], (1)IDAEA-CSIC, Spain, (2)IDAEA-CSIC, Barcelona, Spain*

Bioplastics have been used as a promising solution to fossil-based plastic contamination. These, produced from renewable sources such as starch or corn, that can be biodegraded under different conditions, it is not clear how they are degraded in waste water treatment plants. In addition, it is necessary to evaluate the possible leaching of plastic additives added in bioplastics, used to provide them with specific resistance or malleability, during the depuration process by microorganisms present in the conventional activated sludge (CAS) as well as their subsequent possible elimination or transformation. In this context, we evaluated the elimination of different (bio)microplastics, possible leaching of plastic additives and related compounds and their further elimination facilitated by CAS organisms at laboratory scale. Two commercial garbage bags made of polylactic acid (PLA), as an example of biopolymer, was fragmented to microsize and exposed to CAS. The main results showed the leaching of different plastic additives and among the compounds tentatively identified by Compound Discoverer, 22 were confirmed at level 1 of confidence through standards comparison. Of these 22 compounds, some of them increased their presence along the experiment indicating the leaching and no degradation. This is the case of abietic acid, tris(2-butoxyethyl) phosphate, linoleic acid and Uvinul® 3049 from PLA bag. Finally, comparing these results with fossil-based bags made of PE, these showed that the plasticizers tris(2-butoxyethyl)phosphate and diethyl phthalate increased their presence during the first week of the experiment due to their leaching while they suffered a decrease during the second one because of their elimation or transformation by microorganisms. In the case of the elimination of bioplastics by CAS, a decrease of 98% was observed for biobags reaching the maximum elimination percentage followed by PLA pellets with a 87%. This elimination facilitated by CAS microorganisms that use them as a source of energyis more efficient in the case of biobag because of the surface area to volume ratio that facilitates the microbial accessibility as well as for the higher presence of plastic additives related to degradation that facilitates this process. This process needs to be further evaluated to assure that no-toxic compounds or degradation compounds are released to the media.

Disclaimer/Disclosure: This work was supported by BIOPLASTICMENT project (ref. CNS2022-135615) from the Spanish Ministry of Science, Innovation and Universities and the Generalitat de Catalunya through Consolidated Research Group ON-HEALTH 2021 SGR 01150.

3.06.P-We238 Relating Biotic Degradation to Polymer Characteristics to Better Predict the Fate of Biodegradable Plastics in the Environment

***Melissa Maurer-Jones*[1]*, Thomas Badzinski*[1]*, Ariana Campanaro*[2]*, Margaret Brown*[1]*, Clare List*[1] *and R. Lee Penn*[2]*, (1)University of Minnesota Duluth, United States, (2)University of Minnesota, United States*

Polylactic acid (PLA) and bioplastics alike have a designed degradability to avoid the environmental buildup petro-plastics have created. Yet, to achieve sustainable implementation of these polymer technologies, it is important to characterize the designed biotic-degradation on plastics that have been weathered abiotically, which will occur in their use and supposing their improper disposal in the environment. This work seeks to establish methods that explore biodegradability on a fundamental level considering that biotic degradation is a multi-step, synergist process. Therefore, we explored the interplay between enzyme hydrolysis and biofilm formation on photo-aged PLA. For PLA, biotic degradation was primarily driven by photo-induced reduction in molecular weight that allowed for greater enzyme hydrolysis. Biofilm formation of model organism Shewanella oneidensis was uniformly enhanced with enzymatic hydrolysis, though the characteristics of the biofilm, as quantified by characterizing the extracellular polymeric substance of the biofilms, show the bacteria were more impacted by the extent of photodegradation. Ongoing work to characterize the influence of other plastic characteristics, such as additives, is being pursued. Overall, this work reveals the importance of characterizing the biodegradation with a more complex system. Additionally, our work emphasizes the importance of exploring the interplay between abiotic weathering and biodegradability, which ultimately can inform optimization of production and disposal.

3.06.P-We239 Evaluating Bioplastic Degradation and Fragmentation Using Rainfall Simulation and UV Ageing

***Cherrelle Johnson*[1]*, Sinead Mitchell*[2] *and Noel Harrison*[1]*, (1)University of Galway, Ireland, (2)Management, University of Galway, Ireland*

The accumulation of polymers in the environment due to improper disposal has led to growing concern over their pollution and degradation of ecosystems. Biodegradable polymers are frequently marketed to consumers a sustainable alternative to fossil fuel-based polymers. This has led to a change in consumer behaviour and, often, a misunderstanding that biodegradable polymers are less harmful for the environment than conventional polymers when improperly disposed of. Recent years have seen advancements in biodegradable polymer applications along with their production and use, and it is the expectation that this trend will continue. Although biopolymers are often regarded as a sustainable alternative, the environmental impacts resulting from the improper disposal of biopolymers is an area of research that still contains a significant knowledge gap. Within the EU, Ireland generates the highest amount of plastic packaging waste. The expected growth in biopolymer production along with a gap in the understanding of biopolymer degradation, bundled with Ireland s high plastic waste generation and abundance of rain serve as the foundation of this research. This research aims to evaluate the degradation of degradable biopolymers and nondegradable conventional polymers in a controlled laboratory environment, simulating maritime conditions to gain a better understanding of their degradation in an open environment due to mismanagement or improper disposal. Rainfall simulators replicate naturally occurring rainfall events and provide quantifiable data. In this research, biodegradable and nonbiodegradable polymers undergo rainfall simulation events for twelve weeks. Post rainfall simulation, the polymers are placed in a cold room and exposed to UV ageing lights under controlled conditions with the aim to analyse polymer degradation over time. Rainfall simulation runoff is collected and will be analysed for microplastic persistence to glean insight into possible impacts to environmental receptors such as soil and waterways. Following the rainfall simulation, mechanical testing in the form of tensile strength tests, and imaging through scanning election microscopy will be performed to identify and analyse any degradation. To our knowledge, this is the first study of its kind using rainfall simulation to evaluate biopolymer degradation and this research has the potential to offer a novel method for evaluating polymer degradation in a simulated oceanic climate environment.

3.06.P-We240 Complete Quantification of Products Generated by PBAT and LDPE during Abiotic Degradation Using a Carbon Balance Protocol

Gustave Bertier[1]*, Fabienne Lagarde*[2]*, Arnaud Martel*[2]*, Fabien Boucher*[3]*, Pascale Fabre*[4] *and George Matthieu*[4]*, (1)University of Montpellier, France, (2)Institut des Molecules et Materiaux du Mans, France, (3)IUT Le Mans, France, (4)Laboratoire Charles Coulomb, France*

Plastic pollution is everywhere and might threaten life and ecosystem on a global scale as part of the novel entities group[4,5]. Yet, it is still challenging to assess the impact of any plastic object discharged in the environment, partly because of the diversity of the degradation products (microplastics, nanoplastics, soluble and volatile products) and the difficulty to quantify them. Although the use of carbon as a marker for degradation has already been done for some products, we propose here a novel method for the simultaneous quantification of all degradation products generated by a plastic under abiotic degradation: the carbon mass balance protocol.

We choose to compare the abiotic degradation of two types of industrial plastic granules with different chemical composition but similar use: LDPE that is one of the main plastic used worldwide, and PBAT, used as a biodegradable replacement in some applications. Samples were subjected to a variable UV exposure time (500-3500/4000h) before being stirred in water for 3 days. We separated and analyzed the resulting fragments by weighting and elemental analysis to get their carbon mass. The nanoplastics and solubles were subjected to TOC measurement.

Thanks to this protocol, we made a complete quantitative degradation assessment for both plastics and were able to compare the abiotic degradation of LDPE and PBAT granules, showing great difference in their behavior: the LDPE generated a lot more carbon products and was the only one to significantly produce MPs (~7% of the initial carbon mass at 4000h). Unexpectedly, relatively large amounts of volatile products are also generated for each product, highlighting the importance of taking in consideration all degradation products.

Coupling those rresults with SEM observations of the surface cracking for both plastic gives insights to assess environmental persistence of plastics.

3.06.P-We241 Biodegradation Rates of Polylactic Acid Microplastics in Aquatic Environment: Role of Particle Size and Environmental Aging

Min-Hee Jang Sr and ***Yu Sik Hwang****, korea institute of toxicology (KIT), Republic of Korea*

The increasing adoption of biodegradable plastics as alternatives to conventional plastics aims to reduce environmental pollution. While these materials degrade more rapidly than traditional plastics, their accelerated breakdown may lead to a higher production of microplastics (MPs). Once released into aquatic environments, these MPs undergo aging processes such as physical abrasion, chemical oxidation, weathering, and UV irradiation, which modify their physicochemical properties. These changes, particularly in surface area and functional groups, influence the rate of microbial degradation, as degradation predominantly occurs on particle surfaces. This study investigated the biodegradation of polylactic acid (PLA) microplastics (MPs) of different sizes (5, 20, and 150 ?m) and aging states (unaged, thermal aged, and UV/H2O2 accelerated aged) over a 90-day period using activated sludge. The results demonstrated that smaller particle sizes exhibited faster biodegradation rates, with the rate constant (k, day-1) increasing 0.0006 to 0.0027, highlighting the critical role of surface area in the biodegradation of MPs. Additionally, aging processes, particularly UV/H2O2 accelerated aging, significantly enhanced biodegradation by altering surface proprieties such as fragmentation and surface oxidation. For example, 10 days of UV/H2O2 aging increased the biodegradation rate constant (k, day-1) from 0.0022 to 0.0096 for 20 ?m MPs. These findings suggest that PLA MPs subjected to natural weathering conditions may degrade more rapidly than under controlled laboratory conditions, emphasizing the importance of understanding environmental factors in predicting the fate of biodegradable MPs.

Disclaimer/Disclosure: This research was supported by the National Research Council of Science & Technology (NST) grant by the Korea government (MSIT) (No. CAP20024-000) and the Korea Institute of Toxicology (grant No. 2710008768).

3.06.P-We242 Investigating the Properties and Quantities of Submicrometer Particles and Nanoplastics Released from PET and PLA Teabags

Antonia Kellner[1]*, Nanna B. Hartmann*[2] *and Nicole Rita Elisabeth Posth*[1]*, (1)University of Copenhagen, Denmark, (2)DTU Sustain, Technical University of Denmark (DTU), Denmark*

Food contact materials (FCMs) are predominately made from polyethylene terephthalate (PET), due to its useful properties as a flexible, light weight, and heat-resistant material. In recent years, a shift to polylactic acid (PLA) has occurred as it is biobased and industrially biodegradable. A major concern regarding plastic FCMs is the observed release of micro- and nanoplastics as well as oligomers, for which human health risks are largely unknown. This study aims to fill an analytical gap by quantifying and characterizing the properties of submicrometer particles released from teabags when steeped in boiling water. Using the same experimental setup, leachates from PET and PLA teabags are produced, enabling a direct comparison of the released particles. The study has a specific focus on the detailed analysis of released oligomers, through chemical analysis and through their solubility in different solvents. These experiments will distinguish solid nanoplastic particles from (agglomerated) oligomers, measuring size ranges and concentration. To address this challenge, complementary analytical methods are used, including Fourier-Transform Infrared (FTIR) spectroscopy to determine the composition, Scanning Electron Microscopy (SEM) to observe the surface structural changes, Nanoparticle Tracking Analysis (NTA) determining particle size and concentration, and Liquid Chromatography Mass Spectrometry (LC-MS), identifying the oligomers, such as linear or cyclic, and their relative abundance. We expect a release of particles and hypothesize that in strong solvents most of the oligomers are dissolved and only few to no actual nanoplastics will be detected. The study will contribute to the mechanistic understanding of particle release from plastics, with methodological procedures that can also be extrapolated to other product categories such as household consumer products and synthetic textiles. This study will also contribute to a broader understanding of the release from nanoplastics and oligomers, paving the way for investigations of their environmental fate and potential human health and environmental risks.

3.06.P-We243 Identification of Biodegradable Plastic Fragmentation through Physical Abrasion in Freshwater

Gersan An*, Changhae Kim and jinho jung, Korea University, Republic of Korea*

Biodegradable plastics are increasingly being produced and consumed globally as alternatives to conventional plastics, with their market share steadily rising. However, while these plastics are designed to decompose effectively under specific temperature conditions in treatment plants, such conditions are rarely met in most natural environments, making complete degradation challenging. Similar to conventional plastics, biodegradable plastics undergo physical and chemical weathering, eventually breaking down into microplastics that persist in the environment. Although several researches have been conducted on the toxicity of biodegradable microplastics, there is a notable lack of studies addressing their environmental fate. Therefore, this study aims to investigate the physical weathering mechanism of biodegradable plastics within the laboratory scale. Polymer chips (1 × 1 × 0.2 cm) were exposed in the bottles that contains gravel and deionized water for a period of 90 days using roller and mixer device to simulate the flow. Five types of biodegradable plastics were tested: polylactic acid (PLA), polybutylene adipate terephthalate (PBAT), polybutylene succinate (PBS), polyhydroxybutyrate (PHB), and poly(3-hydroxybutyrate-co-3-hydroxy valerate) (PHBV). For comparison, two types of conventional plastics, polyethylene terephthalate (PET) and polystyrene (PS), were also tested. The physicochemical properties of the resulting microplastics were characterized using several analytical methods: field emission scanning electron microscopy (FE-SEM), Fourier transform infrared spectroscopy (FT-IR), X-ray photoelectron spectroscopy (XPS), while the remaining polymer chip were characterized with atomic force microscopy (AFM), X-ray diffraction (XRD), and Brunauer Emmett Teller (BET) surface area analysis. This study provides critical insights into the degradation mechanisms of biodegradable plastics in freshwater environments.

Disclaimer/Disclosure: Acknowledgments: This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-RS202400335682).

3.06.P-We244 Degradation of Biodegradable Plastics

Sevil Vafadar Afshar[1], *Alessio Boldrin*[2], *Thomas F. Astrup*[3], *Thomas H. Christensen*[1], *Anders E. Daugaard*[1], *Beatrice Rosso*[4], *Fabiana Corami*[4] *and Nanna B. Hartmann*[1], *(1)Technical University of Denmark, Denmark, (2)Quantis, Switzerland, (3)Rambool, Denmark, (4)Ca Foscari University of Venice, Italy*

Decades of extensive production and use of conventional plastics have led to their accumulation in the environment. Bioplastics (bio-based and/or biodegradable) have been promoted as a more sustainable alternative. However, the literature reveals conflicting conclusions regarding their suitability and environmental impact. A primary area of dispute concerns their biodegradability and the conditions necessary for proper degradation. In real-world settings, biodegradable plastics may not degrade as rapidly or efficiently as laboratory tests indicate. Here, we describe three activities that were conducted to address these issues: (1) a systematic literature review to explore the current level of knowledge, (2) a degradation test on consumer products made from biodegradable plastics was conducted based on an identified knowledge gap in the current literature, and (3) development of a novel oil-based method for extracting aged bio-microplastics from compost matrices. The review covered the degradation of biodegradable plastic in waste management environments (e.g., compost, sludge, or landfill) and the open environment (e.g., seawater, freshwater, or soil). The results highlight challenges in comparing and quantitatively analyzing data on plastic degradation due to methodological variations, including differences in testing methods, materials, and quantification strategies. Moreover, several research gaps and limitations exist. Notably, there is a need to intensify research on polyhydroxyalkanoates (PHAs), polybutylene adipate terephthalate (PBAT), and polybutylene succinate (PBS) to match the level of polylactic acid (PLA) and starch-based plastics. A degradation test was carried out on commercially available biodegradable plastics under simulated industrial composting conditions according to ISO 20200. The results indicated disintegration degrees between 75-100 % for all tested biodegradable plastic products, with five of ten reaching complete disintegration within 90 days. Finally, a method was developed to extract microplastics from these compost samples using oleoextraction. The outcomes of these studies offer valuable insights, particularly in guiding discussions about the prospective role of biodegradable plastics within society. Based on our findings, essential knowledge and data gaps will be highlighted, and suggestions will be provided regarding the direction of future research to assess their role as alternatives to conventional plastics.

3.06.P-We245 Toward Standardization in Microplastics Research: Development of an Extraction Protocol from Compost for ISO

Dean Velikov[1], *Frank Von der Kammer*[1], *Patrizia Pfohl*[2] *and Thilo Hofmann*[1], *(1)University of Vienna, Austria, (2)BASF SE, Germany*

The current economic model is producing plastics in large quantities, and despite our best efforts to recycle and reuse them, some still end up in the environment. With the potential to have negative impacts on flora and fauna, with the potential to be harmful to humans as well. These plastics age and fragment over time, generating microplastics, which vary in color, shape, and physicochemical properties. These differences in properties between different particles challenge their treatment as only one type of contaminant. Besides that, despite knowing that microplastics are present everywhere, there is still no standard method for their extraction and characterization from environmentally complex matrices. This is why we are in the process to standardize a method for the extraction and characterization of microplastics from compost, with a plan to have it finalized by 2027 or earlier. This standard will allow for reproducible and homogenized results, allowing the comparison of findings between different studies and laboratories. The developed extraction protocol consists of deagglomeration, organic matter removal, and density separation. The organic matter removal is done by Fenton oxidation, and the density separation employs calcium chloride. Not only would it target the extraction of fossil fuel-based non-degradable microplastics, but also fragments from biodegradable polymers. Fragments from biodegradable plastics could be present during the initial stages of the composting process but are not expected to be found in final composting products. To achieve the extraction of microplastics, the extraction protocol, under standardization, does not apply harsh conditions. Current results show that the herein developed method has high recovery efficiencies for PBAT microparticles without affecting non-degradable plastics and has negligible effect on the size of biodegradable ones. For the characterization of the particles, we are using a micro-Raman system that employs a 785 nm laser and a particle finder/analyzer software to automate the process. Currently, an interlaboratory study is ongoing to test and validate the presented extraction protocol. Furthermore, we aim to sample final compost products from industrial composting plants in Austria and Germany, comparing plants serving small and large communities.

3.06.P-We246 On the Fragmentation of Soil-Biodegradable Mulch Film: Assessment of Interim Particle Size Distributions and Modelling for Half-Life Predictions

Patrizia Pfohl[1], *Lars Meyer*[1], *Glauco Battagliarin*[2], *Sam Harrison*[3], *Cansu Uluseker*[3] *and Wendel Wohlleben*[1], *(1)BASF SE, Germany, (2)Research Biopolymers, BASF SE, Germany, (3)UKCEH, United Kingdom*

Soil-biodegradable mulch films are an innovative solution that not only promotes plant growth, but also helps to reduce plastic accumulation in agriculture, leaving no persistent microplastics behind due to complete polymer mineralization during biodegradation.

Biodegradation of polymers is not a homogeneous process, and several factors influence the fragmentation of biodegradable polymers, such as microbial colonization, the polymer (blend) composition and shape. The formation of defects, peninsula structures and increasing embrittlement during biodegradation leads to interim fragment formation, which is an inevitable part of the biodegradation process and and cannot be avoided. To gain a mechanistic understanding of copolymer blend fragmentation and biodegradation process, we studied biodegradation of a soil-biodegradable mulch film in soil, according to ISO 17556. A validated extraction technique, which is used for isolation of fragments of biodegradable plastics from soil was coupled with IR microscopy analysis to monitor fragment number, shape, size, and identity during biodegradation. The generated data was used for parameterization of the open-source FRAGMENT-MNP model. In addition, we determined the molar mass distribution at different biodegradation time points and assessed the ratio of hydrolyzed polymer to remaining polymer.

The combination of these methods allows for the comparison of fragmentation mechanisms of different types of copolymer blends and enable the prediction of the timepoint where the total particle counts of different size classes peak during the biodegradation process. Modeling approaches, further enable the prediction of half-lives of interim fragments, which will depend on the polymer type and environmental conditions. The revealing conclusion is that although interim fragments are formed during the biodegradation process, they will fully biodegrade until mineralized into CO2 and biomass.

3.06.P-We247 Degradable or Not – Field Study, Laboratory Experiment and Farmer Survey on Biodegradable, Conventional and Oxo-Degradable Plastics in Northern Climatic Conditions

Salla Kristiina Selonen[1], *Liisa Maunuksela*[2], *Venla Forsell*[3], *Annika Johansson*[3], *Sari Kauppi*[1], *Ansa Palojarvi*[4], *Essi Roininen*[2], *Milja Raisanen*[1], *Markus Sillanpaa*[3] *and Jyri Tirroniemi*[3], *(1)Finnish Environment Institute (SYKE), Finland, (2)Finnish Food Authority, Finland, (3)Finnish Environment Institute (Syke), Finland, (4)Natural Resources Institute Finland (Luke), Finland*

Plastic mulches reduce the need of pesticides and irrigation, but cause soil contamination with plastics. To reduce the harm, biodegradable plastics have been developed. Biodegradable mulch films are not collected from the fields after use, but mixed with the soil to decompose. However, the decomposition rate depends on environmental conditions.

We studied plastic residues in agricultural fields after use of conventional and biodegradable plastics in Finland, in northern climatic conditions. Also, degradation in warm and cold temperature were followed in laboratory and a survey for farmers was conducted.

In the field study, the highest concentration of microplastics (20µm-5mm) was observed at sites with oxo-degradable films. Biodegradable plastics in this size fraction were not analysed. In the fraction larger than 2 mm, the highest concentrations were found at sites with biodegradable mulch films for multi-season use, being about 100 times higher than at the sites with conventional polyethylene (PE) mulch films. In the survey for the farmers, 94% of the respondents announced to collect PE plastic fragments actively from soil (n = 66), whilst the corresponding share was only 12% for biodegradable plastics (n = 17). This may explain the low number of PE fragments found in the fields. The long degradation time of biodegradable plastics was also detected in the laboratory experiment. After 21 months of incubation, only slight signs of biodegradation in 21-22ºC and no degradation in 1-3ºC was detected.

These results imply that degradation of biodegradable mulching films can be slow in northern environmental conditions and that also biodegradable plastics can contribute to plastic pollution in agricultural soils. The environmental conditions should be taken into account in test standards and degradation criteria. In addition, product development is needed to find suitable materials for different environmental conditions.

The degradation of biodegradable mulching films in different climate zones is further studied in the project PAPILLONS in field conditions. This will give us valuable information on the factors affecting the degradation process in real environment.

Disclaimer/Disclosure: This presentation is about (1) MicrAgri project, funded by the Ministry of Agriculture and Forestry of Finland, (2) PlastLIFE project, co-funded by the European Union (LIFE21-

IPE-FI-PlastLIFE), and (3) PAPILLONS project, funded by European Union's Horizon 2020 Research and Innovation Programme (Grant Agreement Number 101000210).

3.06.P-We248 Environmental Behavior and Fate of 14C-Poly Lactic Acid in Soils
Sara Adeleh[1]*, Tabea Becker*[2]*, Roland Bol*[3]*, Sonja Herres-Pawlis*[2] *and Thomas Putz*[3]*, (1)Institute of Bio and Geosciences (IBG-3: Agrosphere), Research Center Jülich GmbH, Jülich, Germany, (2)Institute of Inorganic Chemistry, RWTH Aachen University, Germany, (3)Institute of Bio and Geosciences (IBG-3: Agrosphere), Forschungszentrum Julich, Germany*
With the increasing global production of plastics, transitioning to a circular model has become a priority. Bioplastics, derived from renewable sources, present a promising alternative to traditional plastics by potentially reducing CO2 emissions and dependence on fossil fuels. However, challenges persist regarding their recyclability and environmental fate. Understanding plastic degradation, particularly in complex environments like soil, is hindered by multiple variables, including polymer properties and environmental conditions, necessitating advanced techniques for precise evaluation.
The application of Carbon-14 (^{14}C) tracing in plastic degradation research offers a significant advantage by enabling the tracking of polymer decomposition pathways and the quantification of degradation products. Traditional biodegradation studies often overlook the fate of residual polymers, focusing solely on evolved CO_2. In contrast, ^{14}C labeling provides comprehensive insights into the remaining polymer fractions and their interactions within the environment.
Polylactic acid (PLA) is a biodegradable polymer that widely used for different applications due to its composability and potential to reduce dependence on fossil fuels. Previous polymers degradation studies demonstrate that if a polymer is not inherently prone to degradation, or if the environment lacks degrading agents the process is extremely slow. Conventional plastics, such as polyethylene (PE), degrade at a rate of less than 1% per year, whereas bioplastics can degrade completely within a few months. Based on this, we expect the degradation of PLA to occur as rapidly as other bioplastics, given favourable environmental conditions.
To advance this understanding, we have developed a laboratory-scale synthesis procedure for producing ^{14}C-labeled PLA. This modified synthesis pathway optimizes PLA production by addressing challenges such as the presence of unstable stereoisomers and impurities. The resulting ^{14}C-labeled PLA will be utilized in soil degradation and leaching studies, focusing on two soil types: sandy and silty. Conducted over 180 days to 12 months, these experiments will assess the impact of temperature, soil humidity, and organic manure on PLA degradation. The evolved CO_2 will be quantified using Liquid Scintillation Counting (LSC).

Disclaimer/Disclosure: Thanks to the BioPlastiCycle group for funding project number DBADC435 as work package 5.

3.06.P-We249 Chemical Contaminants in Biodegradable Products: A Comparative Study of Per- and Polyfluoroalkyl Substances and Heavy Metals in the Netherlands and New Zealand
Sean O'Connell[1]*, Nargiss Taleb*[2]*, Patricia Aguilar-Alarcon*[1]*, Martijn Korporaal*[1]*, Eva de Rijke*[1]*, Melanie Kah*[2]*, Lokesh Padhye*[3] *and* ***Antonia Praetorius***[1]*, (1)University of Amsterdam, Netherlands, (2)The University of Auckland, New Zealand, (3)Stony Brook University, United States*
Biodegradable products offer a viable solution to plastic waste, particularly for single use disposable plastics that are often entering the environment via littering, such as plastic bags, food packaging and coffee cups. However, these products contain chemical additives whose identity and corresponding environmental impact remain largely unexplored. Chemical additives are of particular concern in biodegradable products as their release into the environment may be accelerated via biodegradation of the product.
This project aims to quantify the amount of per- and polyfluoroalkyl substances (PFAS) and heavy metals in biodegradable products from both the Netherlands and New Zealand. Currently, regulation of biodegradability and compostability is much less rigorous in New Zealand than it is in the European Union. Furthermore, the difference in types and concentration of additives used in these biodegradable products between the two countries is unknown.
To address this knowledge gap, a comprehensive chemical analysis was conducted on ten selected biodegradable products from each region. Heavy metals were quantified via inductively coupled plasma-mass spectrometry (ICP-MS) following acid digestion. Solvent extraction was performed prior to ultra-performance liquid chromatography-high resolution mass spectrometry (UPLC-HRMS) analysis for the quantification of PFAS. Additionally, pyrolysis-gas chromatography-mass spectrometry (Pyr-GC-MS) was used to determine polymer composition. This revealed how the polymer composition influenced the types of additives present.

Our study revealed that many of the biodegradable products contained PFAS, including one composed of bagasse which was certified compostable. This study challenges the common perceptions of biodegradable products as being inherently environmentally benign by examining if their chemical profiles support these claims. This research also sheds light on the influence of regional policies and regulations on the use of chemical additives in biodegradable products, while identifying discrepancies between regions. Ultimately, this study can guide regulatory bodies in shaping future policies to ensure that biodegradable and compostable products meet high standards for both public safety and environmental protection.

3.06.P-We250 Laboratory to Field Scale: Ecological Relevance of Laboratory Tests for Environmental Reliable Ecotoxicity Assessment of Polymers

Marie Winter[1], Gabriele Broll[2], Bodo Philipp[3] and ***Karsten Schlich****[4], (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (2)Institute of Geography, University of Osnabruck, Germany, (3)Institute of Molecular Microbiology and Biotechnology, University of Munster; Fraunhofer IME, Germany, (4)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Polymeric compounds are included into various agrotechnical products. Given that synthetic polymers and modified natural polymers are subject to REACH, biopolymers can be regarded as important substitute components. Due to their natural origin, they remain unregulated, even though their complex molecular structure led to increased accumulation potential in the environment. As regulatory requirements and hazard evaluation concepts are missing, potential ecotoxicological impact is unknown. Our main aim was therefore to develop a systematic ecotoxicological hazard assessment encompassing terrestrial and aquatic toxicity screening for biopolymers. In order to ensure the reliability of the data collected and prove the ecological relevance, a combination of laboratory tests and field studies has been utilized.

We focused on alginate, cellulose fibers and active char formulated in a seed coating with sugar beet. The treated soil was incubated under laboratory conditions in glass vessels (without seed) and under field exposure in small-scale lysimeters (with seed) with drainage system for leachate collection. The components were applied as single substances (1000 mg/kg) and as cryomilled formulations (1 and 3 coatings/2.5 kg). Additionally, seed coatings (1 and 3 coatings/2.5 kg) were exposed (field exposure). Leachate was analyzed for its NPOC content to determine leaching of the substances and formulations. In case of leaching, aquatic ecotoxicity tests with algae (OECD TG 201) and daphnids (OECD TG 202) would be conducted. Soil samples were taken after 28 and 100 days of exposure so far to evaluate substance and formulation impact on microbial functionality. Therefore, we conducted ISO 15685 (Potential nitrification) and ISO 20130 (Extracellular enzymatic activities) test.

The results indicated stimulatory effects of biopolymers and formulations on enzymatic activities after 28 days both under laboratory and field exposure with comparable stimulatory tendencies. After 100 days, these tendencies were not visible anymore. Inhibitory impacts were determined for active char treatment after 28 days on enzymatic activities as well as potential nitrification and after 100 days on extracellular enzymes. Laboratory results overestimated the effects observed under field exposure, indicating that the laboratory approach is a conservative and protective tool for risk evaluation.

3.06.P-We251 The Impact of Fossil and Biobased Microplastics on Human Cells

Miguel Oliveira*[1], Monica Almeida[1], Miguel Tamayo-Belda[2], Carolina Frazao[1] and Francisca Fernandez-Pinas[2], (1)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (2)Universidad Autonoma de Madrid (UAM) Ciudad Universitaria de Cantoblanco, Spain*

Plastic pollution is one of the most significant environmental challenges of the twenty-first century, with microparticles now found in virtually all ecosystems. Humans are exposed to these particles through three primary routes: ingestion, absorption, and inhalation, and the potential effects largely depend on the composition, shape, and size of the particles. While most research on micro- and nanoplastics focuses on spherical or rod-shaped particles, with polystyrene (PS) being the most commonly studied polymer, the most widely produced plastics are polypropylene (PP) and low-density polyethylene (LDPE). Additionally, there has been a rise in the production of biobased polymers, which degrade faster than traditional fossil-based plastics in an effort to mitigate the harmful effects of conventional plastics. However, the impacts of these newer materials remain largely unknown.

To better understand the effects of micro- and nanoparticles on human health, five types of plastic three from fossil sources (LDPE, PS, and PP) and two from biological sources (PLA and PHB) were mechanically degraded and separated by size using stainless steel mesh filtration and the fraction below 1.6?m was chosen. Human cell lines from the liver (HepG2) and intestine (HCT116) were used as biological models and exposed to eight different concentrations of each plastic type and size range, starting from 1.28 µg/L to 100 mg/L. Cellular viability was assessed at three time points (24, 48, and 72 hours) using the MTT assay. In general, HCT116 cells showed greater sensitivity to the plastics than HepG2 cells, with toxicity being similar between fossil-based micro- and nanoplastics, but biobased present a higher impact than biobased microplastics. Our findings highlight the importance of further investigating the impact of novel biobased and biodegradable polymers on human health.

3.06.P-We252 Screening of the Environmental Safety of a Novel Biomaterial for Use as Alternative for Plastics

Lara Pinheiro[1]*, Charlene Smith*[2]*, Pilar Bolumburu*[2]*, Alysia Garmulewicz*[2]*, Liz Corbin*[2]*, Ceri Lewis*[1] *and Tamara Susan Galloway*[1]*, (1)Faculty of Health and Life Sciences, University of Exeter, United Kingdom, (2)Materiom, United Kingdom*

Bioplastics are products with enhanced biodegradability and/or of biobased source whose growing production has the potential to replace conventional petroleum-based plastics. Natural biopolymers such as chitosan and cellulose are the most abundant on the planet and can be used for bioplastic production. Here, a newly-developed chitosan-methylcellulose bioplastic was investigated for its environmental safety in terms of its disposal after use in terrestrial environments as compost. For this, ecotoxicological tests using three higher plant species exposed to different concentrations of the tested bioplastic were ran. Bioplastics were mixed in standard soil at 0.1, 1, and 10% (w/w) concentrations, and parameters of seed emergence, root growth and shoot growth were measured after 3 and 6 days after seed incubation in dark at 25±1ºC. The value for effective concentration to observe 50% of effect (EC50) was also estimated. There was a significant decrease in seed germination in seeds exposed to the 10% bioplastic treatment (avg. 8.3%) when compared to the control (avg. 98.89%). Previous studies have shown that plant seeds exposed to conventional plastic particles can have delayed seed emergence, but this could not be verified here as experiment was terminated at day 6. We hypothesize that delays in seed emergence might be related to reduced water availability caused by the bioplastic hygroscopic nature, and this is being currently tested. Root growth and shoot growth followed a similar pattern as seed emergence, with many zero values for root/shoot length at the 10% bioplastics treatment. EC50 values varied among species, and the dose-response curves highlight the datapoint gaps between treatments of 1%-10% bioplastics which calls for further experiments with a refined range of concentrations. In summary, the tested chitosan-methylcellulose bioplastic material showed no significant effects on seed emergence, root length, or shoot length in tested plant species at concentrations up to 1% bioplastic in soil (w/w). There appears to be a transient effect at a 10% concentration that can be related to changes in water availability caused by the bioplastic addition, and further tests are underway to confirm this. This study adds to the potential for using biobased materials to replace persistent, toxic plastics and for safely disposing the tested bioplastic in terrestrial environments as compost.

3.06.P-We253 The Effects of Microplastics Derived from General Plastics and Biodegradable Plastics on *Daphnia Magna*

Norihisa Tatarazako *and Yukiyo Okazaki, Ehime University, Japan*

The pollution of the oceans by plastics are one of the world's major environmental problems. In particular, there are concerns about the ecological effects of microplastics, which are the small pieces of polymers. In addition, although biodegradable plastics are said to be one solution to the problem of plastic waste in environment, there is no doubt that biodegradable plastics can also become the source of microplastics. There are many studies on the environmental behavior of these materials, but almost no examples of them having a negative impact in the actual environment, and the only reports we have are of laboratory tests, i.e., ecotoxicity tests. Furthermore, the test methods and endpoints used in these tests are diverse, and there is no standardized test method.

We have partially improved standard ecotoxicity testing methods and conducted Daphnia toxicity tests using microplastics of various sizes. We conducted a Daphnia test on microplastics derived from general plastics (PE, PP, PS) and microplastics derived from five types of biodegradable plastics obtained from manufacturers, and found that they showed different endpoints depending on their size. We also report on the differences in adsorption capacity and ecological impact of microplastics derived from biodegradable plastics and general plastics when exposed to polycyclic aromatic hydrocarbons.

3.06.P-We254 Characterization and Potential Toxicity of Environmentally-Aged Bioplastics

Aleksandra Karapetrova[1]*, Lisa Erdle*[2]*, Win Cowger*[3]*, Andrew Gray*[1] *and Jay Gan*[1]*, (1)University of California Riverside, United States, (2)Gyres, United States, (3)Moore Institute for Plastic Pollution Research, United States*

The global bioplastic production is expected to increase from 2.18 million metric tons in 2023 to 7.43 million metric tons in 2028. With bioplastics increasingly positioned as alternatives to traditional plastics, questions remain whether they truly biodegrade and if they can leach harmful additives into the environment. To assess environmental fate and risks of bioplastics, characterization of environmentally aged bioplastics is needed. In this study, three bioplastic drinking straw materials, poly lactic acid (PLA), polyhydroxyalkanoate (PHA), polyhydroxybutyrate (PHB), and a starch-composite bag, and two controls (polyethylene and paper) were considered. Items were exposed in California ocean water and soil environments for 64 weeks. The paper straw fragmented quickly, losing 75% of its initial weight in the first 8 weeks. In comparison, PHA, PLA, and PHB lost 25-50% of their initial weight in that time. Importantly, fragmentation alone does not equate to biodegradation; materials may break apart but persist as microplastics. To differentiate surface and structural changes in the materials, attenuated reflectance Fourier-transform infrared spectroscopy (ATR-FTIR) and scanning electron microscopy (SEM) tracked functional group shifts and morphological changes on the material surfaces. Spectral shifts can indicate whether there was biodegradation of the materials, and morphological changes and potential formation of micro- and nano-plastic particles. Additionally, targeted liquid chromatography and mass spectroscopy (LC/MS) was used to determine the occurrence of common plastic additives over time. A targeted analysis of phthalates, bisphenol-A, and 4-nonylphenol was conducted to determine the release of these common plastic additives from the bioplastic materials. Evaluation of bioplastic persistence in the environment is necessary to mitigate the global plastic pollution. This study provides insight into bioplastic end-of-life scenarios to inform public and policy decision-making.

3.06.P-We255 A Comparison Between Biodegradable and Conventional Mulch Films: Aptake and Impact on Marine Ecosystem Processes

***Rachel Coppock*[1]**, *Matthew Cole[1], Francesca De Falco[2], Elaine Fileman[1], Caroline Louise McNeill[1], Alexander Mead[3], Thomas Mesher[1], Christine Pascoe[1], Karen Tait[1], Richard C. Thompson[4], Michael Wilde[3], Malcolm Woodward[1] and Penelope Lindeque[1], (1)Plymouth Marine Laboratory, United Kingdom, (2)University of Plymouty, United Kingdom, (3)University of Plymouth, United Kingdom, (4)School of Biological and Marine Sciences, University of Plymouth, United Kingdom*

Biodegradable alternatives to conventional plastics are being developed largely in response to the impact of plastic pollution. This is most prevalent for products that are likely to end up in the natural environment, for example agrigultural mulch films. Biodegradable plastics are designed to degrade under certain conditions (e.g., elevated temperatures, low pH, etc). In the natural environment, biodegradables are more persistent, thereby posing a risk to biota and ecosystems. Here we use a flow-through mesocosm system to examine the fate (i.e., uptake and distribution within ecological compartments) and impacts on marine ecosystem processes (i.e., microbial community structure, nutrient flux, benthic-pelagic coupling, bioturbation) of microplastics over a three month period. Microplastics comprised cryo-milled (<500 µm) biodegradable (PBAT/PLA) and conventional (polyethylene) mulch film. Mesocosms were seeded with benthic macrofauna with differing functional traits (vertical conveyors, biodifusers, surface modifiers) and dominant pelagic copepods. Distribution: Abiotic (i.e., sediment, water, fluff layer) and biotic (i.e., invertebrates) samples were analysed by pyrolysis coupled to gas chromatography and mass spectrometry (Py-GC-MS), using chemical markers to detect the specific polymers in biodegradable and polyethylene films. Microbial community impacts: After three months exposure, prokaryotic communities differed between control, biodegradable and polyethylene treatments in the sediment and water column, indicating the added particulate load altered microbial composition in both compartments. Invertebrate communities: Exposure to both treatments resulted in shifts in plankton community composition. There was no effect of treatment on macrofaunal biodiversity, however biomass was significantly reduced when exposed to polyethylene. Benthic-pelagic coupling: Exposure to polyethylene microplastics resulted in copepods producing significantly smaller and slower sinking faecal pellets than controls. Bioturbation: In the polyethylene treatment, we observed shifts in the conveyance of nutrients and particles at sediment depths of 2 6 cm. Further, nutrient levels (e.g., nitrites, phosphates) in treatment sediments differed from controls. Our novel mesocosm exposure system highlights how biodegradable and conventional microplastics can become distributed via abiotic and biotic processes, with substantial impacts on ecosystems.

3.06.P-We256 It Depends Where it Ends - Understanding the Biodegradation Performance of Biodegradable Plastic Polymers Under Variable Environmental Conditions

***Christian Lott*[1]**, *Andreas Eich[1], Julian Rau[1], Alisa Berning[1], Ann-Sophie Rupp[1], Mireno Borghini[2], Giuseppe Suaria[2] and Miriam Weber[1], (1)HYDRA Marine Sciences, Germany, (2)CNR-ISMAR, Italy*

Short-chain-length polyhydroxyalkanoates (scl PHA) are readily biodegradable under suitable laboratory conditions. This makes them good reference materials also for field studies on biodegradable plastic polymers. However, several variables influence the performance of PHA in marine, freshwater and soil systems. In addition to temperature as the most important factor, the small-scale heterogeneity of environmental matrices and geographical locations must also be taken into account. Both area loss of films and surface erosion of thicker test specimens are suitable for assessing biodegradation in the environment if precautions are taken against physical forces and premature losses. Pre-weathering had little or no effect on the biodegradation of PHAs. The biodegradation rates of different co-polymers under different environmental scenarios from Central European agricultural soil to the deep sea are presented. In addition, we show how the results of laboratory, mesocosm and field studies can be made comparable through statistical modeling, how this enables predictions about the lifetime of products made from PHAs in the open environment, and how this can be incorporated into a life cycle analysis (LCA) and thus into the product environmental footprint (PEF).

3.06.P-We257 The Double-Edged Sword of Biodegradability: Lifecycle Carbon Impacts of Bio-Based Polymers vs. Fossil-Based Polymers

*Akshat Sudheshwar, **Kealie Vogel**, Gustav Nystrom, Nadia Ilaria Malinverno, Monica Arnaudo, Carlos Gomez-Camacho, Didier Beloin-Saint-Pierre, Roland Hischier and Claudia Som, EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland*

Bio-based materials are often perceived as climate-neutral, but this assumption requires careful examination. This study conducts a lifecycle scenario analysis of biopolymers made from wood specifically lignin and cellulose nanofibrils, along with common fossil-based polymers (e.g., PET) and PLA to assess their carbon footprints. Results reveal a broad spectrum of climate impacts ranging from carbon-positive to carbon-negative for the woody biopolymers. In contrast, fossil polymers show lower variability in carbon footprints but lack carbon-negative lifecycle scenarios. The variabillity in the woody biopolymers' footprints was influenced by their end-of-life (EoL) scenarios. A no emissions EoL scenario assumes wood derivatives are not biodegradable and release no CO2 or CH4 at EoL, potentially resulting in negative carbon footprints. In contrast, the carbon footprints for landfilling scenarios are the highest owing to the assumed biodegradation and atmospheric emissions of biogenic CO2 and CH4. Thus, the incineration scenario for biopolymers, resulting in only biogenic CO2 emission at EoL, leads to a lower lifecycle carbon footprint vs. landfilling. The EoL possibilities for fossil non-biodegradable polymers are limited (landfilling without degradation, incineration, or recycling), only allowing for CO2 emissions and not the more potent CH4. Hence, while wood derivatives may offer negative carbon footprints, their worst lifecycle scenario has almost thrice the carbon footprint of the worst PET use case.
These results as computed through LCA methods therefore counterintuitively underscore that the non-biodegradability of fossil plastics, which has led to the crises of macro- and micro-plastic pollution, is seemingly favorable from a climate perspective. Strategies to improve the durability and recyclability of biobased products would reduce emissions but may compromise biodegradability. This highlights a potential trade-off in environmental objectives, where priorities like reducing plastic pollution and addressing climate change may demand conflicting EoL strategies. The current focus on carbon emissions has therefore overshadowed the broader motivations behind establishing a bioeconomy. Existing LCA tools may not be ideal to capture all sustainability advantages of biopolymers impacts from, e.g., reliance on intensive agriculture for biopolymer feedstocks are effectively incorporated, but not environmental benefits like reducing plastic pollution.

3.06.P-We258 Bio-Based Polymers in Thermosetting Coatings: Insights and Future Directions From the EU SAFERCOAT Project Towards More Sustainable Solutions

***Joana Figueiredo**[1], João Tedim[2], Ângela Cunha[1] and Roberto Martins[1], (1)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (2)CICECO - Aveiro Institute of Materials, Department of Materials and Ceramic Engineering, University of Aveiro, Portugal*

Polymers are fundamental in modern society due to their versatility and widespread applications, from everyday products to specialized industrial uses, such as protective coatings. However, the environmental impacts of traditional synthetic coatings, including dependence on fossil resources, limited biodegradability, and disposal challenges, have driven the development of bio-based thermosetting coatings (bioTC). BioTC, formulated with a minimum of 30% bio-based building blocks, such as lignin and vegetable oils, are increasingly explored as sustainable alternatives due to their biodegradability potential. Although bioTCs show promise, their thermal stability, chemical resistance, and mechanical durability are limited compared to traditional coatings, which restricts their use in high-demand applications such as maritime protective coatings. To address these issues, nanotechnology might be used to immobilize active ingredients (e.g., polymer-hydrolyzing enzymes) in smart nanomaterials (e.g., layered double hydroxides). The EU SAFERCOAT project proposes this innovative approach to extend the lifespan of TC coatings by controlling the undesired early leaching of active ingredients, offering ecotoxicological benefits compared to commercial soluble forms. The project aims to develop smart or stimuli-responsive nanoadditives to be incorporated in novel multifunctional and eco-friendly bioTC to enhance the polymer s (bio)degradability at the end of service life. Despite these advancements, challenges remain, including achieving high-performance standards, minimizing toxicity, and promoting end-of-life degradation. While bio-based coatings offer eco-friendly potential, their (bio)degradability can be limited to specific conditions. Moreover, although research on the environmental impacts of bio-based polymers is growing, most studies focus on bioplastics, leaving a critical gap in the assessment of the toxicity and hazard of bio-based coatings and their leachates in marine environment. Therefore, this study aims to provide a comprehensive review of the state-of-the-art in terms of bio-based coatings, identifying existing gaps and limitations and addressing the possible future directions towards the development of truly eco-friendly and high-performance thermosetting coatings with enhanced biodegradability at the end of service life.

3.07.A Wide-Scope Target and Non-Target Screening Strategies for Enhanced Chemical Coverage in Environmental Monitoring and Chemical Exposome Assessment

3.07.A.T-01 Assessing Extraction Methods for Chemical and Effect-Based Analysis of Environmental Contaminants in Breast Milk

***Naroa Lopez-Herguedas*[1]**, *Georg Braun[1], Niklas Wojtysiak[2] and Beate Escher[2], (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Department of Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Population growth has increased chemical production and human exposure to xenobiotics that may impact health. Under the "One Health" approach, which links human, animal, and environmental health, exposomics investigates cause-effect relationships of exogenous compounds. This study aimed to develop an extraction method for detecting a broad range of xenobiotics in breast milk using an effect-based approach to assess their biological impact. An existing method for human plasma combining passive equilibrium sampling (PES) with solid-phase extraction (SPE) was adapted for high-throughput analysis of breast milk samples from volunteers, both spiked and unspiked. However, neurotoxicity bioassay results revealed precipitation-associated interferences in the final extracts, indicating that the initial protocol inadequately removed matrix components such as lipids. A simplified solvent precipitation method with 0.22 µm PTFE filtering was introduced to enhance fat removal.Polar and semi-polar contaminants were analyzed with liquid chromatography-high resolution mass spectrometry (LC-HRMS), and hydrophobic compounds with gas chromatography-high resolution mass spectrometry (GC-HRMS). A neurotoxicity bioassay based on the inhibition of neurite outgrowth in differentiated SH-SY5Y cells evaluated the effects of the contaminants.
Results highlighted challenges in integrating chemical analysis and bioassays within the same workflow. The adapted protocol failed to sufficiently remove fat content, likely causing the cytotoxicity observed during neurite outgrowth measurement. Meanwhile, solvent precipitation led to compound loss and insufficient matrix removal: recovery rates in the chemical analysis were below 60% for over 80% of compounds, while effect recoveries reflected matrix effects rather than neurotoxic activity. Further optimization is required to reduce lipid content and enhance compound extraction before scaling up to larger sample sets. Incorporating a saponification step into the plasma protocol may improve lipid removal. Additionally, a non-target screening prioritization would provide a more comprehensive overview, reducing the risk of overlooking neurotoxic compounds excluded from the target analysis.

3.07.A.T-02 CPxplorer and Silicone Wrist Bands as Rapid Tools for Evaluating Human Exposure to Polychlorinated Alkanes

***Idoia Beloki Ezker*[1]**, *Alex Javelle[2] and Thanh Wang[1], (1)Department of Physics, Chemistry and Biology (IFM), Linkoping University, Sweden, (2)Sciences et Proprietes de la Mati re, University of Rennes, France*

Chlorinated paraffins (CPs) are complex industrial mixtures primarily made of polychlorinated alkanes

(PCAs, CnH2n+2-xClx) but also byproducts. CPs are used in metalworking fluids, lubricants, flame retardants, and PVC additives. Despite their extensive utility, PCAs are considered persistent, bioaccumulative, and toxic, leading to the international ban of short-chain CPs (C10-13, SCCPs) in 2017. Medium- and long-chain CPs (C14-17, MCCPs; C17-30, LCCPs) remain unregulated due to lack of exposure and risk assessment data. This results from the analytical challenge of PCA quantification, which lacks suitable standards and must address the strong overlap of millions of isomers. Accordingly, there is a knowledge gap on human exposure to PCAs. Dermal contact, and ingestion of indoor dust and organic films (IOFs) are some of the main pathways for human exposure to PCAs. Silicone wristbands (SWBs), made of polydimethylsiloxane, are non-invasive, flexible and cost-effective tools for monitoring personal exposure to chemicals like pesticides and flame retardants. However, due to analytical challenges with PCAs, only one study has explored their use for PCA exposure assessment. Our study evaluates SWBs as a personal sampling tool for measuring indoor PCA exposure and proposes the use of the open-source Skyline software together with an in-house developed app (CPxplorer) for rapid data processing and quantification of PCAs. In this study, 32 volunteers wore pre-cleaned SWBs for seven days during June 2024 in Sweden. The data from the SWB study was evaluated and quantified using Skyline and CPxplorer. Preliminary results showed the highest levels for ?PCAs-C14-17 (37.0 µg/g) in the SWBs, followed by ?PCAs-C10-13 (7.8 µg/g) and ?PCAs-C18-30 (3.9 µg/g). In combination with our previous data from indoor dust and IOF, these PCA patterns suggested indoor dust as a key exposure contributor. Moreover, higher PCA levels were found in households built after 2017, aligning with the SCCP ban. Children showed higher exposure than adults, likely due to greater dust contact. Dermal exposure estimates were measured at 12.4, 43.7, and 0.2 µg/kg bw/day for ?PCAs-C10-13, ?PCAs-C14-17 ,and ?PCAs-C18-30, respectively. These results indicated that SWBs, combined with data from indoor matrices, offer a promising method for assessing PCA exposure. The study also validates the use of Skyline and as efficient tools for PCA analysis and quantification.

3.07.A.T-03 Exploring Metal-Organic Framework-Coated Blades for Direct and High-Throughput Screening of Xenobiotics in Urine

Juan Francisco Ayala Cabrera[1], *Isaac Negrin-Santamaria*[2], *Juan H. Ayala*[2], *Jorge Pasan*[3], *Veronica Pino*[2] *and Olatz Zuloaga*[4], *(1)Plentzia Marine Station, University of the Basque Country, Spain, (2)Laboratorio de materiales para Analisis Qu mico (MAT4LL), Departamento de Qu mica, Unidad Departamental de Qu mica Anal tica, Universidad de La Laguna, Spain, (3)Laboratorio de materiales para Analisis Qu mico (MAT4LL), Departamento de Qu mica, Unidad Departamental de Qu mica Inorganica, Universidad de La Laguna, Spain, (4)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain*

The analysis urine is one of the most desirable matrices to assess the exposure of humans to a vast variety of xenobiotics that could lead to hazardous and undesirable effects on our health. From an analytical point of view, the application of human biomonitoring programs in hospitals poses a huge challenge since the analysis of urine usually requires a high working load which results in the delay of the results difficulting the decision making. In this way, high-throughput screening approaches such as ambient ionization mass spectrometry (AIMS) that allows both the preconcentration, clean-up and fast analysis of the samples could provide a step forward to the implementation of biomonitoring programs of complex matrices in the medical field. To expand such biomonitoring tools, in this work, metal-organic fragmework (MOF) coated blades were tested for the target and suspect screening analyses of xenobiotics in urine by coated blade spray-high-resolution mass spectrometry (CBS-HRMS).
First of all, three different MOF-coated blades were synthesized and properly characterized. After that, both the extraction and desorption of selected analytes was carefully optimized by chosing a fast extraction procedure as well as the most suitable MOF-coated blade type, desorption solvent and voltage. Under optimal conditions, the CBS-HRMS methodlogy was validated achieving limits of detection down to 0.03 ng/mL as well as a good precision (RSD < 30%) and linearity (R2 > 0.99). To enhance the throuhput and the reliability of the analysis, a semi-automated acquisition consisting of 3 desorptions in 5 min and an adequate suspect screening workflow was proposed to sort out the challenges of carrying out these approaches with AIMS. The screening method was then applied to the analysis of urine samples collected from volunteers at the University of the Basque Country (Spain) showing the capabilities to both fastly quantify and identify xenobiotics in this complex biofluid and its potential for the medical field.

3.07.A.T-04 Prioritizing Candidate Structures in Non-Targeted LC/ESI/HRMS Analysis by Combining Machine Learning Predictions

Wei-Chieh Wang*, Chimnaz Emrah, Amina Souihi, Pilleriin Peets and Anneli Kruve, Department of Materials and Environmental Chemistry, Stockholm University, Sweden*

Non target screening with liquid chromatography high resolution mass spectrometry (LC/HRMS) has rapidly gained popularity in detecting and identifying environmental hazards. The primary tool for structural elucidation of the detected LC/HRMS features is MS2 spectra. However, the ambiguity in these spectra results in long lists of candidate structures, necessitating further investigation to identify the correct one. Empirical analytical information predicted by machine learning (ML) models holds promise in reducing the candidate list and increasing the confidence in certain candidate structures by deprioritizing the candidates that mismatch experimental results.

To evaluate the efficiency of different types of empirical analytical information, we assess five ML prediction models for their ability to reduce the candidate lists. Specifically, these included: (1) two retention time (RT) prediction models, MultiConditionRT and Retention Time Index (RTI); (2) an ionizability prediction model; (3) a sodium adduct prediction model, and (4) the similarity between experimental and in-silico MS2 spectra from CFM-ID. The selected models were used to prioritize the structural candidate lists generated from SIRIUS+CSI:FingerID. Various thresholds were applied to determine whether candidates should be deprioritized, allowing for the evaluation of each model's performance. Additionally, the potential of combining information from these models was explored. The results indicated that RT predictions could provide the best performance in terms of eliminating the greatest number of candidates (efficiency) while avoiding filtering out the correct structures (accuracy). Nonetheless, the results from the preliminary tests for combining the predictions revealed an undesirable rate of correct candidate removal and highlighted the shortcomings of the harsh filtering implementation. A probabilistic approach to prioritize structure candidates is being considered to address the current challenges and facilitate structure elucidation in NTS analysis. In particular, the proposed method will leverage Bayesian learning, treating the predictions from ML models as expert knowledge to prioritize the candidate and increase confidence in structure elucidation.

3.07.P-Mo226 What's in Our Consumer Products? Target, Suspect, and Non-Target Screening

Lisa Marina Reinhardt[1]*, Sam Hulscher*[2]*, Maria Margalef Jornet*[2] *and Sicco Brandsma*[2]*, (1)University of Copenhagen, Denmark, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands*

Various studies have examined the presence of potentially harmful additives in consumer products like food contact materials and children's toys. These additives, including flame retardants (FRs), plasticizers, and other substances, are intentionally added to improve the performance of plastics. However, because most additives are not tightly bound to the polymer, they can leach out during use, potentially exposing users to toxic chemicals. While the European Union has regulations to control certain harmful substances in plastic toys, such as PBDEs, phthalates, and BPA, these chemicals still enter the market due to poor recycling practices or lack of regulation in manufacturing countries.

To assess whether consumer products purchased in the Netherlands and the U.S. were contaminated with regulated or unregulated compounds, a selection of 65 food contact items, hair accessories, kitchen utensils, and toys was analyzed for the presence of various flame retardants, phthalates, and plasticizers. In the second phase of the project, non-targeted and suspect screening was conducted to explore additional substances present in these consumer products.

The results showed widespread contamination with hazardous chemicals. TBBPA was the most commonly detected flame retardant, followed by BDE-209. In 70% of the plastic products, BDE-209 exceeded the EU's unintentional trace contaminant limit of 10 mg/kg, and more than six different FRs were detected in 60% of the products. DecaBDE replacements like DBDPE and TTBP-TAZ were also found. High levels of phthalates and plasticizers were found in toys, including five substances classified as substances of very high concern (SVHCs) by ECHA, which are linked to hormone disruption, reproductive toxicity, and cancer. Legal limits were exceeded for four of these substances, with DBP surpassing the limit by 200 times. The plasticizer DEHTP was found in twelve toys, with concentrations up to 50% of the total weight.

The data processing for the non-target and suspect screening is ongoing. The detected features were annotated using publicly available Spectral Libraries (MassBank EU and MassBank North America) and the plastCHEM Analyte List. Additionally, the polymer type of each consumer product was determined to examine any patterns related to the type of polymer used.

3.07.P-Mo227 Can the Use of Menstrual Products Contribute to Chemical Exposure?

Lara Cioni, *Julia Calvo Salvador and Ethel Eljarrat, Institute of Environmental Assessment and Water Research - Spanish Council for Scientific Research (IDAEA-CSIC), Spain*

Menstrual products, fundamental to maintaining hygiene, preventing infections and ensuring participation in our society during menstruation, have been shown to contain chemicals with potential toxic effects, like phthalates (PAEs) and per- and polyfluoroalkyl substances (PFAS). Since the vulvar and vaginal tissues in contact with these products have high chemical absorption capacity, the use of these products might contribute significantly to human exposure. However, the studies investigating this exposure pathway are still scarce and limited to few products and chemicals. In this study, we wanted to expand our understanding of human exposure through the use of menstrual products by quantifying 4 classes of chemicals of concern for human health, PAEs, organophosphate esters (OPEs), non-phthalate plasticizers (NPPs) and PFAS, in both single-use and reusable menstrual products. A total of 41 menstrual products (10 sanitary pads, 8 panty liners and 9 tampons, 4 reusable sanitary pads, 4 menstrual panties and 6 menstrual cups) were analyzed for 9 PAEs, 17 OPEs, 10 NPPs 21 PFAS. To estimate the contribution of dermal contact with menstrual products to human exposure, the estimated daily intakes (EDI) were calculated assuming the worst-case scenario of 100% release of the chemicals from the products and 100% absorption through the skin. The combination of PFAS and plasticizers analysis showed that a wide variety of chemicals can be present in menstrual products. All types of menstrual products analyzed had detectable concentrations of PAEs, OPEs and NPPs, while PFAS were only detected in reusable menstrual products. Differences in detection frequencies and concentrations were observed across different products potentially due to differences in product design. Reusable sanitary pads showed the highest concentrations of PAEs and OPEs and menstrual panties showed the highest PFAS concentrations. The highest NPPs concentrations were observed in single-use sanitary pads and panty liners. For PAEs, OPEs and NPPs, worst-case scenario estimates showed that using these products might contribute significantly to human exposure. As an example, for reusable sanitary pads the EDI for OPEs (median: 213 ng/kg bw/day) was above estimates for dietary exposure (62-103 ng/kg bw/day), which is considered the main OPEs exposure route. These results highlight the need investigate the release of these chemicals from menstrual products to the skin to provide more realistic estimates.

3.07.P-Mo229 Chemical Background in Blood Microsampling Devices by Non-Target Chemical Exposomics

Solveig Thiele, *Benilde Bonnefille, Stefano Papazian and Jonathan W. Martin, Department of Environmental Science (ACES, Exposure & Effects), Science for Life Laboratory, Stockholm University, Sweden*

Blood microsamplers are of interest for exposomics applications as they enable quantitative and high-frequency self-sampling of individuals outside of the clinic. These devices, being simple to use and minimally invasive, may be deployable by laypeople and shipped at room temperature, facilitating high-throughput sampling at cohort-scale to comprehensively characterize the chemical exposome in human blood. One challenge in their implementation is the chemical background they can introduce, which may lead to false-positives when characterized by liquid-chromatography coupled to high-resolution mass-spectrometry (LC-HRMS). Here, the chemical background of several popular dried- and liquid-blood devices was assessed by sampling high-purity water, contrasting the resulting total ion current (TIC) intensities, number of non-target molecular features detected, the peak area distributions of all features, and their chemical characterization.

Using LC-MS grade water as a blood proxy, we assessed the chemical background of 8 commercially available devices: Capitainer® B and B50 (Capitainer AB, Solna, Sweden); Neoteryx Mitra® VAMS® (Neoteryx, Torrance, CA, USA); Tasso-M20 and 3 versions of Tasso+ (Tasso, Inc., Seattle, WA, USA); and TAP® II Lithium Heparin (LiH) (YourBio Health, Inc., Medford, MA, USA). After sampling, the water was left to dry overnight. Then, each device (n = 4 replicates) was extracted with either 60:40 ACN:H2O or 60:40 MeOH:H2O with a 15 min sonication, followed by centrifuge filtration (0.2 µm, Nylon). Analysis was performed by reversed-phase chromatography (Acquity BEH C18, Waters), and mass spectral data were aquired in full scan (m/z range 80 920) and by data-independent MS/MS in ESI±, using an Orbitrap Exploris 480 (ThermoFisher Scientific). Raw data were pre-processed using the open source software MS-DIAL (v4.9).

Our study showed that chemical background varies greatly between devices, with some specific contaminations (e.g., nicotine in Capitainer B50) and some being shared across multiple devices (e.g., diphenyl phosphate in all Tasso devices and Mitra VAMS). Overall, 3 samplers have a comparably low chemical background: Neoteryx Mitra VAMS, Tasso+ Plasma, and TAP II LiH. Other devices may still be more appropriate considering sampling volumes and ease of use. Investigating the chemical background of microsamplers facilitated by the use of collection and field blanks will be crucial for chemical exposome studies in human blood.

3.07.B Wide-Scope Target and Non-Target Screening Strategies for Enhanced Chemical Coverage in Environmental Monitoring and Chemical Exposome Assessment

3.07.B.T-01 Echoes of Exposure: Unveiling Chemical Exposome in Human Reproductive System with A Non-Target Analysis Approach Using High-Resolution Mass Spectrometry

Han Sun[1]*, Emil Egede Frøkjær*[1]*, Michala R. Birch*[2]*, Lærke Priskorn*[2]*, Niels Jorgensen*[2]*, Margit Bistrup Fischer*[2]*, Gylli Mola*[2]*, Casper P. Hagen*[2]*, Violetta Dubiel Stæhr*[3]*, Henri Goldstein*[3]*, Niels E. Skakkebaek*[2]*, Anders Juul*[2]*, Ursula Bentin-Ley*[4]*, Hans Krog*[4]*, Li J. Mortensen*[5]*, Martin Blomberg Jensen*[5]*, Mette Lorenzen*[5]*, Anna-Maria Andersson*[2]*, Anders Rehfeld*[2] *and Martin Hansen*[1]*, (1)Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (2)Department of Growth and Reproduction, Copenhagen University Hospital Rigshospitalet, Denmark, (3)Gyn kologisk Klinik v/ Henri Goldstein, Denmark, (4)Dansk Fertilitetsklinik, Denmark, (5)International Center for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health (EDMaRC), Copenhagen University Hospital & Division of Translational Endocrinology, Department of Endocrinology and Internal Medicine, Co, Denmark*

Parental exposure to synthetic chemicals prior to conception may have critical impacts on fertility and reproduction. Therefore, it is essential to establish highly sensitive analytical methods to investigate the occurrence of xenobiotics and their metabolites at trace level in the reproductive fluids from females and males. In this study, a sophisticated solid-phase (micro)extraction (µSPE) method covering a broad spectrum of chemicals was applied to prepare analytical samples from various biological matrices, including serum paired with follicular fluid (FF) from 12 female participants and blood paired with seminal fluid (SF) from 12 male participants, all receiving fertility treatment. The chemical exposome was characterized by a non-target analysis (NTA) approach using Orbitrap-based high-resolution tandem mass spectrometry (HRMS) platform hyphenated to capillary- (cLC)/nano-flow liquid chromatography (nLC). The NTA workflow was optimized and applied using commercially available software Compound Discoverer 3.3 to decipher the acquired HRMS data, including spectra analyses, structural elucidation and annotation via in-house and public available databases matching for identifications. Isotope-enriched analogues of xenobiotics were added to every sample to enable recovery calculation, matrix effect evaluation, and feature identification.

By applying the NTA workflow, we could assign unambiguous molecular formulas to 234 and 83 prioritized features detected in nLC- and cLC-HRMS, respectively. Further spectral inspections achieved identifications of a total of 117 compounds with high confidence (? level 2). Notably, 21 xenobiotics were detected in FF or SF for the first time, indicating that they can cross blood-follicle/testis barriers and highlighting their potential risks for fertility. Moreover, multiple PFAS were detected in FF but not in SF samples, addressing gender-specific accumulation in the reproductive system and possible implications for infertility. In conclusion, significant preconception exposure to various xenobiotics was observed in both males and females undergoing fertility treatment. Multiple endocrine disruptors have been shown to cross blood-follicle/testis barriers, suggesting their potential relevance to male and female fertility impairments. The results provide knowledge needed for the construction of realistic human low-dose mixture exposure for the study of its putative impacts on human fertility.

Humans are exposed daily to a myriad of xenobiotics through diet, inhalation, and direct contact. Collectively, these lifelong exposures constitute the chemical exposome. However, exposure during pregnancy and early childhood is particularly concerning, as it can lead to significant adverse health outcomes. To comprehensively characterize this exposome, chemical profiling via high-resolution mass spectrometry serves as a powerful tool for uncovering the intricate chemical landscape affecting human health.
This study focuses on identifying xenobiotics in cord blood serum samples from pregnant women, aiming to assess the prenatal chemical exposome. Over 500 samples were collected from the Barcelona Life Study Cohort (BiSC) and processed using a standardized protocol involving deproteinization, evaporation to dryness, and reconstitution in MeOH:H2O (50:50), targeting polar to moderately polar non-volatile xenobiotics. The analysis was conducted using liquid chromatography coupled with trapped ion mobility spectrometry and high-resolution mass spectrometry (LC-TIMS-HRMS), employing optimized data acquisition modes (bbCID and PASEF). More than 2,500 xenobiotics were screened in a targeted manner, identifying >100 chemicals across various classes along with their metabolites, in concentration ranges from high ng/mL to low mg/mL. These included many pharmauceuticals, with those associated with labor at detection frequencies >80% (e.g., bupivacaine), food-derived compounds with high detection frequencies (around 90-100%) (e.g., caffeine and its metabolites), plastic additives in varying detection frequencies, from 10 to 90% (such as phthalate metabolites and bisphenols), pesticide metabolites at low detection frequencies (e.g., the captan metabolite 1,2,3,6-tetrahydrophthalimide), as well as highly frequent industrial chemicals (e.g., certain PFAS) among some others.
The findings revealed that specific exogenous chemicals can cross the placental barrier, potentially posing risks to the developing fetus. The study demonstrated the ability of advanced instrumentation, such as LC-TIMS-HRMS, in combination with generic sample preparation protocols, to be leveraged for broad targeted chemical coverage in the investigation of fetal exposure to xenobiotics. Future efforts will incorporate expanded suspect screening strategies to identify additional chemicals, further refining the holistic definition of the chemical exposome during prenatal stages.

Disclaimer/Disclosure: The BiSC cohort study has been funded by the European Research Council (ERC) under Grant Agreement No. 785994 (AIR-NB). We thank all the BiSC families for their kind participation in the project. This research has received funding from the European Union under the Marie Skłodowska-Curie Postoctoral Fellowship Grant Agreement 101104517. The study was also supported by the Hellenic Foundation for Research and Innovation under the 3rd call for H.F.R.I. scholarships for PhD candidates (Grant number: 6627), and SETAC Europe with the SETAC Europe 2025 Registration Grant - SETAC Europe Students.

3.07.B.T-03 Single Drop, Multiple Findings: Feasibility of Dried Blood Spots for Broad Chemical Coverage in Exposomics/Metabolomics

***Vinicius Verri Hernandes**[1], Maximilian Zeyda[2], Benedikt Warth[3] and Lukas Wisgrill[2], (1)University of Vienna, Austria, (2)Department of Pediatrics and Adolescent Medicine, Comprehensive Center for Pediatrics, Medical University of Vienna, Austria, (3)1.Faculty of Chemistry, Department of Food Chemistry and Toxicology, University of Vienna, Austria / 2.Exposome Austria, Research Infrastructure and National EIRENE Hub, Vienna, Austria, Austria*
Dried blood spots (DBS) are a stablished sample at newborn screening program for the screening of metabolic diseases. As such, it holds great potential as a simple, non-invasive and alternative sample for the assessment of chemical exposure. Nevertheless, the systematic evaluation of extraction efficiency and matrix effects for a large set of exposure compounds, along with the evaluation of additional compounds detected by non-targeted data analysis has not yet been conducted. Here we present the results of a 20-min LC-HRMS methodology for non-targeted exposomics research on DBS samples, including detailed analytical performance for 223 highly diverse exposure chemicals. Four distinct extraction protocols were compared by using pre- and post-spiked DBS prepared and extracted in a quantitative manner. The selected optimal extraction protocol presented promising results for a large number of compounds, with around one third of all compounds fulfilling a narrow analyte acceptable range (80 120%) and more than 50% falling into a broader acceptable recovery range (50 150%). Reproducibility was also acceptable, with median RSD for recovery at 18%. Similarly, matrix effects presented a median value of 72%, with

RSD at 14%. Untargeted data analysis was used for the annotation of endogenous molecules such as amino acids at high confidence levels, showcasing the potential for combined exposomics/metabolomics research. Ongoing experiments and data analysis include the application of the method to a small pilot study with DBS collected from six smoking and non-smoking donors as well as the estimation of limits of detection by using DBS samples spiked a low concentration level . In the future, the method should be applied to a large-scale screening programme for the evaluation of exposure levels and trends in such a vulnerable population.

3.07.B.T-04 Chlorinated Paraffins in Novel Plant-Based Foods
Alicia Macan Schonleben[1]*, Adam Cseresznye*[1]*, Shanshan Yin*[2]*, Thomas McGrath*[3]*, Stijn Bosschaerts*[1]*, Alexander van Nuijs*[1]*, Adrian Covaci*[1] *and Giulia Poma*[1]*, (1)Toxicological Centre, University of Antwerp, Belgium, (2)Key Laboratory of Pollution Exposure and Health Intervention of Zhejiang Province, Zhejiang Shuren University, China (Mainland), (3)Institute of Health and Environment, Seoul National University, Republic of Korea*
In recent years, plant-based (PB) diets (such as veganism or vegetarianism) have become increasingly popular in Western countries. Along with this popularity, the demand and market for novel plant-based foods (NPBFs) grew rapidly in the last years, offering a large variety of often ultra-processed alternatives. The degree of food processing has been associated with potential contamination of different chemicals, among these also chlorinated paraffins (CPs). CPs are complex mixtures of polychlorinated n-alkanes (PCAs). They vary in chain-length and chlorine content (30-70%) and can be divided into short-chain (SCCP, C10-13) restricted as persistent organic pollutants (POPs) , medium chain (MCCP, C14-17) and long-chain (LCCP, C>17) CPs. These compounds are of high concern for the environment due to their persistent, toxic and bioaccumulative properties and their high production volume.
In this study, we investigated the occurrence and patterns of CPs (C8-36, Cl3-30) in NPBFs (n = 50) purchased in Europe using liquid chromatography coupled to high-resolution mass spectrometry. Homologue identification and integration were performed with the R-based open-source software CP-Seeker v1.1. The quantification of each CP class was conducted by chlorine-content calibration using mixtures of SCCPs, MCCPs and LCCPs (C18-20). Exposure and risk assessment was performed for three assumptive dietary scenarios; flexitarian, vegetarian and vegan diet.
?SCCPs could be detected in 56% of the samples with values ranging from <LOQ to 27 ng/g wet weight (ww), ?MCCP had a detection frequency (DF) of 88% (<LOQ-133 ng/g ww) and ?LCCPs had a DF of 24% (<LOQ-19 ng/g ww). PB-cheese was the most contaminated food category for ?SCCPs (<LOQ-27 ng/g ww) and LCCPs (<LOQ-13 ng/g ww), ?MCCPs were higher in PB-cold meat (<LOQ-133 ng/g ww). PB-cheese consists mostly of coconut oil and CP contamination has been associated with lipid content, which could explain the elevated levels found in the samples. The consistently high ?MCCP levels in PB-cold meat samples suggest a specific similar processing technique, which could introduce this contamination. Compared with conventional foods, NPBFs had higher CP concentrations than their animal-based homologues. Dietary exposure and risk assessment showed a limited risk for all scenarios. However, based on the elevated levels in NPBFs and their increasing popularity more studies are recommended to provide a comprehensive food safety assessment.

Disclaimer/Disclosure: The authors thank EU Horizon 2020 for providing a PhD fellowship to AMS (MSCA-FoodTraNet project, Grant agreement no. 956265). 3.07.B.T-05 Pyrolysis-GC-MS for Quantitative Analysis of Micro- and Nanoplastics in Liver Samples for Exposome Assessment
Federica Nardella[1]*, Martin van Velzen*[1]*, Henk Roest*[2]*, Luc van der Laan*[2] *and Marja Lamoree*[1]*, (1)Amsterdam Institute for Life and Environment (A-LIFE), Section Chemistry for Environment and Health, Vrije Unversiteit, Netherlands, (2)Erasmus MC Transplant Institute, University Medical Center, Netherlands*
Micro- and nanoplastics (MNPs), defined as solid particles ranging between 5000 µm and less than 1 µm, are contaminating food, water, air, and eventually accumulating within the human body. Accurate quantification of MNPs in human biological samples is essential for assessing human exposure and understanding the potential health implications of these pollutants. Previous research has confirmed the

presence of MNPs in human blood and other biological tissues. The liver is a particularly relevant organ for evaluating MNP levels, as it plays a central role in filtering, storing, and eliminating toxins, offering valuable insights into bodily exposure. However, detecting MNPs in human samples is an analytical challenge due to the complex nature of biological matrices and the limited availability of sensitive detection methods.
Pyrolysis-Gas Chromatography-Mass Spectrometry (Py-GC-MS) is a powerful technique for MNPs analysis, providing mass-based quantitative data with high specificity and sensitivity. This makes it especially suitable for analysing complex matrices like liver tissue. In this study, we developed and validated a Py-GC-MS-based analytical method to measure the mass of six common plastic polymers poly(methyl methacrylate), polyethylene, polypropylene, polystyrene, polyvinyl chloride, and polyethylene terephthalate in liver samples. Method development employed chicken liver as a model matrix, creating a strong foundation for applications to human liver samples. The digestion procedure was carefully optimized to completely remove the organic matrix while preserving the target particles. Strict quality control protocols were established to ensure analytical accuracy and to minimize contamination from lab equipment, airborne particles, and reagents. The detection of MNPs in human liver tissue can enhance our understanding of how these particles are absorbed, accumulate, and potentially impact health over time. The method was successfully validated for liver samples, confirming its reliability. This work emphasizes the importance of robust digestion protocols tailored to complex biological matrices, facilitating accurate MNPs quantification in health-related research. The developed method represents a significant step forward in human biomonitoring of plastic pollutants and evaluating MNPs exposure through human tissue analysis.

3.07.C Wide-Scope Target and Non-Target Screening Strategies for Enhanced Chemical Coverage in Environmental Monitoring and Chemical Exposome Assessment

3.07.C.T-01 Non-Target Analysis of Micropollutants in Drinking Water From China: Profiles and Prioritization

Ruolin Liu[1]*, Emil Egede Frøkjær*[2]*, Martin Hansen*[2]*, Lu Zhao*[3] *and Qinghua Zhang*[4]*, (1)Sino-Danish College, University of Chinese Academy of Sciences; Environmental Forensics and Metabolomics Lab, Department of Environmental and Resource Engineering, DTU Sustain, Technical University of Denmark; State Key Laboratory of Environmental Chemis, China (Mainland), (2)Environmental Forensics and Metabolomics Lab, Department of Environmental and Resource Engineering, DTU Sustain, Technical University of Denmark, Denmark, (3)Department of Epidemiology and Biostatistics, School of Public Health, Peking University, China (Mainland), (4)State Key Laboratory of Enviro nmental Chemistry and Ecotoxicology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, China (Mainland)*

Micropollutants are increasingly detected in drinking water. Due to their persistence, bioaccumulation and toxicity, they pose potential risks to human health and aquatic ecosystems even at low concentrations. Low concentrations and the complexity of the water matrices present great challenges to the analysis of micropollutants in drinking water. With narrow scope of target pollutants, incomplete toxicity data, and the inadequacy of conventional monitoring methods, many contaminants may be overlooked. Advanced non-target analysis offers a promising solution to these limitations, providing a more comprehensive understanding of water contamination and aiding in the development of more effective treatment and risk assessment strategies. A nontarget screening strategy was performed on drinking water samples from 12 different provinces in China, using capillary-flow liquid chromatography coupled to high-resolution Orbitrap mass spectrometry. Across all samples, more than 40,000 chemical features was annotated, and after strict filtering and prioritization, 189 organic micropollutants with high confidence levels (level 1-3) were annotated, including pharmaceuticals, pesticides, flame retardants, and emerging and legacy per- and polyfluoroalkyl substances. Differences in the profiles of contaminants in different regions and different types of samples were observed. With combination of an deep-learning endocrine-disrupting chemicals predictor, the study provide a comprehensive understanding of micropollutants cocktails in drinking water.

3.07.C.T-02 Anthropogenic Profiling of European Surface Water Using Feature-Based Molecular Networking and Non-Target Analysis

Emil Egede Frøkjær[1]*, Lana Graves*[2]*, Daniel Petras*[3]*, Martin Hansen*[4]*, Alistair Boxall*[5]*, Caroline Swan*[6] *and John Wilkinson*[7]*, (1)Technical University of Denmark, Denmark, (2)University of Tuebingen, Germany, (3)Department of Biochemistry, University of California, (4)Environmental Forensics and Metabolomics Lab, Department of Environmental and Resource Engineering, DTU Sustain, Technical University of Denmark, Denmark, (5)University of York, United Kingdom, (6)University of York, Environment and Geography Department, United Kingdom, (7)Environment and Geography, University*

of York, United Kingdom
In 2023, a large study was undertaken to understand the spatial and temporal exposure of 54 active pharmaceutical ingredients across European surface water systems. A total of 280 sites across 31 European countries were sampled in each season (summer, autumn, winter, and spring) and analysed using a targeted analysis approach. To expand on this, a comprehensive analysis of the total anthropogenic contamination profile of European surface waters was performed using non-target chemical analysis methodologies. Complimentary nanoflow liquid chromatography high-resolution mass spectrometry platforms were utilised to obtain chemical information on thousands of detected features across a wide chemical space. Network-based data analysis was utilised for elucidation of compounds, revealing the presence of hundreds of xenobiotics and transformation products. In silico tools were used to increase the annotation rate of unknowns by structure, class, and formula predictions. Semi-quantification was used to detemine chemical concentrations across the European fresh water systems.
This is the first study of its kind to apply non-targeted chemical analysis to surface waters at such a large spatial scale. Thousands of annotated features were present in European surface waters many of these from anthropogenic sources. The findings demonstrate the power of combining large-scale monitoring campaigns with non-targeted analysis approaches to understand chemical contamination of the natural environment.

3.07.C.T-03 Advanced Micropollutant and Contaminant (CEC) Wastewater Surveillance for Strategic Targeted Sampling
George Ruck[1]*, Arnaud Chaumot*[2]*, Olivier Geffard*[1]*, Alexandre Deletang*[3] *and Didier Neuzeret*[4]*, (1)INRAE, France, (2)INRAE, ., France, (3)Viewpoint, France, (4)ViewPoint, France*
The increasing prevalence of contaminants of emerging concern (CECs) in water systems, coupled with diminishing water resources, underscores the need for innovative monitoring and treatment strategies at wastewater treatment plant (WWTP) outlets, for chemical identification. Traditional evaluation approaches often rely on interval-based sampling for a narrow range of chemicals, overlooking many micropollutants and their transformation products. Given the temporal variability of CEC discharges and their dynamic presence in water networks, real-time, targeted monitoring strategies are essential.
This study demonstrates the utility of ToxMate online biomonitoring, which leverages organism avoidance behavior as a biomarker for non-targeted, effect-based effluent characterization. Laboratory experiments have established a behavioral database of avoidance responses for over 40 micropollutants, including pesticides, pharmaceuticals, and hydrocarbons. Using functional data analysis (FDA), this data forms "behavioral fingerprints," enabling classification of avoidance response based on chemical nature of the pollution. Early results reveal structural similarities among overlapping micropollutants, suggesting a pathway for real-time identification of persistent or unknown CECs. Furthermore, the ToxMate device is equipped with an automatic grab sampler, only triggering samples for analysis upon micropollutant surge events. Fieldwork at a WWTP site in northwestern France, operational since January 2022, highlights the practical application of this approach. Over two months, 14 micropollutant surge events triggered automated grab sampling for wide-scope chemical analysis. Notably, control samples collected outside alert events exhibited minimal concentrations of all dosed chemicals, reinforcing the sensitivity of the biomonitoring system. The results also show that events with similar behavioural profiles show striking resemblance in their chemical profile, dosed for over 803 chemicals in a targeted chemical approach. These findings suggest that coupling behavioral fingerprinting with high-resolution mass spectrometry (HRMS) can narrow the scope of chemical analysis, facilitating targeted monitoring and real-time alerting. By identifying critical moments of CEC surge, this strategy offers WWTPs the ability to optimize contaminant management, refine advanced treatment processes, and potentially minimize environmental risk.

3.07.C.T-04 Quantification Without Reference Standard: How Semi-Quantitative Tools Performed in Water Sample?
Eloi Marilleau[1]*, Yvan Gru*[1]*, Ronan Colin*[1] *and Nicolas Cimetiere*[2]*, (1)Inovalys, France, (2)Univ Rennes, ENSCR, CNRS, ISCR, France*
The quality of water (ground, surface and tap) is a major societal issue. Both public and private authorities are dedicated to upholding quality standards in accordance with regulatory mandates. The list of parameters subjected to sanitary control may evolve with the identification of new substances (active substances, metabolites) or new toxicity information. Therefore, it is essential to be able to provide answers regarding the identity and concentration of these substances to assess information on environmental pollution. The unavailability of standards (not commercially synthetized, expensive costs) raises questions about confidence levels attributed to compounds identification and semi-quantification. Semi-quantitative approaches aim to estimate compound concentration based on its properties and signal

intensity without using the associated reference standard.
This work introduces the development of a quantitative and semi-quantitative screening method for organic contaminants in water. This method is based on Liquid Chromatography coupled with High Resolution Mass Spectrometry (HRMS). Analyses were carried out with Data Independent Analysis (DIA) acquisition mode to perform targeted, suspect and retrospective analysis by querying internal and external databases. The objective was to be able to identify a maximum of organic contaminants through two acquisitions (positive and negative ionization)
To characterize method performance, limits of quantification were determined for more than 450 molecules. In addition, several multi-residue proficiency tests (>100 compounds) were conducted to demonstrate the applicability of the method. The results were promising with a majority of the expected molecules detected; the remaining ones can mainly be analysed using other separation techniques (HILIC, IC, GC). The database query made it possible to identify molecules without a reference standard. For these, semi-quantification tests based on existing methodologies (2D structure similarities, ionization efficiency prediction) were carried out to evaluate the performances of these approaches. Furthermore, semi-quantification will be done on real water sample, from the intake and output of drinking water treatment plants, to evaluate the level of contamination of these resources. Future work will involve testing semi-quantification approaches on other samples and food matrices to better assess the capacities of this approach.

3.07.C.T-05 Non-Target Screening in Suspended Particulate Matter and Biota Using GC-HRMS
Daniela Kruger[1]*, Caroline Camen*[2]*, Georg Dierkes*[2]*, Arne Wick*[2] *and Thomas A Ternes*[1]*, (1)Federal Institute of Hydrology; University of Koblenz, Germany, (2)Federal Institute of Hydrology (BfG), Germany*
Chemicals are indispensable to modern life and industry, yet they also present a significant risk to human health and the environment. Despite the registration of over 350,000 chemicals worldwide, more than 120,000 of them remain unidentified, which complicates monitoring efforts.
The aim of this project was to develop a method for the detection of both known and unknown apolar substances in suspended particulate matter (SPM) and fish fillet. Within this process, the establishment of a discrimination free non-target screening for the detection of spatial and temporal trends in samples from the German Environmental Specimen Bank was prioritized.
Methods for sample extraction and clean-up, GC-MS analysis and data analysis were developed and validated using a mixture of 76 compounds. For SPM ultrasonic extraction and silica clean-up was used. For fish filet an additional gel permeation chromatography step was established.
LODs in SPM for a variety of different substances, such as PAHs, PCBs, UV-filter, pesticides etc., were determined to be between 0.2 and 5 ng/g for the most substances. The workflow enabled the detection of all spiked substances, resulting in a qualitative recovery of 100%.
The initial findings demonstrate that the newly developed methods are able to detect a broad range of known contaminants, such as PAKs and phthalates, as well as previously unrecognized environmental pollutants such as Plastic Additive 11 (Octadecyl-3-(3,5-di-tert-butyl-4-hydroxyphenyl)propionat). This highlights the potential of the method to detect future contamination trends and to respond to new types of pollutants at an early stage.
This project makes an important contribution to environmental monitoring due to its capacity to perform a comprehensive analysis of the occurrence of contaminants and demonstrates how new and potentially harmful substances can be identified and assessed at an early stage. The workflow can be used complementary to non-target LC-MS methods to extend the polarity range, thus representing a valuable contribution to a more comprehensive monitoring.

Disclaimer/Disclosure: The authors thank the German Environment Agency (PN 150649) for funding this work.

3.07.P Wide-Scope Target and Non-Target Screening Strategies for Enhanced Chemical Coverage in Environmental Monitoring and Chemical Exposome Assessment

3.07.P-Mo226 What's in Our Consumer Products? Target, Suspect, and Non-Target Screening
Lisa Marina Reinhardt[1]*, Sam Hulscher*[2]*, Maria Margalef Jornet*[2] *and Sicco Brandsma*[2]*, (1)University of Copenhagen, Denmark, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands*
Various studies have examined the presence of potentially harmful additives in consumer products like food contact materials and children's toys. These additives, including flame retardants (FRs), plasticizers,

and other substances, are intentionally added to improve the performance of plastics. However, because most additives are not tightly bound to the polymer, they can leach out during use, potentially exposing users to toxic chemicals. While the European Union has regulations to control certain harmful substances in plastic toys, such as PBDEs, phthalates, and BPA, these chemicals still enter the market due to poor recycling practices or lack of regulation in manufacturing countries.
To assess whether consumer products purchased in the Netherlands and the U.S. were contaminated with regulated or unregulated compounds, a selection of 65 food contact items, hair accessories, kitchen utensils, and toys was analyzed for the presence of various flame retardants, phthalates, and plasticizers. In the second phase of the project, non-targeted and suspect screening was conducted to explore additional substances present in these consumer products.
The results showed widespread contamination with hazardous chemicals. TBBPA was the most commonly detected flame retardant, followed by BDE-209. In 70% of the plastic products, BDE-209 exceeded the EU's unintentional trace contaminant limit of 10 mg/kg, and more than six different FRs were detected in 60% of the products. DecaBDE replacements like DBDPE and TTBP-TAZ were also found. High levels of phthalates and plasticizers were found in toys, including five substances classified as substances of very high concern (SVHCs) by ECHA, which are linked to hormone disruption, reproductive toxicity, and cancer. Legal limits were exceeded for four of these substances, with DBP surpassing the limit by 200 times. The plasticizer DEHTP was found in twelve toys, with concentrations up to 50% of the total weight.
The data processing for the non-target and suspect screening is ongoing. The detected features were annotated using publicly available Spectral Libraries (MassBank EU and MassBank North America) and the plastCHEM Analyte List. Additionally, the polymer type of each consumer product was determined to examine any patterns related to the type of polymer used.

3.07.P-Mo227 Can the Use of Menstrual Products Contribute to Chemical Exposure?

***Lara Cioni**, Julia Calvo Salvador and Ethel Eljarrat, Institute of Environmental Assessment and Water Research - Spanish Council for Scientific Research (IDAEA-CSIC), Spain*

Menstrual products, fundamental to maintaining hygiene, preventing infections and ensuring participation in our society during menstruation, have been shown to contain chemicals with potential toxic effects, like phthalates (PAEs) and per- and polyfluoroalkyl substances (PFAS). Since the vulvar and vaginal tissues in contact with these products have high chemical absorption capacity, the use of these products might contribute significantly to human exposure. However, the studies investigating this exposure pathway are still scarce and limited to few products and chemicals. In this study, we wanted to expand our understanding of human exposure through the use of menstrual products by quantifying 4 classes of chemicals of concern for human health, PAEs, organophosphate esters (OPEs), non-phthalate plasticizers (NPPs) and PFAS, in both single-use and reusable menstrual products. A total of 41 menstrual products (10 sanitary pads, 8 panty liners and 9 tampons, 4 reusable sanitary pads, 4 menstrual panties and 6 menstrual cups) were analyzed for 9 PAEs, 17 OPEs, 10 NPPs 21 PFAS. To estimate the contribution of dermal contact with menstrual products to human exposure, the estimated daily intakes (EDI) were calculated assuming the worst-case scenario of 100% release of the chemicals from the products and 100% absorption through the skin. The combination of PFAS and plasticizers analysis showed that a wide variety of chemicals can be present in menstrual products. All types of menstrual products analyzed had detectable concentrations of PAEs, OPEs and NPPs, while PFAS were only detected in reusable menstrual products. Differences in detection frequencies and concentrations were observed across different products potentially due to differences in product design. Reusable sanitary pads showed the highest concentrations of PAEs and OPEs and menstrual panties showed the highest PFAS concentrations. The highest NPPs concentrations were observed in single-use sanitary pads and panty liners. For PAEs, OPEs and NPPs, worst-case scenario estimates showed that using these products might contribute significantly to human exposure. As an example, for reusable sanitary pads the EDI for OPEs (median: 213 ng/kg bw/day) was above estimates for dietary exposure (62-103 ng/kg bw/day), which is considered the main OPEs exposure route. These results highlight the need investigate the release of these chemicals from menstrual products to the skin to provide more realistic estimates.

3.07.P-Mo228 Untargeted Screening for PFAS Chemicals Using Comprehensive Feature Detection

*Jeff Goshawk[1], Andrew Tudor[1], Sarah E. Dowd[2], Jonathan Fox[1], Hania Khoury-Hollin[1], **Michael andrew McCullagh**[1], Isabel Riba Dr[1], Susan Slade[1] and Russell Mortishire-Smith[1], (1)Waters Corporation, United Kingdom, (2)Waters Corporation, Milford, United States*

PFAS (poly/per-fluorinated aliphatic substances) are of increasing concern environmentally and the determination of PFAS levels within test samples is strategically important. According to the published literature, known PFAS chemicals, quantitated on the basis of reference standards, have been shown to

account for only 20-30% of the total organic fluorine in a sample. The remaining 70-80% is derived from other PFAS entities that are either commercial chemicals for which no reference standards are available, or downstream degradation/metabolism products of commercial chemicals with novel structures.
Methods
LC/HR-MS and LC/HR-IMS-MS data on a variety of representative environmental samples were acquired on Waters SYNAPT XS, SELECT SERIES Cyclic IMS and SELECT SERIES MRT spectrometers coupled with ACQUITY UPLC. Targeted screening was undertaken using a library of several hundred known PFAS chemicals, and during processing all detected components were evaluated against a list of common PFAS product ions and neutral losses. 12C/13C isotope ratios were also determined during peak detection and componentisation.
Preliminary data
We present outcomes obtained using a new software application, PFAS Targeter, which takes comprehensive advantage of the idiosyncratic properties of PFAS chemicals when compared with naturally occurring compounds. The approach uses class-specific product ions and neutral losses, mass defect, 12C/13C isotope ratio, trendlines on Kendrick plots and the distinctive relationships between both m/z and CCS, and between m/z and 12C/13C isotope ratio, in order to discriminate those components which are most likely to be PFAS-related from the matrix background. Given that many PFAS structural classes are inherently polymeric in nature, the software also iterates end group-monomer-end group signatures for common classes of PFAS, and uses these during processing to attempt to rationalise components which were not matched during targeted screening. The value of this approach to analysis of complex environmental samples is exemplified using both LC/MS and LC/IMS-MS data, and validated the use of ion mobility as an additional discriminator for PFAS in that greater enrichment of PFAS-probable components was obtained when ion mobility endpoints were included in component ranking and filtration.

3.07.P-Mo229 Chemical Background in Blood Microsampling Devices by Non-Target Chemical Exposomics

***Solveig Thiele**, Benilde Bonnefille, Stefano Papazian and Jonathan W Martin, Department of Environmental Science (ACES, Exposure & Effects), Science for Life Laboratory, Stockholm University, Sweden*

Blood microsamplers are of interest for exposomics applications as they enable quantitative and high-frequency self-sampling of individuals outside of the clinic. These devices, being simple to use and minimally invasive, may be deployable by laypeople and shipped at room temperature, facilitating high-throughput sampling at cohort-scale to comprehensively characterize the chemical exposome in human blood. One challenge in their implementation is the chemical background they can introduce, which may lead to false-positives when characterized by liquid-chromatography coupled to high-resolution mass-spectrometry (LC-HRMS). Here, the chemical background of several popular dried- and liquid-blood devices was assessed by sampling high-purity water, contrasting the resulting total ion current (TIC) intensities, number of non-target molecular features detected, the peak area distributions of all features, and their chemical characterization.
Using LC-MS grade water as a blood proxy, we assessed the chemical background of 8 commercially available devices: Capitainer® B and B50 (Capitainer AB, Solna, Sweden); Neoteryx Mitra® VAMS® (Neoteryx, Torrance, CA, USA); Tasso-M20 and 3 versions of Tasso+ (Tasso, Inc., Seattle, WA, USA); and TAP® II Lithium Heparin (LiH) (YourBio Health, Inc., Medford, MA, USA). After sampling, the water was left to dry overnight. Then, each device (n = 4 replicates) was extracted with either 60:40 ACN:H2O or 60:40 MeOH:H2O with a 15 min sonication, followed by centrifuge filtration (0.2 µm, Nylon). Analysis was performed by reversed-phase chromatography (Acquity BEH C18, Waters), and mass spectral data were aquired in full scan (m/z range 80 920) and by data-independent MS/MS in ESI±, using an Orbitrap Exploris 480 (ThermoFisher Scientific). Raw data were pre-processed using the open source software MS-DIAL (v4.9).
Our study showed that chemical background varies greatly between devices, with some specific contaminations (e.g., nicotine in Capitainer B50) and some being shared across multiple devices (e.g., diphenyl phosphate in all Tasso devices and Mitra VAMS). Overall, 3 samplers have a comparably low chemical background: Neoteryx Mitra VAMS, Tasso+ Plasma, and TAP II LiH. Other devices may still be more appropriate considering sampling volumes and ease of use. Investigating the chemical background of microsamplers facilitated by the use of collection and field blanks will be crucial for chemical exposome studies in human blood.

3.07.P-Mo230 Effect-Directed Analysis of Human Cord Blood to Identify Potential Thyroid Hormone System Disrupting Chemicals

Maria Margalef Jornet[1], *Peter Cenijn*[1], *Manuel Heinzelmann*[1], *Quinn Groenewoud*[1], *Gerda Hopman*[1], *Tina Kold Jensen*[2], *Henriette Boye*[3], *Anne Marie Vinggaard*[4], *Timo Hamers*[1] *and Marja Lamoree*[1], *(1)Vrije Universiteit Amsterdam, Netherlands, (2)University of Southern Denmark, Denmark, (3)Odense University Hospital, Denmark, (4)Technical University of Denmark, Denmark*
The study of chemicals with endocrine-disruptive properties in human cord blood is crucial for understanding early-life exposure to environmental contaminants and their potential health effects. Traditional methods face challenges in identifying active chemicals within complex mixtures due to the diversity of compounds present. Effect-directed analysis (EDA) offers a solution by combining biological activity assessment with chemical profiling in a single workflow. This involves fractionating sample extracts, testing fractions in bioassays, and identifying chemicals in active fractions. Here, a high-throughput EDA was employed to examine the ability of chemical mixtures in human cord blood to compete with thyroid hormone (TH) for binding to transthyretin (TTR), a protein essential for TH regulation.
Cord blood samples from the Odense Child Cohort (500 boys, 250 girls) were extracted using lipophilic-hydrophilic balanced solid-phase extraction. TTR-binding activity was measured, and samples were pooled into four groups based on sex and activity (High/Low IC10). Pooled extracts and their matching procedural blank were fractionated by high performance liquid chromatography (HPLC) coupled to a fraction collector (FractioMate). TTR-binding activity was measured in all fractions. Chemical profiling was conducted with non-targeted high-resolution mass spectrometry (Data Dependent Acquisition), using the same chromatographic conditions. Annotation of candidates was performed aligning different publicly available spectral libraries and a suspect list of chemicals of emerging concern to the extracted features. The analysis revealed sex-specific and within-sex variations in TTR-binding activity. Active fractions showed consistent patterns at the end of chromatographic runs, although some bioassay interferences were excluded. Ongoing alignment of bioassay data with chromatograms aims to identify key activity drivers. This study highlights the successful application of high-throughput EDA, enabling the prioritization of chemicals for identification and enhancing confidence in identifying drivers of endocrine disruption in early-life exposures.

Disclaimer/Disclosure: This study was funded by the European PANORAMIX project (Green Deal H2020). Grant Agreement No. 101036631.

3.07.P-Mo231 Throughput Enhancement and Modelling Dimensionality Reduction by Sampling LC-HRMS Data

Deirdre de Boon, *Viktoriia Turkina and Saer Samanipour, Van t Hoff Institute for Molecular Sciences (HIMS), University of Amsterdam, Netherlands*
Classification models are applied to various chemistry-related challenges, such as in wastewater treatment plant to determine which contaminants are present. Creating a robust classification model requires a large dataset with a limited number of descriptors. However, analysing many samples can be expensive and time consuming, and in the case of Liquid chromatography coupled with High Resolution Mass Spectrometry (LC-HRMS), the datasets generated per chromatogram are large. As a result, in reality, the data often include numerous features derived from only a few samples. While the feature reduction problem has been thoroughly investigated to identify the most prominent markers for classification, reducing the complexity of acquired data through compression can minimize the need for extensive feature reduction and potentially facilitate optimization of data acquisition and its processing.
Instead of using the whole chromatogram, a part of the chromatogram (e.g., a peak list or chromatogram region of interest) could be representative enough to solve a classification problem. This approach can improve data processing and collection speed as well interpretability of the results, however, it is more prone to error since it represents a reduced data set resulting from preprocessing steps. Besides, different peak finding algorithms could be compared since they may result in different amounts of features. Therefore the investigation of the balance between data number of features and the amount of important information for classification should be investigated.
For this study, we explored various approaches to data (pre-)processing of LC-HRMS/MS data to identify the minimal information and resolution requirements necessary for accurate classification and marker detection. The various approaches include experiments with different wideness s of retention time bins, range of mass channels, and the use of compressed chromatograms.
By reducing the time and amount of data acquired while maintaining resolution, we can accelerate and improve the accessibility of classification and diagnostic tasks.

3.07.P-Mo232 Suspect Screening of Endocrine Disruptive Compounds (EDCs) in the European Environment

Nina HUYNH[1], *Selim AIT-AISSA*[1], *Nikiforos Alygizakis*[2], *Azziz Assoumani*[1], *Anna Bialk-Bielinska*[3], *Elise Chatillon*[1], *Charlotte Coureau*[4], *Gaud Dervilly*[5], *Abd-El-Rahman El-Mais*[6], *Tina Kosjek*[7], *Martin Krauss*[8], *Antonio Lopez*[9], *Nicolas Macorps*[5], *Georgios Niarchos*[10], *Petra Pribylova*[11], *Kerstin Putz*[12], *Michael Schluesener*[13], *Coralie Soulier*[4], *Gunnar Thorsen*[12], *Linyan Zhu*[14], *Nikolaos S. Thomaidis*[15], *Katrin Vorkamp*[14] *and Valeria Dulio*[1], *(1)Institut National de l Environnement Industriel et des Risques (INERIS), France, (2)National and Kapodistrian University of Athens, Athens, Greece, (3)Department of Environmental Analysis, Faculty of Chemistry, University of Gdańsk, France, (4)Bureau de recherches geologiques et mini res (BRGM), France, (5)LABERCA, ONIRIS, INRAE, France, (6)INERIS, France, (7)Jo ef Stefan Institute, Ljubljana, Slovenia, Slovenia, (8)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (9)Foundation for the Promotion of Health and Biomedical Research in the Valencia Region, FISABIO-Public Health, Spain, (10)Dept. of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Sweden, (11)RECETOX, Masaryk University, Czech Republic, (12)Swedish Environmental Research Institute (IVL), Sweden, (13)Bundesanstalt fur Gewasserkunde (BfG), Germany, (14)Aarhus University, Department of Environmental Science, Denmark, (15)National and Kapodistrian University of Athens, Greece*

Endocrine disruptive compounds (EDCs) represent a class of structurally diverse chemicals, emitted to the environment from multiple sources, that may interfere with human and animal hormonal systems and lead to adverse health effects. Identifying and quantifying EDCs in the environment is needed to better characterize the chemical mixture and exposure. However, due to the complexity of environmental matrices, the large number and variety of compounds, several analytical challenges and knowledge gaps still exist.

In this context, the Partnership for the Assessment of Risks from Chemicals (PARC) aims to develop the next-generation chemical risk assessment. A pilot study in the field of Environmental Monitoring aims to characterize and quantify EDCs in air, soil, surface water and biota by combining target chemical analyses, suspect screening and bioassays. Samples were collected throughout Europe considering different anthropogenic pressures. This presentation will focus on the suspect screening analysis. From an initial aggregation of several lists of known or suspected EDCs, resulting in more than 7000 potential EDCs, a suspect screening list was created with relevant information for EDC identification. Standard operating procedures for sample collection and preparation were developed to ensure comparable results. Since the work involved several partners, quality standards were set to ensure that interpretation of the results would be feasible.

This collaborative effort of a dozen European institutes over the last year will be presented and lessons learned so far for a study of this scale will be provided. Analyses are currently being carried out on the 180 samples collected for all matrices and first results will be presented. Expected outcomes are the identification of EDC hotspots in Europe and identification of the most prominent compounds classes in different matrices and parts of Europe. Initial discussions of the potential origin and the environmental fate of relevant EDCs will be provided, based on their occurrence in the different environmental compartments.

3.07.P-Mo233 Usage of Liquid Chromatography and High-Resolution Mass Spectrometry to Detect and Monitor New Contaminants in Resources and Drinking Water

Alexandre Guironnet, *Christyne Videloup and Mar Esperanza, CIRSEE (Centre International de Recherche Sur l Eau et l Environnement), France*

In France, drinking water production is regulated through several parameters. The micropollutants are monitored with targeted methods, to detect and quantify their presence. While adequate for assessing treated water quality, this approach may overlook emerging pollutants, as only pesticides and their metabolites are regulated. High-Resolution Mass Spectrometry (HRMS) coupled with Liquid Chromatography (LC) enables non-targeted screening to detect compounds without preselection. Key steps in this process include optimized sample preparation and data treatment.

We applied a sample preparation method using Vacuum Evaporation Concentration (VEC), evaluated with a mixture of 195 compounds from various families, molecular masses, and physicochemical properties, to cover a wide part of the chemical space occurring in water samples. Evaporates were analyzed on an LC-qOrbitrap system, and data were processed with Thermo Compound Discoverer. Compounds were classified using an adapted Schymanski framework into identified, suspected, and features. Filters on analytical factors such as peak shapes were added to enhance data quality and confidence.

This method was applied to raw water resources (surface and groundwater) and treated drinking water from various locations in France and abroad. 99 compounds were identified based on retention time, exact mass, and fragmentation pattern, including pesticides (42%), drugs (31%), and their transformation

products. Additionally, 112 compounds were suspected and categorized into pesticides, drugs, and industrial or natural products. Based on occurrence, toxicity, and family type, 81 compounds were prioritized, and analytical standards were obtained for 67. Of these, 38 were confirmed. All of them were integrated into an internal database to reduce false positives in future analyses. To track ubiquitous versus sporadic pollution, monthly grab samples of the Seine River were collected from April 2023 to July 2024. This methodology identified 72 compounds and suspected 56, with 18 compounds detected consistently, including drugs like lidocaine, pesticides like methyldesphenyl chloridazon, or industrial chemicals such as benzotriazole and its metabolite methyl-benzotriazole.
Non-targeted suspect screening complements targeted methods by detecting and identifying a broader range of compounds, guiding future targeted studies and monitoring.

3.07.P-Mo234 Setting the Baseline of Contamination by Emerging Pollutants in the Saronikos Gulf, Greece, Utilizing State-of-the-Art HRMS Techniques and Novel Chemometric Tools
Rallis Lougkovois[1]*, Constantinos Parinos*[1]*, Georgios Gkotsis*[2]*, Maria-Christina Nika*[2]*, Alexandra Pavlidou*[1]*, Ioannis Hatzianestis*[1] *and Nikolaos S. Thomaidis*[2]*, (1)Hellenic Centre for Marine Research, Greece, (2)National & Kapodistrian University of Athens, Greece*
Comprehensive monitoring of environmental pollution is considered the basis for exploring the chemical imprint of human-related activities in the marine environment, which adversely impact its quality. The E.U. has enacted the Water Framework Directive (WFD) and the Marine Strategy Framework Directive (MSFD) to promote continuous scientific investigation and expedite regulatory bodies research towards preserving the marine realm.
Aiming to destress the Mediterranean Sea from chemical pollution, the E.U. has launched the RHE-MEDiation Lighthouse project. The characterization of the baseline of pollution close to areas considered as contamination hotspots is included in its framework. Wastewater treatment plants comprise major point sources of pollution in the vicinity of Saronikos Gulf. Assessing the quality of surrounding marine ecosystems sheds light towards WWTPs efficiency in wastewater stream cleanup processes. Saronikos Gulf is a heavily urbanized and industrialized area, while its two WWTPs of Thriasio and Psytallia cover more than half of the country s population in terms of wastewater management.
To determine as many emerging pollutants (EPs), along with their respective metabolites and transformation products (TPs) as possible, collected seawater and sediment samples were pre-treated via generic sample preparation protocols. Samples were analyzed utilizing novel LC-TIMS-HRMS workflows, aiming to determine EPs with a wide spectrum of physicochemical properties.
Preliminary results indicate that polar organic EPs, such as pharmaceuticals and plant protection products are mainly detected in seawater samples, while compounds with higher log P values, like industrial chemicals and long chain PFAS are generally concentrated in deep seawater samples and in sediments. Antiepileptic substance Carbamazepine and its metabolite 10-hydroxy-Carbamazepine and polar psychoactive substances Venlafaxine and Sulpride, along with their respective metabolites Amisulpride and o-desmethyl-Venlafaxine were determined in concentrations ranging between 0.235 and 10.4 ng/L in seawater samples. Sediments mainly contained semi- to non-polar compounds, like quinolone antibiotics Cinoxacin, Ofloxacin and Norfloxacin, as well as sulfonamide antibiotics Sulfadiazine and Sulfisoxazole, in concentrations levels ranging between 0.126 and 7.65 μg/kg d.w.

Disclaimer/Disclosure: This work was funded by the E.U. s HORIZON EUROPE under the RHE-MEDiation Lighthouse project (HORIZON-MISS-2022-OCEAN-01-03-101113045).

3.07.P-Mo235 Investigating the Chemical Imprint of Human-Related Activities on the Red Sea Marine Ecosystem Utilizing Novel Complementary Mass Spectrometric Techniques
Panagiota Kontogianni[1]*,* ***Rallis Lougkovois***[1]*, Georgios Gkotsis*[1]*, Maria-Christina Nika*[1]*, Nikolaos S. Thomaidis*[1]*, Constantinos Parinos*[2]*, Ioannis Hatzianestis*[2]*, Yasser Abualnaja*[3] *and Alexandra Pavlidou*[2]*, (1)National & Kapodistrian University of Athens, Greece, (2)Hellenic Centre for Marine Research, Greece, (3)King Abdullah University of Science and Technology, Saudi Arabia*
Environmental monitoring of chemical pollution is deemed necessary to provide information about ecosystem quality. Anthropogenic chemicals such as pharmaceuticals, industrial chemicals, PFAS, PAHs, and PCBs end up in environmental substrates via different pathways. Upon reaching the marine environment, biotic and abiotic processes take place, producing metabolites and transformation products, suspected to cause even more potent effects than parent compounds, further degrading the marine environment.
Extensive urbanization and industrialization on the Red Sea coasts lead to unavoidable chemical encumbrance. The Kingdom of Saudi Arabia has launched the Marine and Coastal Environment

Protection Initiative to assess the current state of its coastal environment. Jeddah lagoons act as large banks of sediment formation, an environmental compartment which can be potentially burdened with pollutants with high log P values and volatile organic compounds, due to sorption and precipitation mechanisms. Besides sea bottom degradation, polluted sediments become potential sources of seawater recontamination, adding to the existing sources of pollution to which marine organisms are exposed to. Aiming to determine a wide variety of organic pollutants in collected sediments from Jeddah lagoons, generic sample preparation protocols and complementary analytical techniques were applied. Pollutants of various polarities and physicochemical properties were determined utilizing both GC-MS/MS and LC-HRMS techniques. HRMS-based wide-scope target screening was employed using an in-house developed dataset of more than 2,500 substances.
Preliminary results show that Jeddah lagoons are chemically encumbered by different groups of pollutants, based on different point sources in the vicinity. Antibiotics, psychoactive substances, as well as pollutants linked to industrial activity, such as PFAS were determined. GC-amenable compounds like hydrocarbons were detected, further indicating an evident chemical burden. Total aliphatic hydrocarbons concentrations ranged between 404 mg/kg d.w. and 8.90 g/kg d.w., while PAHs concentration levels ranged between 288 ?g/kg d.w. and 13.7 mg/kg d.w. Total PCBs and linear alkylbenzenes fluctuated from 0.100 to 15.6 ?g/kg d.w. and 173 ?g/kg d.w. to 41.8 mg/kg d.w., respectively. These results indicate the inevitable chemical encumbrance linked to anthropogenic activities and sewage disposal throughout the Red Sea area.

Disclaimer/Disclosure: This work was funded through Hellenic Centre for Marine Research's funds derived from a collaboration with the Red Sea Research Center, King Abdullah University of Science and Technology.

3.07.P-Mo236 Investigating Fire Fighter and E-waste Handlers Exposure to PFAS Using Liquid Chromatography and Cyclic Ion Mobility Mass Spectrometry
***Michael Andrew McCullagh*[1]**, *David Megson*[2], *Pennante Bruce-Vanderpuije*[3] *and Stuart Adams*[1], *(1)Waters Corporation, United Kingdom, (2)Manchester Metropolitan University, Manchester, UK, Chemistry Matters, United Kingdom, (3)CSIR-Water Research Institute, Ghana*
Polyfluorinated alkyl substances (PFAS) exposure is a potential contributor to increased cancer and disease in the human population. Firefighters and E-waste handlers have a high exposure to PFAS due to their occupational demands. Monitoring of PFAS levels in human biofluids helps gain understanding into exposure levels and pathways.
PFAS isomeric compounds can be challenging to efficiently separate using liquid chromatography (LC). Cyclic ion mobility (cIM) provides an added dimension of separation, enhancing peak capacity and collision cross section (CCS) values, which serve as a complementary identification descriptor. Using a 22 min reversed phase separation gradient, LC-cIM-MS (cIM resolution (R)~65-145) non-targeted analysis has been performed to analyse anonymised human serum samples of Ghanaian firefighters and E-waste handlers. Human serum sample extraction was performed using SPE 96-well µElution plates, containing a polymeric reversed-phase, weak anion exchange mixed-mode sorbent.
Typically, ? CCS < 1% has been observed compared to the PFAS library CCS values. For E-waste handler serum samples, PFAS, including, PFBS, PFOA, PFOS, 6:2 FTS and N-MeFOSSA (? CCS < 0.5%), have been identified. In Firefighter serum samples, PFAS, including, PFHxS, PFOS, PFHpS and PFNA (? CCS < 1%), have been identified. Additionally, we present identification of perfluoroalkyl carboxylic acids (PFCA) in human serum using ion mobility conformeric profile specificity, enabling highly specific identification at low intensities where product ions are absent.
LC-cIM-MS has been used to analyse a series of PFAS analytical standards comprised of structurally equivalent PFOA and PFOS branched isomers. Characteristic br-PFAS CCS values have been determined for branched PFOS and PFOA isomers, to extend PFAS library content. A comparison between br-PFAS travelling wave ion mobility (TWIM) CCS values, drift tube and trapped ion CCS measurements, ? CCS < 0.6% has been obtained. For PFOA characteristic isomer dimer CCS values have also been determined providing additional CCS fingerprint specificity. LC-cIM-MS can form a critical part of analytical strategy to enhance identification specificity of br-PFAS and provides an opportunity to correlate genotoxicity and environmental fate of br-PFAS. LC-cIM-MS is a highly specific non-targeted analysis strategy that can be used to identify known and unknown PFAS in complex samples.
For Research Use Only. Not for use in diagnostic procedures.

3.07.P-Mo237 The Occurrence of Contaminants of Emerging Concern in Swedish Landfill Leachate
***Tsz Yung Wong*[1]**, *Alberto Celma*[2] *and Oksana Golovko*[3], *(1)Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Swedish University of Agricultural Sciences (SLU), Sweden*

Landfill is one of the most common waste management methods, but it is not the final destination for many chemicals. Contaminants of emerging concern (CECs) are hazardous organic chemicals widely used in consumer and industrial products that can eventually leach into the environment from, among others, landfills. Before stricter waste management regulations were implemented in Sweden, a wide range of waste was deposited in landfills, highlighting the importance of investigating the occurrence and levels of CECs in order to fully understand their ecological and human health impacts. Non-target screening (NTS) and suspect screening (SS) using ultra high performance liquid chromatography-electrospray ionization-high resolution mass spectrometry (UHPLC-ESI-HRMS) are commonly used method for identifying unknown compounds in water samples. The goal for this study is to create a list of representative CECs in Swedish landfill leachate for future monitoring and quantification.
In our study, samples (untreated and treated leachate) were collected from five different Swedish landfills of different locations, age, and treatment methods. Both individual samples and pooled samples were prepared before analysis. Extraction was performed on homemade multi-layer Solid Phase Extraction (SPE) cartridges in order to capture a wide spectrum of CECs. Given the high sensitivity and selectivity of the UHPLC-ESI-Orbitrap instrument, analysis of pooled samples addresses some common challenges in NTS. For instance, the composition of pooled samples can help generating a suspect list of CECs representative of the Swedish scenario for later on application into individual samples, therefore significantly reducing total data processing time. Pooling samples can also address issues with different peak shape and shifted retention time due to varying matrix effects.
In this study, a total of 74 CECs were identified in the landfill leachate via NTS and included in a suspect list of CECs in Swedish landfills. Among the spotlighted CECs, 35 industrial chemicals, 21 pharmaceuticals, 10 PFASs, and 9 pesticides were detected. From them, 39 CECs were confirmed at level 1 and 35 were confirmed at level 2. Our findings underscore the diverse presence of CECs in landfill leachate, which aligns to previous studies.

3.07.P-Mo238 Improved Environmental Contaminant Identification using a Novel Dual-Ionization GC-EI&CI-TOFMS

Philippe Diederich[1], *Sonja Klee*[3], *Steffen Braekling*[2], *Eliška Ceznerová*[2], *Sonja Klee*[3] *and Arnd Ingendoh*[4], *(1)Bruker Daltonics Gmbh & Co KG, Germany, (2)TOFWERK AG, Switzerland, (3)University of Applied Sciences (ZHAW), Zurich, Switzerland, (4)Bruker Daltonics GmbH & Co KG, Germany*
The accurate identification of environmental contaminants is essential for protecting public health and preserving ecosystems. Persistent organic pollutants (POP), such as dioxins and polychlorinated biphenyls (PCB), are of particular concern due to their long-term stability, bioaccumulation potential, and toxicity even at trace levels. Emerging pollutants like tire wear particles (TWP) and other contaminants such as pesticides and pharmaceuticals further exacerbate environmental challenges.
Traditional GC-MS approaches using EI offer reliable fragmentation data but often lack the molecular ion information needed for unambiguous identification. Chemical ionization (CI) enhances molecular ion detection while reducing the fragmentation necessary for structural elucidation.
To address these challenges, we introduce a novel dual-ionization GC-EI&CI-TOFMS system. This technique integrates the strengths of EI and CI within a single analysis, enabling robust fragmentation data alongside clear molecular ion signals. This dual-ionization approach enhances the identification of challenging contaminants providing a significant advancement in environmental monitoring and regulatory compliance.
Different environmental samples, e.g., soil extracts were investigated focusing on the identification of contaminants. For these studies a Bruker GC was coupled to an ecTOF (Bruker, Bremen, Germany). Various GC methods and sampling procedures were employed depending on the analytical need of the study. To generate the ideal molecular ion information different reactant ions were used for the chemical ionization process.
The results of the studies show that the EI&CI-TOFMS is feasible for standard procedures employed by routine laboratories. Whilst standard GC-MS methods mainly focus on target analysis, especially suspect screening and non-target analysis is enabled and improved by the EI&CI-TOFMS as detector. Especially when EI library hits are only accounted as fair with low corresponding probability, the additional CI information can be used to increase compound identification confidence. False positives from an EI-only approach can easily be identified and often correctly annotated. Furthermore, compounds not listed at all in libraries have a much higher confidence for identification using the combined EI&CI approach. Additionally, using the accurate mass information and isotopic pattern fit on the molecular ion provided by CI often tentative identification can be derived.

3.07.P-Mo239 Non-Targeted Analysis of Contaminants of Emerging Concerns (CECs) in Consumer Food Packaging using Ultra-Performance Liquid Chromatography High-Resolution Mass

Spectrometry (UPLC-HRMS)
*Martijn Korporaal, **Patricia Aguilar-Alarcon**, Eva de Rijke, Sean O'Connell and Antonia Praetorius, Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands*
Recent concerns have increased regarding the migration of substances from food packaging materials into food. Chemicals such as bisphenols, phthalic acid diesters, colorants, lubricants, and stabilizers are well-recognized as intentionally added substances. Additionally, non-intentionally added substances can also be present, these may include impurities and by-products generated during the packaging production process or at any stage of the material s lifecycle. These substances together with the intentionally added substances can pose migration risks into food, resulting in unforeseen contamination and potential health hazards. The comprehensive identification of these potential migrants is required to assess the safety of these packaging materials. The analysis of potential migrants is complex and challenging due to the numerous steps involved in the production of multilayer packaging, from raw materials to finished films. While targeted analysis using ultra-performance liquid chromatography mass spectrometry (UPLC-HRMS) is effective for detecting and quantifying certain intentionally added chemicals, it may not identify unknown substances. Therefore, non-targeted analyses are essential for enhancing and streamlining the comprehensive identification of these unidentified compounds.
In this study, 30 samples from various biodegradable food packaging materials, including straws, pizza boxes, and containers, were analyzed, among others, using non-targeted and suspect screening in both positive and negative ion mode. This analysis was conducted with (UPLC) coupled to quadrupole time-of-flight mass spectrometry. The identification and semi-quantification of unknown compounds were performed using patRoon, specifically focusing on poly- and perfluoroalkyl substances, phthalates, and bisphenols. The results obtained from the different food packaging materials were reported and compared between the Netherlands and New Zealand.
This research highlights the role of non-target analysis for identifying potentially overlooked substances present in biodegradable food packaging materials. The findings from this study significantly enhance the identification of chemicals present in food packaging materials, which is crucial for ensuring consumer safety. By improving the detection of both known and unknown compounds, the research contributes valuable data that can inform future studies and regulatory frameworks.

3.07.P-Mo240 Uncovering the Chemicals in House Dust
***Pim Leonards**, Anniek Verstegen, Matina Violaki, Ike van der Veen, Eva Sugeng and Sicco Brandsma, Vrije Universiteit Amsterdam, Netherlands*
Humans spend approximately 90% of their time indoors, increasing their likelihood of exposure to hazardous chemicals, many of which may accumulate in indoor environments. Young children are particularly vulnerable to higher exposures due to the frequent hand-to-mouth behaviors. Indoor dust, a complex matrix, contains a wide range of chemicals and is one of the exposure pathways for humans and a source of chemicals to the environment. The aim of this study was to annotated chemicals in house dust of different European countries.
In the EU-funded INQUIRE project, which aims to enhance indoor air quality, 200 house dust samples were collected in 8 European countries. Samples were analysed with liquid chromatography-high resolution mass spectrometry quadrupole time-of-flight (LC-HRMS-QTOF) and in addition with ion mobility HRMS using suspect and non-target screening (SNTS) approaches. A fast SNTS screening method was developed and optimized. A larger number of chemicals were detected, more than 20000. Regional differences of chemicals in house dust were found showing that for instance the UK had a distinct chemical profile from the other countries. Various groups of chemicals were identified such as lipids, steroids, insect repellents, fragrances, herbicides, and plasticizers, present at varying concentrations.

Disclaimer/Disclosure: This project has received funding from the European Commission Horizon Europe, European health and Digital Executive Agency (HADEA), research and innovation programme under grant agreement Project No 101057499 - INQUIRE.

3.07.P-Mo241 The Capability of Silicone Wristbands for Targeted and Suspect Screening of Toxic Compounds in Primary Schools
***Hale Demirtepe**, Zulfikar Akmermer and Sait C. Sofuoglu, Izmir Institute of Technology, Faculty of Engineering, Department of Environmental Engineering, Turkiye*
Silicone wristbands (SWBs) have proven effective in assessing human exposure to environmental chemicals, while their chemical uptake capacity is still under investigation. Limited studies have examined SWB chemical uptake in controlled conditions, but variations in temperature, ventilation, and multiple pollution sources in real-world indoor settings may affect their performance. This study investigated the chemical uptake capacity of SWBs under varying temperatures, focusing on their potential as tools for

screening toxic chemicals in primary school classrooms where children spend significant time. Five classrooms were equipped with SWBs and polyurethane foam (PUF) passive samplers to monitor polycyclic aromatic hydrocarbons (PAHs), organophosphate esters (OPEs), and phthalate esters (PEs) in indoor air for 36 days. The sampling was repeated twice more at different air temperatures. All samples were screened for targeted and suspect compounds using GC-MS. As a result, phenanthrene, fluorene, and fluoranthene were the dominant PAHs, with decreasing concentrations as the temperature increased. Tri-n-butyl phosphate and tris(2-chloroethyl) phosphate were the abundant OPEs in the indoor air, and diethyl phthalate, diisobutyl phthalate, and di-n-butyl phthalate were the dominant PEs. With increasing temperatures, OPE and PE concentrations increased. The chemical uptake capacity of SWBs for target compounds generally decreased with the increased air temperature, although no statistical relationship was found. Suspect screening of toxic compounds in indoor air using SWBs and PUFs revealed 4-hydroxy-4-methylpentan-2-one, 2,2,4-Trimethyl-1,3-pentanediol diisobutyrate, galaxolide, and Cyclopenta[g]-2-benzopyran as the priority compounds that have higher toxicity and abundance in indoor air. These chemicals, used mainly in surfactants, personal care products, cleaning products, and insect repellents, require regular monitoring and special efforts for reduction. The results demonstrated that SWBs can be used as passive air samplers to screen targeted and suspect compounds in indoor air.

3.07.P-Mo242 Reaching High Throughput for Chemical Exposomics of Human Serum by Phospholipid Removal and LC – HRMS

Solveig Thiele[1]*, Benilde Bonnefille*[2]*, Stefano Papazian*[2] *and Jonathan W. Martin*[2]*, (1)Department of Environmental Science, Exposure and Effects Unit, Science for Life Laboratory, Stockholm University, Sweden, (2)Department of Environmental Science, Exposure and Effects Unit, Science for Life Laboratory, Stockholm University; National Facility for Exposomics, Metabolomics Platform, Science for Life Laboratory, Stockholm University, Sweden*

There is a growing interest to delve into the chemical exposome in human samples to help understand the potential link between diseases and our environment, lifestyle, and occupation. Blood chemical exposomics is facing a number of challenges to investigate sufficiently large-scale population cohorts, which typically provide hundreds to thousands of samples with a limited volume of serum/plasma. For instance, current methods investigating the blood chemical exposome are usually limited to a small number of target analytes with low throughput which does not support large cohort designs.

To overcome these issues, we optimized a protein precipitation and phospholipid removal method for sensitive chemical exposomics analyses in blood previously published by Sdougkou et al. (2023), and modified it to enable high throughput applications in 96-well plates with low sample volumes. Following protein and phospholipid removal of 100 µL serum, a partial evaporation step was optimized to improve the chromatographic separation and detection of 273 analytes, some of which are detected in both ionization modes, by liquid chromatography (LC) and high-resolution mass spectrometry (HRMS). The targets that were selected for the method validation cover a wide variety of class uses (e.g., industrial, pharmaceuticals, pesticides, etc.), including endogenous metabolites (e.g., testosterone, progesterone, corticosterone). These targets are exhibiting a wide range of chemical properties, and are eluting between 5% (initial condition) and 100% of methanol using a gradient elution, with the earliest and latest eluting compound being trifluoromethanesulfonic acid (PFAS, eluting 0.5 min after the void volume) and 4-nonylphenol (various industrial uses), respectively.

The method proved to be repeatable, with 145 out of 155 targets detected in positive mode (93.5%) and 162 out of 168 targets detected in negative mode (96.4%) having a relative standard deviation (RSD) below 20%. Satisfactory recoveries (80 120%) were obtained for 109 of the targets (70.3%) in positive mode and 108 (64.3%) targets in negative.

Overall, this method holds promise to reach the high throughput needed for the comprehensive characterization of the human blood chemical exposome.

3.07.P-Mo243 Integrated Exposure Assessment of Bisphenol A and Bisphenol S Considering both Life Stages and Exposure Route

Inhye Lee[1]*, Sunmi Kim*[2] *and Kyunghee Ji*[3]*, (1)Department of Environmental Health Sciences, Seoul National University, Republic of Korea, (2)Chemical Platform Technology Division, Korea Research Institute of Chemical Technology, Republic of Korea, (3)Department of Environmental Health, Yongin University, Republic of Korea*

Bisphenol A (BPA) and Bisphenol S (BPS) are endocrine-disrupting chemicals widely found in plastics, canned foods, dust, and thermal paper receipts. BPA is frequently detected in polycarbonate plastics and epoxy resins, while the use of BPS as an alternative to BPA has increased in recent years. This study aimed to evaluate exposure levels of BPA and BPS and assess associated risks across different life stages. A literature review covering the years 2010 to 2023 was conducted to identify sources and concentrations of BPA and BPS in food, air, dust, and consumer products. A total of 92 studies on BPA and 32 studies on BPS were analyzed. In addition, eight capsule coffee samples were analyzed to detect BPA and BPS using liquid chromatography-mass spectrometry. Using data from the literature review and capsule coffee analysis, exposure amounts for each route were calculated using exposure scenarios. Exposure assessments for BPA and BPS were conducted across different life stages, including infants, children, adolescents, and adults. Regardless of life stages, grains showed the highest intake contribution rate among foods, followed by baby food (including breast milk and powdered milk) for infants and meat for adults. Infants and young children have a specific food consumption behavior, so when exposure targets were classified by life stages, differences were found in the main exposure sources. The results highlight the need for further monitoring of bisphenol analogues, particularly BPS, and their emerging sources. This study provides an integrated exposure assessment that can inform risk evaluations and regulatory decisions.

3.07.P-Mo244 Innovative Non-Targeted Screening Approach using High-Resolution Mass Spectrometry for the Screening of Organic Chemicals and Identification of Specific Tracers of Soil and Dust Exposure in Children

***Natalia Soares Quinete**[1], Luciana Cappelini[2], Olutobi Daniel Ogunbiyi Sr[1], Mymuna Monem[2], Monica Perez[2], Lisandra Menendez[2], Daniel Bagner[2], Piero Gardinali[2] and Florence George[2], (1)Florida International University, Miami, United States, (2)Florida International University, United States*

Environmental contamination through direct contact, ingestion and inhalation are common routes of children s exposure to chemicals, in which through indoor and outdoor activities associated with common hand-to-mouth, touching objects, and behavioral tendencies, children can be susceptible and vulnerable to organic contaminants in the environment. In this study, we have implemented and optimized a methodology based on non-targeted analysis (NTA) for comprehensive screening and identification of a wide range of organic contaminants in indoor dust, soil, food, drinking water, and urine matrices (N = 439) in the greater Miami area, Florida, U.S., prioritizing chemicals to assess children s environmental exposure. Families with children between 6 months and 6 years of age of underrepresented groups were recruited and samples were provided by the caregivers. The main goal was the selection of unique tracers of soil and dust ingestion in young children by NTA using Q-Exactive Orbitrap MS followed data processing by the Compound Discoverer software (v3.3, SP2). Identified features were plotted using Kendrick mass defect plot and Van Krevelen diagrams to show unique patterns in different samples and regions of anthropogenic compound classifications. Chemical features were first prioritized based on their predominant abundance (peak area>500,000), detection frequency (in >50% of the samples), available information on their uses and potential toxicological effects. Specific tracers of soil and dust exposure in children were selected in this study including Tripropyl citrate and 4-Dodecylbenzenesulfonic acid. The criteria for selection of the tracers were based on their higher abundance, detection frequency, unique functional uses, measurable amounts in urine (suitable biomarker), and with information on gastrointestinal absorption, metabolism, and excretion, and were further confirmed by authentic standards. We are proposing for the first time suitable unique tracers for dust ingestion by children.

3.07.P-Mo245 Deepen the Characterisation of the Perinatal Chemical Exposome Thanks to SS/NTS Global Profiling Strategies

*Tarek Moufawad[1], Solene Motteau[1], Ingrid Guiffard[1], Emmanuelle Bichon[1], Laurent Debrauwer[2], Sylvia Sanquer[3], Marja Lamoree[4], Bruno Le Bizec[1] and **Jean-Philippe ANTIGNAC**[1], (1)Oniris, INRAE, LABERCA, France, (2)Toxalim (Research Centre in Food Toxicology), INRAE UMR 1331, ENVT, INP-Purpan, Paul Sabatier University (UPS), France, (3)Service de Biochimie Metabolique, H pital Necker-Enfants Malades, France, (4)Chemistry for Environment & Health, Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands*

The exposome encompasses all environmental and socio-economic factors encountered over a lifetime, complementing the genome in explaining their roles in health outcomes. Since the concept's introduction in 2005, significant progress has been made in advancing methods, tools, and knowledge to assess the exposome and its impact on human health. However, chemical exposure during the perinatal period remains understudied, largely due to the challenges of accessing appropriate and sufficient amount of biological samples required to conduct multiple analysis to detect a broad range of chemicals.

To overcome these limitations, the application of innovative suspect screening (SS) and non-targeted screening (NTS) approaches based on high-resolution mass spectrometry (HRMS) offers a more effective approach by one analysis to characterize and chemically profile a wider range of substances. These advanced analytical approaches allow, with a single analysis, for the detection of a wide array of compounds covering a broad spectrum of physicochemical properties. This strategy not only enhances global human biomonitoring but also improves the identification of chemicals of emerging concern in an early warning perspective.
We have developed streamlined workflows, from sample preparation to data analysis, to investigate various maternal (urine, serum, maternal milk) and foetal (cord blood, amniotic fluid) biological matrices from diverse mother-child cohorts. These methods were applied in a range of research projects conducted at national and EU level. The proposed presentation will describe these different proo f-of-concepts enabling the determination of real-life chemical mixtures composing the internal exposure related to the perinatal period

3.08 Sampling and Analysis Methodologies, and Environmental Behavior Studies for Emerging Organic Contaminants in the Aquatic Environment: Recent Advances and Perspectives

3.08.T-01 Passive Sampling of PFAS in the Aquatic Environment
***Rainer Lohmann**[1], Matt Dunn[1], Jarod Snook[1], Jitka Becanova[2] and Simon Vojta[1], (1)University of Rhode Island, United States, (2)University of Rhode Island, Kingston, United States*
Per- and polyfluoroalkyl substances (PFAS) are a group of compounds of high concern due to their ubiquity, persistence, and adverse health impacts. With a diversity of chemical structures and properties, versatile detection tools are needed to capture as many PFAS as possible. Different passive samplers (microporous polyethylene tube, MPT, and a diffusive gradients in thin film, DGT, were hence calibrated for the uptake of different PFAS. The MPT was tested with target PFAS, and suspect PFAS and extractable organofluorine (EOF) during 1-2 week deployments in groundwater, a freshwater river, and an estuary contaminated by aqueous film-forming foam (AFFF). Targeted analysis, suspect screening, and EOF were performed on passive and grab samples to derive sampling rates, Rs. Median measured and fluorine-normalized estimated EOF Rs in groundwater (7.1 vs 8.4 mL day-1 respectively) and river water (55 vs 66 mL day-1 respectively) were within 20% of each other. For suspect PFAS, Rs were similar to targeted PFAS of alike functional group chemistry and perfluorinated carbon chain length. For example, for 6:2 and 8:2 FTSAS-sulfoxide, estimated Rs were 1.8- and 6.0-mL day-1, respectively, similar to Rs measured for 6:2 and 8:2 FTS of 2.2- and 6.3-mL day-1. These results suggest targeted and suspect PFAS, and EOF, are taken up by MPT passive samplers in a predictable manner, expanding passive sampling capabilities. The DGT sampler, in contrast, we calibrated mostly to test the effect of temperature on sampling rates based on a diffusive model. In joint deployments, results from the DGT were closer to grab sample results, while the PMT was sturdier during field deployments, with greater recovery rates. Both samplers offer the advantage of being able to derive time-weighted average concentrations of PFAS in the field, with the potential to estimate those for non-target and suspect PFAS, too.

3.08.T-02 Evaluation of the Performances of a Biofilm-Based Passive Sampler to Monitor Micropollutants in Wastewater
***Anna Voiland**[1], Benedicte Lepot[1], Nina Huynh[1], Selim Ait-Aissa[1], Francois Lestremau[2], Elisa Robotti[3], Abd-El-Rahman El-Mais[1] and Azziz Assoumani[1], (1)Institut National de l Environnement Industriel et des Risques (INERIS), France, (2)HSM, Univ Montpellier, IMT Mines Ales, CNRS, IRD, France, (3)Dipartimento di Scienze e Innovazione Tecnologica, Universit del Piemonte Orientale, Italy*
Passive samplers (PS) are powerful tools for monitoring micropollutants due to their ability to accumulate them over weeks or months, providing great time-representativeness. Additionally, they enable to achieve lower detection limits compared to traditional methods like grab or composite sampling.
However, in wastewater this sampling method faces the constraint of biofouling, which hampers the transfer of micropollutants from water to the receiving phase. This work aims to investigate an innovative PS, the Prebio cell STEP, that uses the biofilm as a receiving phase, and thus turns biofouling into an advantage.
The operating conditions of the Prebio cell STEP were defined, through the kinetic study of biofilm growth, and accumulation of targeted micropollutants over several months in influents and effluents of an urban wastewater treatment plant (WWTP), to determine the optimal deployment duration of this sampler. In parallel, the performances of the Prebio cell STEP were compared with conventional 24h water composite sampling regarding the detection of the same micropollutants targeted for the kinetic study, and number of compounds detected by suspect and non-target screenings using LC/HRMS analysis.
First results showed major differences in appearance of biofilm, and growth kinetics between WWTP

influents and effluents which could be explained in relation with the various complexity of these water matrices.
Chemical analysis of the biofilm revealed the ability of the biofilm to capture micropollutants present in the wastewater samples. The kinetic of accumulation of some of these micropollutants in the biofilm will be presented (metals, alkylphenols, polycyclic aromatic hydrocarbons). Moreover, LC/HRMS suspect and non-target screening highligthed the presence of a variety of micropollutants in the biofilm, including some not detected in wastewater composite samples.

3.08.T-03 Pesticide Pathways Revealed: Comprehensive Analytical Methods for Multi-Compound Monitoring in Urban and Agricultural Catchments

Kim Ngoc Tram Luong*, Vera Ganz, Elia Ceppi, Johannes Schorr and Heinz Singer, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Pesticides can pose an ecotoxicological risk to humans and aquatic organisms. To develop effective mitigation measures, it is essential to investigate their environmental entry pathways. However, their authorisation for different applications (i.e., as plant protection products or as biocides) makes source identification challenging. Moreover, nonpolar pesticides, such as pyrethroids, are toxic at low pg/L concentrations, tend to adsorb to particles and may bioaccumulate due to their hydrophobicity. Combining sensitive analytical methods is indispensable to determine the total concentration (i.e., the dissolved and the particle-bound fractions) and the concentration in the dissolved fraction only. This study aims to a) assess the occurrences of a broad spectrum of pesticides and b) gain insights on their entry pathways from urban and agricultural catchments.
River and wastewater effluent samples were collected from February to November 2023 at five different sites. A liquid-liquid extraction followed by extract splitting and analysis using gas chromatography with atmospheric pressure chemical ionisation (GC-APCI) or liquid chromatography with electrospray ionisation (LC-ESI) coupled to a triple quadrupole mass spectrometer (QqQ-MS) enabled the quantification of the total concentration of 70 nonpolar compounds (LogP > 4). For the quantification of about 240 more polar pesticides in the dissolved fraction, enrichment by vacuum-assisted evaporative concentration followed by LC-ESI coupled to a high-resolution mass spectrometer (HRMS) was used. Glyphosate was measured using ion chromatography HRMS.
Pyrethroids - namely lambda-cyhalothrin, cypermethrin, permethrin, deltamethrin - remain the main risk drivers, with contributions from previously understudied nonpolar pesticides (e.g., fipronil, aclonifen, diflufenican) and more polar insecticides (e.g., imidacloprid, thiacloprid) and herbicides (e.g., dimethachlor, metazachlor, nicosulfuron). Approximately 80% of the detected substances enter the environment largely via wastewater treatment plants. Hypotheses about the source can be made by considering the regulatory data and the mode of action of the substance in question, together with site-specific information like land use, meteorology, and hydrology. The present study offers important data on the main entry pathways of non- and polar pesticides, thereby providing critical insights for effective mitigation strategies.

3.08.T-04 Dynamics of Persistent and Mobile Chemicals, Including Ultra-Short Per- and Polyfluoroalkyl Substances, in Groundwater: Distribution, Influencing Factors, and Risk

Xiaojing Zhu[1]*, Till Meier*[1]*, Qiuguo Fu*[2] *and Thorsten Reemtsma*[1]*, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Department of Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Persistent and mobile (PM) chemicals, including pesticides, pharmaceuticals, industrial compounds, and PFAS (per- and poly-fluoroalkyl substances), pose significant environmental and public health concerns due to their resistance to degradation and potential toxicity. These chemicals, along with their transformation products, are often challenging to detect in previous monitoring, resulting in gaps in understanding their occurrence, behavior, and risks. Our study investigates the distribution, influencing factors, and risks of PM chemicals in groundwater from Saxony, Germany. 82 groundwater samples from 25 groundwater bodies were collected and analysed for 180 PM chemical candidates using our optimized analytical method, including freeze-drying and supercritical fluid chromatography mass spectrometry measurement (capable of trace analysis). A total of 163 PM chemicals were detected with the median summed PM chemical concentration of 23,000 ng/L. Trifluoroacetic acid (TFA) was identified as the most prevalent compound, with concentrations reaching µg L?¹ levels. Statistical analysis revealed that PM chemical properties, such as solubility and soil-water partitioning, significantly influenced PM chemical distribution, while lipophilicity (log D) showed limited correlation. Water characteristics, including inorganic ions (e.g., nitrate, sulfate, calcium, and sodium), also played a pivotal role in shaping PM chemicals distribution. Cluster analysis highlighted co-occurrence patterns, identifying benzothiazole and N,N-dimethylformamide as key indicators of mixed contamination from industrial sources. Spatial distribution patterns linked PM chemicals to regional land-use activities, with certain compounds as potential indicators of specific pollution sources. Risk assessment using ToxPi (Toxicological Priority Index) scoring and risk indices prioritized 35 PM chemicals with the highest environmental and public health risks, including TFA, benzothiazole, N-methylpiperidine, and chloridazon-desphenyl, suggesting that agricultural and industrial activities are the major sources for the groundwater bodies as at higher risk levels. These findings provide insights into the behaviors of PM chemicals in groundwater and suggest the need of tailored monitoring, regulation, and remediation strategies to mitigate PM chemical risks.

Disclaimer/Disclosure: The authors thank the financial support of the project re:PM in the framework of the German-Israeli Water Technology Cooperation by BMBF and MOST (BMBF FKz 02WIL1658; MOST Project Number 1001541168).

3.08.P-Th116 Source Control of Industrial Emissions: Monitoring Strategies to Discern Pollutant Spills

Tom Galle[1]*, Denis Pittois*[1]*, Viola Huck*[1]*, Carole Lacroix*[2]*, Laurene Chochois*[2]*, Parviel Chirsir*[3]*, Emma Schymanski*[4]*, Kenzo Fabbro*[5]*, Carine Guilloteaux*[5] *and Raymond Erpelding*[5]*, (1)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (3)University of Luxembourg, Luxembourg, (4)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (5)SIACH, Luxembourg*

Micropollutant emissions from industry often blend with household contributions stemming from consumer goods. In addition, industrial emissions can be very sporadic. There are therefore two major challenges that need to be addressed to assess the emissions in the technical catchment of a WWTP: covering a large enough period of time to catch emissions with low return times and identifying the compounds that are emitted. The SourceControl project adopted a monitoring strategy that combined collecting samples at the inlet of a WWTP with passive and autosamplers with non-target analysis of soluble compounds (LC-MS). Passive samplers were deployed for one week each during 8 weeks in total while autosamplers covered daily dynamics (3-hour mixed samples) over three weeks within that period. Passive sampler extracts were first screened with non-target analysis to identify compounds of relevance and then quantified with target analysis. The combination of statistical analysis of autosampler results and in sewer tracking allowed to dress emitter profiles. WTTP inlets show typical diurnal dynamics of domestic organic loads in highly resolved autosampler campaigns. NH4 and DOC were used to verify the regularity of household emissions and the absence of strong industrial contributors. Pharmaceuticals and in-house biocides were strongly correlated to NH4 and DOC. Pollutants with diffusive emission from consumer goods like flame retardants had a binary behaviour with a background emission from households and peak spills from industry (example TCPP). Some compounds showed very regular emission patterns from industry and were associated to other compounds showing synchronized peaks. A semi-quantitative screening with passive-samplers in sewer systems at points in the network that isolated distinct industrial zones allowed for specific source allocation. Two single weeks were covered by passive samplers and the stronger precipitation during one week enabled a cluster analysis to discern specific industrial inputs but also continuous domestic input from urban surface runoff. The approach complemented the results of the WTTP inlet analysis revealing similar pollutant profiles. The contribution will discuss the opportunities and limits of combining different monitoring and analytical methods as well as the further investigations needed for the identified compounds.

Disclaimer/Disclosure: The project SourceControl was granted by the Luxembourgish Water Management Fund.

3.08.P-Th117 Wide Pesticide Screening Assessment in Aquatic Environments: Comparisons of Sampling and Extraction Techniques

Caterina Cacciatori[1]*, Jackie Myers*[1]*, Giulio Mariani*[2]*, Bernd Manfred Gawlik*[2] *and Vincent J. Pettigrove*[3]*, (1)RMIT University, Australia, (2)European Commission, Joint Research Centre (JRC), Italy, (3)Aquest Research Group, RMIT University, Australia*

Amidst increasing use of pesticides worldwide and their discharge into aquatic environments, there is a need improve our understanding of pesticide occurrence and improve water quality monitoring. Addressing the data gaps associated with pesticide contamination, this research combines wide-screening technology and citizen engagement. By employing both passive and grab sampling methods alongside wide-screening techniques, we can detect a broader range of pesticides in water. Involving local citizen groups in water quality monitoring expands the temporal and spatial scale of environmental data. This strategic collaboration between society and scientists not only strengthens community connection but also

raises awareness about sustainable water quality management.
In the context of sampling and analytical techniques for wide pesticide screening, this research examines the synergies, advantages and disadvantages of passive sampling (Chemcatcher and POCIS) and grab sampling in combination with Solid Phase Extraction (SPE), and the Stir Bar Sorptive Extraction (SBSE). The comparison encompasses the number and concentration of detected pesticides, based on a wide-screen of 230 compounds analysed by Gas Chromatography Quadruple Time of Flight High Resolution Mass Spectrometry. The evaluation of the analytical techniques is grounded in field data from a month-long monitoring campaign conducted in March 2023 at three sampling sites in Melbourne, Australia. Grab sampling coupled with SBSE detected the highest number of pesticides, though its quantification was 2 to 3 times lower than that of grab samples extracted by SPE. Passive samplers detected the fewest pesticides. The hydrophobicity and characteristics of the sampling locations partly explained these results. The advantages and disadvantages of the different sampling and extraction methods have been analysed in terms of temporal information provided, sensitivity, complexity of the analytical procedures, and their applicability for citizen-based water quality monitoring. Beyond the novelty of evaluating different analytical techniques for an extensive list of pesticides, this study is significant due to its implementation in a citizen engagement initiative by the Joint Research Centre of the European Commission.
This presentation will highlight the comparative effectiveness of the different wide-screening techniques and explores the potential of citizen science to contribute to monitoring pesticides in water.

3.08.P-Th120 Occurrence, Remove Efficiency and Modelling of Pharmaceutical and Personal Care Products (PPCPs) in a Typical Wastewater Treatment Plant in Wuhan
***Zhe Qian*[1]**, *Chi Zhang*[2]*, Shihua Qi*[3] *and Wei Chen*[2]*, (1)State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, China (Mainland), (2)School of Environmental Studies, and MOE Key Laboratory of Groundwater Quality and Health, China University of Geosciences, China (Mainland), (3)State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences; School of Environmental Studies, and MOE Key Laboratory of Groundwater Quality and Health, China University of Geosciences, China (Mainland)*
Pharmaceuticals and personal care products (PPCPs) are among the emerging organic contaminants, posing significant risks to human health and ecological safety. Wastewater treatment plants (WWTPs) serve as critical control points for the release of PPCPs into the environment. However, the high data uncertainty in current research compromises the accuracy of exposure model predictions. In this study, the occurrence, temporal variation and removal efficiency of 15 PPCPs across 5 categories were investigated in a WWTP using diffusive gradients in thin-films (DGT) technology. The EU exposure model SimpleTreat 4.0 was modified and optimized according to the characteristics of the Chinese WWTP scenario. Accurate data obtained through DGT were used to validate the model predictions and assess their reliability. A total of 11 PPCPs were detected in influent and effluent, with total concentrations ranging from 141-5287 ng L-1. The time-averaged weighted concentrations provided by passive sampling effectvely reduced data unvertainty. Temporal variations in preservatives, estrogens, antimicrobials, and antioxidants in influent primarily related to changes in rainfall and temperature, while bisphenols were likely impacted by industrial production activities. Additionally, changes in PPCP concentrations may also have been influenced by the effects of the COVID-19 pandemic. PPCPs were mainly removed in the secondary treatment. Among the 31 basic WWTP scenario parameters in the SimpleTreat 4.0 model, sensitivity asnalysis identified 11 parameters with a significant impact on model predictions, and 7 of which were optimized. The improved model yielded more accurate prediction for bisphenols, antioxidants and biocides.

3.08.P Sampling and Analysis Methodologies, and Environmental Behavior Studies for Emerging Organic Contaminants in the Aquatic Environment: Recent Advances and Perspectives

3.08.P-Th115 Tracking Pesticide Peaks: Time-Integrated vs. Flow-Proportional Sampling in Agricultural Streams
Kajsa Weslien, *Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden*
A variety of factors affect the leaching of pesticides from treated agricultural land. For instance, heavy

rainfall can transport pesticides into nearby streams, generating water flow peaks where pesticide concentrations can be temporarily elevated. How and when surface water samples are collected will consequently have a large impact on the results. Conventional water quality monitoring based on grab sampling, typically done once or every three months, can struggle to provide reliable estimates when sampling streams due to the temporal variability in pesticide concentration.
In this study, we compare two sampling methods used within the Swedish national pesticide monitoring program, time-integrated and flow-proportional sampling, focusing on their ability to capture temporal peak concentrations linked to high flow events. In time-integrated sampling, 100 subsamples are collected each week to give weekly average concentrations of each substance, reflecting the long-term, chronic exposure of pesticides in the stream. In contrast, flow-proportional sampling involves collecting samples in proportion to stream flow velocity, with more samples collected during higher flow conditions, capturing short-term, acute toxicity. The monitoring program targets four small agricultural catchments in southern Sweden, with flow-proportional and time-integrated sampling used simultaneously in one catchment since 2009. Data from 2009-2021 are included in the comparisons.
Our results show that pesticide concentrations in small streams can vary more than hundredfold within just a few hours during high flow events. Flow-proportional samples collected during these events generally display higher pesticide concentrations than weekly time-integrated samples collected over the same time period, often reaching concentrations around ten times higher than the weekly average. Flow-proportional sampling can therefore provide valuable insights into the large variability of pesticide concentrations in agricultural streams, which is important as even short-term peaks in pesticide concentrations (hours to days) can have negative effects the ecosystem. Together, the two sampling methods offer a comprehensive understanding of both the chronic and acute impacts of pesticides in streams, insights that can be overlooked when relying solely on grab sampling.

3.08.P-Th116 Source Control of Industrial Emissions: Monitoring Strategies to Discern Pollutant Spills

Tom Galle[1]*, Denis Pittois*[1]*, Viola Huck*[1]*, Carole Lacroix*[2]*, Laurene Chochois*[2]*, Parviel Chirsir*[3]*, Emma Schymanski*[4]*, Kenzo Fabbro*[5]*, Carine Guilloteaux*[5] *and Raymond Erpelding*[5]*, (1)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (3)University of Luxembourg, Luxembourg, (4)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (5)SIACH, Luxembourg*

Micropollutant emissions from industry often blend with household contributions stemming from consumer goods. In addition, industrial emissions can be very sporadic. This strategic collaboration between society and scientists not only strengthens community connection but also raises awareness about sustainable water quality management.

In the context of sampling and analytical techniques for wide pesticide screening, this research examines the synergies, advantages and disadvantages of passive sampling (Chemcatcher and POCIS) and grab sampling in combination with Solid Phase Extraction (SPE), and the Stir Bar Sorptive Extraction (SBSE). The comparison encompasses the number and concentration of detected pesticides, based on a wide-screen of 230 compounds analysed by Gas Chromatography Quadruple Time of Flight High Resolution Mass Spectrometry. The evaluation of the analytical techniques is grounded in field data from a month-long monitoring campaign conducted in March 2023 at three sampling sites in Melbourne, Australia. Grab sampling coupled with SBSE detected the highest number of pesticides, though its quantification was 2 to 3 times lower than that of grab samples extracted by SPE. Passive samplers detected the fewest pesticides. The hydrophobicity and characteristics of the sampling locations partly explained these results. The advantages and disadvantages of the different sampling and extraction methods have been analysed in terms of temporal information provided, sensitivity, complexity of the analytical procedures, and their applicability for citizen-based water quality monitoring. Beyond the novelty of evaluating different analytical techniques for an extensive list of pesticides, this study is significant due to its implementation in a citizen engagement initiative by the Joint Research Centre of the European Commission.

This presentation will highlight the comparative effectiveness of the different wide-screening techniques and explores the potential of citizen science to contribute to monitoring pesticides in water.

3.08.P-Th118 Analysis of Pesticides, Pharmaceuticals and Personal Care Products in Water Samples According to the Proposal for a Directive Amending the EU Water Framework Directive

Claudia Rathmann[1] *and Douglas Michael Stevens*[2]*, (1)Waters GmbH, Eschborn, Germany, (2)Waters Corporation, United States*

The monitoring of harmful substances in drinking and environmental water is essential for protecting human health and maintaining environmental quality standards. Accurate measurements at ultra-low levels are a crucial part of any trace monitoring program. As more pesticides, pharmaceuticals, and personal care products (PPPCPs) are released into the environment, there is a growing demand for analytical methods that can handle multiple compound groups. One major analytical challenge lies in the wide chemical diversity of compound classes and structures. Annex V of the proposal for a Directive amending the Water Framework Directive lists Environmental Quality Standards (EQS) for priority substances in surface water. This list of substances was extended to include more pesticides, pharmaceuticals, and personal care products, forming the basis of the presented work. Further compounds of interest were added based on our experience with requests from water testing labs in Europe.

The purpose of this work was to demonstrate a direct injection UPLC -MS/MS method for the ultra-low-level determination of PPPCPs in drinking and environmental waters, in alignment with the EU WFD proposal. The method performance study was completed on an ACQUITY Premier LC System with a Xevo TQ Absolute MS system. A method validation study was carried out on drinking and surface water matrices. Average method performance for trueness, repeatability, linearity, and sensitivity was assessed through inter- and intra-laboratory studies.

The sensitivity of the UPLC-MS/MS system allows for the use of a direct injection approach, which eliminates complex sample preparation and enables the simple, high-throughput analysis of pesticides, pharmaceuticals, and personal care products in drinking and environmental water.

3.08.P-Th119 Pharmaceutical and Personal Care Products (PPCPs) in Typical Wastewater Treatment Plants (WWTPs) in Wuhan, China

Wei Chen[1]*, Jiapei Yi*[1]*, Zhe Qian*[2]*, Junwu Xiong*[1]*, Huanfang Huang*[3]*, Shihua Qi*[2] *and Kevin Jones*[4]*, (1)School of Environmental Studies, China University of Geosciences, China (Mainland), (2)State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, China*

(Mainland), (3)South China Institute of Environmental Sciences, Ministry of Ecology and Environment, China (Mainland), (4)Lancaster Environment Centre, Lancaster University, United Kingdom
Pharmaceuticals and personal care products (PPCPs) are a group of daily used compounds that may have adverse effects on organisms even at trace concentrations, so PPCPs have become one of the research hotspots in recent years. To Understand the occurrence and removal of PPCPs in wastewater treatment plants (WWTPs) is of great significance for the prevention and control of PPCPs. This study investigated nine WWTPs with different processes in Wuhan and used high performance liquid chromatography tandem-mass spectrometry (HPLC-MS/MS) to study the occurrence and distribution of 75 PPCPs in three media (dissolved phase, suspended particle phase, and sludge) in the WWTPs. The main conclusions are as follows:
The concentration ranges in the influent dissolved phases, effluent dissolved phases, influent suspended particle phases, effluent suspended particle phases and sludges from the 9 WWTPs were 666 - 3585 ng·L-1, 103 - 1287 ng·L-1, 196 - 8473 ng·L-1, 4.51 - 130 ng·L-1 and 2479 - 14224 ng·g-1 (dry weight), respectively. Antibiotics were the PPCPs with the highest concentrations, followed by nonsteroidal anti-inflammatory drugs and β-blockers. The distribution patterns of PPCPs in the three media were related to the physicochemical properties of the target substances, with hydrophobic PPCPs having higher concentrations in the suspended particle phase or sludge.
The removal efficiencies of different PPCPs in different WWTPs showed that the nine WWTPs in Wuhan had relatively high removal efficiencies for target substances, with an overall average removal efficiency of 70.8%. Biological treatment is the main unit for removing PPCPs, which is mainly achieved through microbial degradation and sludge adsorption. Different biological treatment processes have different removal efficiencies on target PPCPs, with the anaerobic-anoxic-aerobic and membrane bioreactor processes having higher removal efficiencies than the oxidation ditch and sequencing batch reactor processes.

Disclaimer/Disclosure: The study was financially supported by the National Natural Science Foundation of China (41907327 and 42007178), the Natural Science Foundation of Hubei (2019CFB372), the National Key Research and Development Program (2019YFC1805502), and the Fundamental Research Funds (G1323523063) for the Central Universities, China University of Geosciences (Wuhan).

3.08.P-Th120 Occurrence, Remove Efficiency and Modelling of Pharmaceutical and Personal Care Products (PPCPs) in a Typical Wastewater Treatment Plant in Wuhan

Zhe Qian[1]*, Chi Zhang*[2]*, Shihua Qi*[3] *and Wei Chen*[2]*, (1)State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, China (Mainland), (2)School of Environmental Studies, and MOE Key Laboratory of Groundwater Quality and Health, China University of Geosciences, China (Mainland), (3)State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences; School of Environmental Studies, and MOE Key Laboratory of Groundwater Quality and Health, China University of Geosciences, China (Mainland)*
Pharmaceuticals and personal care products (PPCPs) are among the emerging organic contaminants, posing significant risks to human health and ecological safety. Wastewater treatment plants (WWTPs) serve as critical control points for the release of PPCPs into the environment. However, the high data uncertainty in current research compromises the accuracy of exposure model predictions. In this study, the occurrence, temporal variation and removal efficiency of 15 PPCPs across 5 categories were investigated in a WWTP using diffusive gradients in thin-films (DGT) technology. The EU exposure model SimpleTreat 4.0 was modified and optimized according to the characteristics of the Chinese WWTP scenario. Accurate data obtained through DGT were used to validate the model predictions and assess their reliability. A total of 11 PPCPs were detected in influent and effluent, with total concentrations ranging from 141-5287 ng L-1. The time-averaged weighted concentrations provided by passive sampling effectvely reduced data unvertainty. Temporal variations in preservatives, estrogens, antimicrobials, and antioxidants in influent primarily related to changes in rainfall and temperature, while bisphenols were likely impacted by industrial production activities. Additionally, changes in PPCP concentrations may also have been influenced by the effects of the COVID-19 pandemic. PPCPs were mainly removed in the secondary treatment. Among the 31 basic WWTP scenario parameters in the SimpleTreat 4.0 model, sensitivity asnalysis identified 11 parameters with a significant impact on model predictions, and 7 of which were optimized. The improved model yielded more accurate prediction for bisphenols, antioxidants and biocides.

Disclaimer/Disclosure: The authors thank financial supporting by the National Natural Science Foundation of China (41907327 and 42007178), the Natural Science Foundation of Hubei (2019CFB372), the National Key Research and Development Program (2019YFC1805502), and the Fundamental Research Funds (G1323523063) for the Central Universities, China University of Geosciences (Wuhan), and the asisitence from the staff from the WWTPs for the sample collection.

3.08.P-Th121 Seasonal Study of the Presence of Pharmaceuticals in Mero-Barcés River Basin (NW Spain)

Jorge Lejo Santiago, Estefania Concha-Graña, Purificacion Lopez-Mahia and ***Soledad Muniategui-Lorenzo****, University of A Coru a, Spain*

Pharmaceuticals are being found in the environment because WWTPs do not have the technology to remove all the organic pollutants. These compounds reach WWTPs through wastes or excretions by human and animal after their consumption. Due to this situation, the EU has recently approved the Urban Waste Water Treatment Directive (91/271/EEC) which will regulate 11 pharmaceuticals. As it will be a challenge to remove the different CECs,it is important to have environmental data on which compounds affect the ecosystem and need to be removed.
The aim of this work is to study the presence and behavior of 56 pharmaceuticals in a reservoir where drinking water is provided to the population using liquid chromatography coupled to triple quadrupole mass spectrometry (LC-MS/MS (QqQ)) for their determination. The seasonal study was performed collecting samples from 7 sampling sites in the Mero-Barcés River Basin (NW Spain). These points represent the whole river basin taking points in the two rivers before they reach the reservoir, two points inside the reservoir where the water of both rivers is not yet mixed, one point where the water is mixed, another in the dam and the last one in the river after leaving the reservoir. Each point was measured during 6 seasons between June 2022 and December 2023.
37 pharmaceutical compounds were detected at levels ranging from 0.1 to 143 ng/L, with antibiotics, cardiovascular drugs, NSAIDs and psychiatric drugs being the most representative therapeutic classes. Of all the pharmaceuticals found in the samples, 5 of them are proposed to be regulated by the EU in Surface (azithromycin, carbamazepine, clarithromycin, diclofenac and erythromycin). There appears to be an increase in the concentrations of pharmaceuticals during summer and fall, which could be due to the rainfall during these seasons. All therapeutic classes studied were found distributed in all sampling points except for anticoagulants, which were found in only 3 of the 7 sites.

Disclaimer/Disclosure: This work is part of the project PHARMASEA (ref. PCI2021-121987) supported by MCIN/AEI/10.13039/501100011033 and the European Union NextGenerationEU/PRTR . The Program Consolidación e Estructuración de Unidades de Investigación Competitivas of the Galician Government (Xunta de Galicia) is also acknowledged (Grant ED431C 2021/56).

3.08.P-Th122 Seasonal Trends and Consumption Habits of Addictive Substances in the Community of Madrid (Spain) Through Wastewater Analysis

Emma Gracia-Lor[1]*, Natalia Melones-Pena*[1]*, Susana Torrado-del Rey*[2]*, Azara Perez-Valenciano*[2] *and Maria Justina Martin-Gutierrez*[3]*, (1)Department of Analytical Chemistry, Complutense University of Madrid, Spain, (2)Laboratorio de Salud Publica de Madrid, Subdireccion General de Salud Publica. Madrid Salud. Ayuntamiento de Madrid, Spain, (3)Laboratorio de Salud Publica de Madrid, Subdireccion General de Salud Publica. Madrid Salud. Ayuntamiento de Madrid., Spain*

The consumption of illegal drugs, as well as benzodiazepines, whether prescribed or not, has increased considerably in recent years in Spain. Their continued consumption leads to addiction, becoming a problem that harms both the consumer and society. Therefore, accurate and updated data on their use is essential.
In this work, wastewater-based epidemiology was applied to expand the existing information on the consumption habits of the population of the Community of Madrid (Spain). A study was carried out on the consumption of about twenty addictive substances, including illegal drugs, new addictive substances and benzodiazepines. The samples were collected from eight wastewater treatment plants (WWTP) at four different times: December 2023 (winter), April 2024 (spring), June 2024 (summer)) and October 2024 (autumn) (224 samples in total). This made it possible to assess whether consumption of the investigated substances varied among the populations investigated and whether it changed according to the time of the year. Samples were analyzed using an optimized analytical method based on solid phase extraction (SPE) followed by liquid chromatography-coupled to mass spectrometry (HPLC-MS/MS), using a triple quadrupole analyzer.
Our data reflect that, in the Community of Madrid, cannabis and cocaine are by far the most consumed illegal substances. Among the new psychoactive substances (NPS) investigated, ketamine was found in all the samples whereas other NPS, such as mephedrone, were measured in a few samples. In the case of benzodiazepines, two of them (lorazepam and lormetazepam) were present in all the samples analyzed.

Regarding the differences in consumption observed between the populations investigated, statistical analysis indicated that they are not due to sociodemographic or socioeconomic factors but rather to the consumption habits of each population. On the other hand, similar consumption levels were observed throughout the year, with no clear seasonal variation, except for certain substances like codeine, whose consumption, in some populations, was slightly higher in December 2023; this variation could be attributed to its legal use in medications to relieve symptoms of cough and colds, which are more common in winter.

Disclaimer/Disclosure: This work has been supported by Madrid Salud (Ayuntamiento de Madrid, Spain) and also by the Government Delegation for the National Drugs Plan (Ministry of Health, Spain), with funds from the European Union NextGenerationEU [EXP2022/008817] and by the Spanish Ministry of Science, Innovation and Universities [PID2023-148425NB-I00].

3.08.P-Th123 Nationwide Monitoring of Organophosphate Esters in Korean Surface Waters

***Junseong Park**[1], Sori Mok[1], Daeho Kang[2], Jun Yub Kim[3], Sun-Hong Lee[4], Sojeong Han[4], Tae Jin Park[4], Sang Don Kim[5], Junho Jeon[2] and Hyo-Bang Moon[1], (1)Department of Marine Science and Convergence Technology, College of Science and Convergence Technology, Hanyang University, Republic of Korea, (2)Department of Environmental Engineering, Changwon National University, Republic of Korea, (3)Water Environmental Management Dept., Korea Water Resources Corporation (K-water), Republic of Korea, (4)Water Environmental Engineering Research Division, National Institute of Environmental Research, Environmental Research Complex, Republic of Korea, (5)School of Earth Sciences and Environmental Engineering, Gwangju Institute of Science and Technology, Republic of Korea*

With the regulation of production and use of halogenated flame retardants, their alternative, organophosphate esters (OPEs), are considered emerging concerns due to severe contamination in aquatic environment. OPEs are widely applied as flame retardant and plasticizer in a wide range of commercial and industrial products, such as electronic equipment, furniture, rubber, lubricant, and textile. In this study, nationwide monitoring of OPEs in Korean surface water was conducted to elucidate their occurrences and profiles, providing essential data for effective management. Surface water samples were collected from 130 sites of four major rivers of Korea the Han, Nakdong, Geum, and Yeongsan Rivers during three sampling campaigns in 2023. Gas chromatography and liquid chromatography with high-resolution mass spectrometry (GC-HRMS and LC-HRMS) were employed to identify and quantify 18 target OPEs. Tris(1-chloro-2-propyl) phosphate (TCIPP) was predominant compound in all river water samples, accounting for over 50% of the total OPEs, followed by tris(2-butoxyethyl) phosphate (TBOEP) and tris(2-chloroethyl) phosphate (TCEP). Generally, the Han River exhibited higher concentrations of OPEs compared to the other rivers, likely due to the proximity to urbanized areas. Relatively high concentrations of OPEs were observed near the outlets of wastewater and sewage treatment plants, implying that these facilities serve as point sources of OPE contamination. Several sites exhibited distinct contamination patterns, indicating the need for detailed investigations to identify the sources of contamination. Seasonal variation was observed in TCIPP, with relatively lower concentrations during the summer; however, no significant differences were found in TBOEP and TCEP. This study provides fundamental data for developing effective chemical management strategies for OPEs in aquatic environments.

Disclaimer/Disclosure: This work was supported by a grant from the National Institute of Environmental Research (NIER), funded by the Ministry of Environment (ME) of the Republic of Korea (NIER-SP2023-349).

3.08.P-Th124 Nationwide Evaluation of Polyfluoroalkyl Substances Abundance in Reservoirs of Taiwan

***Cat Tuong Le Tuong**[1], Ferlian Vida Satriaji[2] and Jheng-Jie Jiang[3], (1)Advanced Environmental Ultra Research Laboratory (ADVENTURE) & Department of Environmental Engineering, Chung Yuan Christian University, Taoyuan 320314, Taiwan, Vietnam, (2)Advanced Environmental Ultra Research Laboratory (ADVENTURE) & Department of Environmental Engineering, Chung Yuan Christian University, Taoyuan 320314, Taiwan, Indonesia, (3)Advanced Environmental Ultra Research Laboratory (ADVENTURE) & Department of Environmental Engineering, Chung Yuan Christian University, Taoyuan 320314, Taiwan, Taiwan (Greater China)*

Per- and polyfluoroalkyl substances (PFASs) are a group of versatile chemicals known for their exceptional properties and associated toxicity. These substances can enter and disperse throughout the environment through various pathways. Concerns about PFASs have been growing due to emerging

research highlighting their increased health risks and complex behaviors, particularly with newly identified PFAS compounds. Reservoirs in Taiwan are critical in providing water for domestic, agricultural, and industrial use, making it essential to maintain water quality and prevent harmful contaminants from impacting public health. To assess the potential sources and risks of 10 PFASs, water samples were collected from the surface and bottom layers of six reservoirs in Taiwan between November 2019 and April 2020. The concentrations of PFASs were measured using ultra-performance liquid chromatography-tandem mass spectrometry (UPLC/MS-MS). The studied reservoirs included Feicui Reservoir, Shimen Reservoir, Liyutan Reservoir, Mingde Reservoir, Renyitan Reservoir, and Cheng Ching Lake Reservoir. The total concentrations of PFASs ranged from below the limit of detection (LOD) to 12.3 ng/L in the surface water and from below the LOD to 9.93 ng/L in the bottom water. The predominant compounds detected were perfluorooctane sulfonic acid (PFOS), perfluorobutane sulfonic acid (PFBS), and perfluorooctanoic acid (PFOA). Their average concentrations in the surface water were 1.09 ng/L, 0.86 ng/L, and 0.85 ng/L, respectively, while in the bottom water, the average concentrations were 0.92 ng/L, 1.06 ng/L, and 0.75 ng/L, respectively (Mann-Whitney U test, p-value > 0.05). Source apportionment was conducted using principal component analysis (PCA) and positive matrix factorization (PMF), identifying two primary sources. The first source was attributed to domestic daily activities and metal plating processes, while the second source was linked to food packaging, outdoor equipment, and consumer products. Risk quotients (RQs) and the Health Risk Index (HRI) were calculated to evaluate potential risks. The RQ values were all below 0.01, indicating negligible risk to aquatic organisms. Similarly, HRI values were below 1, suggesting that consumption of treated drinking water from these reservoirs poses no significant health risks to the Taiwanese population.

3.08.P-Th125 Quantifying the Impact of Photolysis on Micropollutant Attenuation in a Natural River System

Malte Posselt[1], *Magdalini Sarntaridou*[1], *Joeselle Serrana*[2] *and Jonas L. Schaper*[3], *(1)Department of Environmental Science, Stockholm University, Sweden, (2)Stockholm University Center for Circular and Sustainable Systems, Stockholm University, Sweden, (3)Department of Geosciences, Eberhard Karls University of Tubingen, Germany*

Natural removal processes play a crucial role in the environmental fate of organic micropollutants, yet there remain considerable gaps in understanding the environmental factors that influence their relative importance and spatial and temporal variability. Micropollutants, such as pharmaceuticals and personal care products, are widely detected in water bodies and subject to a complex interplay of removal processes, including photolysis, adsorption, and biodegradation. While field studies have advanced the in-situ quantification of micropollutant attenuation in river systems, they often fail to decouple biodegradation widely regarded as the most significant mechanism from other simultaneous processes. Photolysis, in particular, presents a challenge due to its dependence on spatially and temporally variable factors such as water transparency, dissolved organic matter, and solar irradiance. Knowledge on the dynamics of the relative importance of photolysis with respect to overall removal of micropollutants in natural and urban streams is scarce but considered essential for predicting micropollutant behavior and informing water management strategies.

This study aims to distinguish micropollutants susceptible to photolysis under real-world conditions from those that are not. We conducted two consecutive field sampling campaigns, one at night and one during the day, under the same hydrological conditions along a 5 km stretch of the Ammer River near Tübingen, Germany. Using fluorescein dye tracer injections, we measured accurate travel times for day and night conditions, helping us evaluate photolytic and non-photolytic effects on attenuation. Water samples collected using a Lagrangian sampling scheme were analyzed through non-targeted suspect screening with a high-resolution UHPLC-Orbitrap-MS/MS instrument. The sensitivity ranking for over 100 micropollutants, based on their real-world susceptibility to photolysis, established in this study provides a foundation for future work aimed at more precisely quantifying biodegradation processes. The results improve our ability to characterize micropollutant attenuation in natural aquatic systems and will enhance the accuracy of estimates regarding their environmental persistence and fate.

Disclaimer/Disclosure: Formas a Swedish Research Council for Sustainable Development is acknowledged for funding this project (grant 2021-02059).

3.08.P-Th126 Different Factors Affecting the Seawater Sample Processing for the Trace Analysis of Organophosphate Triesters and their Metabolites: Application to the Loire Estuary (France)

Pablo Zapata-Corella[1], *Miguel Velazquez-Gomez*[2], *Charles Pollono*[1] *and Javier Castro-Jimenez*[1], *(1)IFREMER, Chemical Contamination of Marine Ecosystems (CCEM), France, (2)Department of Chemical and Environmental Engineering, Underwater Vehicles Lab LVS, Technical University of*

Cartagena, Spain
Organophosphate (tri)esters (OPEs) are high production volume chemicals currently in use as additives and/or flame retardants in a variety of plastics and polymers and are considered as contaminants of emerging concern widely distributed in the environment. Their environmental degradation can lead to the formation of the corresponding organophosphate diesters (diOPEs). Therefore, suitable analytical methods for both tri- and di-OPEs are needed for a comprehensive assessment of their environmental occurrence, especially in marine environments where knowledge on the presence and distribution of these pollutants is still scarce. Most studies rely on different sample treatment methods to detect and quantify tri- and di-OPEs in surface waters due to the differences in their physicochemical properties (e.g., Kow values, anionic nature of diOPEs). In this study, we investigated 3 factors affecting the recovery of 19 triOPEs and 6 diOPEs from seawater samples in a single step method based on SPE. We used a 33 factorial experimental design to evaluate the influences of the stationary phase, elution solvents and the washing and drying steps on the SPE performance. Target compounds were analyzed by isotopic dilution LC-MS/MS. Differences in the recovery rates were related to the physicochemical characteristics of the compounds; better recoveries were found for diOPEs using mixed mode WAX cartridges while DSC-NH2 showed better performances for linear alkyl triOPEs. The best extraction protocol consisted on HLB SPE followed by an acid wash and drying step and elution with MeOH and ethyl acetate. This method was then validated by means on native OPE spiking experiments and later successfully applied for the simultaneous determination of tri- and diOPEs in 12 seawater samples from the Loire estuary (north west France). The sample sites included highly industrialized areas and near and offshore samples from touristic areas. Results showed up to 20-fold higher levels for certain OPEs (e.g., TEP, TBOEP) in the industrialized area with respect to reference offshore samples, and a widespread presence of aryl OPE and DPhP in seawaters. The developed method may improve the performance of monitoring programs for OPEs in marine environments allowing the inclusion of diOPE without significant increases in economical and temporal costs of the analytical process.

Disclaimer/Disclosure: This study was financially supported by project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union. We would like to thank Olivier Pierre Duplessix and Anne Schmitt from the LER/MPL for their support on the coastal sampling campaigns.

3.08.P-Th127 Exploring the Effects of PFAS on Wild Populations of Mosquitofish: Focus on Behaviour and Reproduction

***Clelia Gasparini*[1]*, Francesco Santi*[1]*, Bianca Melita Palmas*[2]*, Edoardo Pietropoli*[3]*, Andrea Barbarossa*[4]*, Giovanni Polverino*[2]*, Anisa Bardhi*[5] *and Marianna Pauletto*[3]*, (1)Department of Biology, University of Padova, Italy, (2)Italy, "Dipartimento di Scienze Ecologiche e Biologiche" (3)Department of Comparative Biomedicine and Food Science, University of Padova, Italy, (4)Department of Veterinary Medical Sciences, University of Bologna, Italy, (5)Department of Veterinary Medical Sciences, University of Bologna, Italy*

The widespread contamination of surface and groundwater with per-/poly-fluoroalkylated substances (PFAS) is alarming due to their persistence, bioaccumulation, and adverse effects on living organisms. This work takes advantage of the naturally occurring high concentrations of PFAS detected in some areas of the Veneto region (Italy) caused by extensive environmental contamination. The aim is to assess the impact of PFAS in the wild using the mosquitofish (Gambusia holbrooki), a small freshwater fish, as a model organism. Mosquitofish is an invasive species that inhabits small rivers and streams worldwide. We have investigated the effects of PFAS exposure in polluted vs non-polluted areas on phenotypic traits, including life history, reproduction, and behaviour, as well as bioaccumulation in wild populations (complementary -omics analyses are planned to explore gene expression changes). Field sampling has been conducted across 8 sites, spanning regions with high and low PFAS contamination, to compare the ecological and physiological responses of resident mosquitofish populations. Chemical analyses of water samples were performed to quantify PFAS concentrations in the water at the moment of sampling (long-term data are available from ongoing assessment by local authorities), as well as bioaccumulation in males and females. Behavioural, reproductive, and life-history traits were assessed. Behavioural analyses included sexual behaviour, risk-taking behaviour and exploration (using an open-field test) repeated to identify population-level effects, but also within- and among-individual differences. Reproductive and life history traits included sperm number and quality, body size, and reproductive allocation. By investigating the chronic and multigenerational effects of PFAS (mosquitofish populations have likely been exposed for at least 30 generations) in natural conditions, the project captures the complexity of real-world scenarios, including interactions with other stressors such as additional contaminants, fluctuating environmental factors, and ecosystem dynamics. The comprehensive dataset generated will enhance our understanding of how wildlife responds to PFAS contamination at multiple biological levels, paving the way for future research in alternative assessments of PFAS (and possibly other ED pollutants) and conservation strategies.

3.08.P-Th128 Non-Target Analysis of Wastewater Treatment Plant Samples: Comparison of Fingerprint of Inflow and Outflow Water

***Isabella Gambino**[1], Elisa Terzaghi[2], Alessandro Rozzoni[2], Cristiana Morosini[2], Renzo Bagnati[3], Sara Castiglioni[3] and Antonio Di Guardo[2], (1)DiSAT, University of Insubria, Varese, Italy, (2)Environmental Modelling Group, Department of Science and High Technology, University of Insubria, Italy, (3)Department of Environmental Health Sciences, Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Italy*

Wastewater treatment plants (WWTPs) are fundamental for pollutants removal from wastewater. However, the WWTP removal efficiency is very low for many xenobiotic compounds and, based on the European legislative framework (i.e., Urban WastewaterTreatment Directive), few compounds of those produced and used are routinely monitored in WWTPs inflow and outflow samples. This lack of suitable removal technologies and of knowledge of the full spectrum of contaminants potentially present in wastewater lead to an increase of the uncertainty in evaluating the risk for the aquatic ecosystem. While traditional target approaches are feasible for assessing a limited number of compounds, they become very expensive and challenging due to the numerous compounds typically present in wastewater samples. On the contrary, non-targeted analysis (NTA) is a promising approach that allow the characterization of the chemical composition of a sample without prior knowledge of its chemical content and resulting in dataset containing both known and unknown compounds.
Here, we conducted a study on inflow and outflow samples from a WWTPs located in Como (Northern Italy) characterized by a population equivalent of 168000, and with various inlet sources. Composite 24-h samples of influent and effluent wastewater were collected for 1 day, following the water path in order to collect the same entering water which went through the 14-h treatment. Samples were extracted by Solid Phase Extraction (SPE) and analysed with an ultra-high performance liquid chromatography (UHPLC) coupled to a high-resolution mass spectrometer (HRMS) (Orbitrap Exploris 120). The raw data were then analyzed with Compound Discoverer software (Thermo Fisher) for untarget analyses using a dedicated workflow. Data were manually validated applying some filters in order to obtain a confidence identification level 2a - probable structure . Many compounds were identified in inflow samples, while compounds in outflow samples were much lower. More than 70% of the identified compounds were industrial chemicals. Other categories were represented by pesticides, personal care products, and pharmaceuticals.
This study highlighted the importance of this approach in discovering xenobiotic diversity in wastewater influent and effluent, identifying also compounds not included in the current monitoring lists, but that can pose a risk to the aquatic ecosystem.

3.08.P-Th129 Machine Learning-Driven Forecasting of Organic Micropollutants in Aquatic Environments

***Michael C. Welle**[1] and Oksana Golovko[2], (1)KTH Royal Institute of Technology, Stockholm, Sweden, Sweden, (2)Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, Sweden*

The contamination of aquatic ecosystems by organic micropollutants (OMPs), including pharmaceuticals, personal care products, hormones, pesticides, and washing agents, has raised significant environmental and public health concerns due to their bioaccumulative and toxic properties. The increasing levels of OMPs in freshwater bodies have prompted the enactment of chemical regulations to assess and mitigate associated risks. However, the detection and quantification of OMPs often require advanced and costly analytical techniques, posing challenges for comprehensive monitoring efforts.
This project leverages machine learning (ML) as a transformative tool to address these challenges by developing predictive models trained on datasets containing known OMP concentrations and corresponding environmental parameters. These environmental parameters, such as precipitation, water temperature, and flow, are obtained from trusted sources and matched to legacy grab samples. Since obtaining these auxiliary environmental parameters does not require additional fieldwork, these models can facilitate cost-effective prediction of OMP levels.
Additionally, the models highlight critical environmental variables to enhance future sampling and data collection campaigns. Our approach employs techniques from the field of explainable ML, such as Grad-CAM (Gradient-weighted Class Activation Mapping) and SHAP (SHapley Additive exPlanations), to

identify which auxiliary environmental parameters are most crucial for prediction.
These models will inform decisions on necessary treatments at wastewater treatment plants (WWTPs) and upstream interventions, ultimately supporting the national goal of achieving a non-toxic environment. This work has significant implications for enhancing the protection and sustainability of aquatic ecosystems in Sweden and beyond, ensuring the health of both the environment and human populations.

3.08.P-Th130 Accerlerating Effect-Directed Analysis Through Constructing Non-Target HRMS Libraries for AhR Agonists by Deep Learning

***Jing You**[1], Fei Cheng[2] and Huizhen Li[1], (1)Jinan University, China (Mainland), (2)Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, China (Mainland)*

Sediments are influenced by chemical mixtures. Effect-directed analysis (EDA) is promising for identifying bioactive contaminants, especially when combined with non-target screening (NTS), but time-consuming workflows have hindered its large-scale applications. Herein, we developed an event-driven taxonomy (EDT)-Screening strategy to effectively identify suspect and non-target bioactive contaminants in sediment, taking aryl hydrocarbon receptor (AhR) activity as an example. To accelerate EDA and NTS workflows, the EDT-Screening strategy integrated fractionation, bioassay, and identification into one step by embedding two newly constructed effect-based spectral libraries to LC-HRMS screening templates. The event driver (ED) library was assembled from data-mined AhR-active compounds, and event driver ion (EDION) library contained effect-related fragment ions generated by deep learning models. The AhR-ED library identified more AhR-agonists with lower incidence of false positives for tentative candidates compared to the ChemSpider database. Furthermore, AhR-EDION facilitated the identification of additional AhR agonists in sediment, especially industrial intermediates and transformation products that were often overlooked due to lack of priori knowledge. This highlighted the effectiveness of the EDT-Screening strategy in expanding the pool of unknown unknowns in bioactive contaminants. In conclusion, the construction of effect-based HRMS libraries provided a rapid solution for the identification of bioactive contaminants in complex chemical mixtures.

3.08.P-Th131 Proving That Aquatic Toxicity Testing Is Technically Not Feasible: Not So Simple. Case Study of UVCB Emulsifiers

***Rija Samsera**[1], Christopher Boagni[2], Suzanne Zvalaren Schneider[2], Jonas Kind[3] and Lise Mata[4], (1)International Flavors & Fragrances Inc., France, (2)Eurofins EAG Agroscience, United States, (3)ibacon GmbH, Germany, (4)Laboratoire des Pyrenees et des Landes, France*

According to OECD 23, difficult to test substances are defined, but not only, as being either poorly or sparingly water-soluble, volatile, hydrophobic, multi-component, and/or highly adsorptive. For most of these substances, technical adaptations are available to allow an accurate measurement of the substance in water to perform a robust study.
In a regulatory context, Annex XI section 2 of REACH stipulates that testing for a specific endpoint may be omitted if it is technically not possible to conduct the study because of the properties of the substance. REACH R.5, section 5.2.2, however, states that, for poorly water-soluble substances, different test durations and alternative test methods need to be considered, i.e., chronic testing instead of acute testing. In some instances, all reasonable technical adaptations may have been exhausted and the substance is still not measurable in water. The key question is, to what extent do analytical method and sample preparation optimization need to be performed to consider that, for a particular test substance, a study is technically not feasible?
Here we explore this question with four substances under OECD 201. Substances were two glycerides (mixtures of glycerol mono ester, acetylated, diacetylated) and two polyols (mixtures of Di-, Tri-, glycerol), with chain length variation between C12 and C24 for all substances. Water solubilities were between 45 µg/L and 91 µg/L in pure water. MS/MS methods were used leading to Limit of Detection < 5µg/L. Water Accommodated Fraction parameters were optimized to maximize water solubility whilst avoid microdroplets and all prepared under sterile conditions to avoid biodegradation.
In one trial out of six, a substance was detected below the water solubility. Once the trial was repeated with a longer settling period (24h instead of 4 h), no substance was detected. This led to the hypothesis that the substance was so insoluble, that once there was enough time of settlement in water, the substance reaggregated to form microdroplets instead of staying solubilized. The same trials were performed with the other substances. Similarly, no substance was detected leading to the conclusion that aquatic testing with these substances was not feasible.

3.08.P-Th132 From Microalgae to Gastropods: Understanding the Kinetics and Toxicity of Silver Nanoparticles in Freshwater Aquatic Environment

***Ting Wang**[1], Joao Santos[1], Vera Slaveykova[2], Serge Stoll[2] and Wei Liu[1], (1)University of Geneva,*

Switzerland, (2)University of Geneva, ., Switzerland
Silver nanoparticles (AgNPs) are increasingly used in various consumer products and industrial applications, raising concerns about their potential environmental impact on aquatic ecosystems. This study aimed to evaluate the effects of AgNPs on both a primary producer, diatom Cyclotella meneghiniana, and freshwater gastropod Lymnaea stagnalis, by assessing waterborne, foodborne, and combined exposure routes. Our objective was to determine whether AgNPs disrupt the physiology of diatoms and whether these disruptions and Ag accumulation transfer to higher trophic levels, causing physiological stress in gastropods. We found that AgNPs exposure in C. meneghiniana significantly disrupted trace metal homeostasis, notably reducing iron, copper, and manganese concentrations while increasing zinc levels. Additionally, diatoms secreted extracellular polymeric substances, which likely served as a protective mechanism against NPs toxicity. However, the disruption of trace metal balance raised concerns about the potential transfer of Ag and physiological disruptions to organisms that feed on these primary producers. The alteration in trace metal concentrations, particularly the depletion of critical cofactors involved in photosynthesis and antioxidative defenses, suggests that diatom metabolic function might be compromised, potentially affecting nutrient cycling and energy transfer within aquatic ecosystems. In L. stagnalis, waterborne exposure resulted in the highest silver accumulation, followed by rapid depuration. However, this clearance process triggered oxidative stress during depuration, as evidenced by increased malondialdehyde levels. Foodborne exposure, simulating trophic transfer from algae to gastropods, resulted in slower silver depuration, prolonged retention, and increased hemocyte mortality, indicating significant immune stress. Combined exposure led to the most severe oxidative stress during uptake, with increased reactive oxygen species production and protein synthesis in hemolymph, suggesting an intensified physiological response. These findings demonstrate that AgNPs not only disrupt primary producers but could also transfer across trophic levels, leading to significant physiological stress and toxicity in higher organisms. This study emphasized the importance of considering multiple exposure routes in environmental risk assessments and highlights the potential for AgNPs to bioaccumulate and possibly biomagnify within aquatic ecosystems.

3.08.P-Th133 Prediction of the Surface Charge of TiO2-Nanoparticles in Surface Waters

*Narjes Tayyebi[1], Michel Gad[2], **Allan Philippe**[1], Oliver Lechtenfeld[2], Vanessa Trouillet[3], Alexander Welle[3] and Stefan Kunz[1], (1)University of Kaiserslautern-Landau (RPTU), Germany, (2)UFZ Helmholtz-Centre for Environmental Research, Germany, (3)Karlsruhe Institute of Technology (KIT), Germany*

Anthropogenic nanoparticles, both incidental and engineered, are released into the environment in increasing amount, with unclear ecological consequences for aquatic ecosystems. Understanding how nanoparticles interact with natural surfaces is complicated by limited knowledge of their surface chemistry in real-world conditions. This study focuses on the ?-potential (surface charge) of nanoparticles in natural waters and propose a model to predict how it is influenced by environmental factors. Five types of TiO2-nanoparticles, commonly used in commercial products, were exposed to 20 surface water sites across Germany and Switzerland, over three seasons. The ?-potential was measured using laser Doppler velocimetry, and we trained random forest models to predict ?-potential from water composition. The importance of the environmental factors for the prediction was assessed using permutation tests and individual conditional expectation (ICE) plots. Further, surface characterization was done using infrared spectroscopy (IR), time of flight secondary ion mass spectrometry (ToF-SIMS), and X-ray photoelectron spectroscopy (XPS).

The concentration in divalent cations (Ca²? and Mg²?) was the most important factor influencing the ?-potential, with higher ion concentrations reducing surface charge. Once a threshold was reached, further increases in ion concentration had no effect. Surprisingly, pH had little impact, possibly due to a narrow pH range in natural waters and the shielding effect of organic matter on surface charge. DOM composition influenced ?-potential, confirmed by the importance of fluorescence data for the models, showing that organic coatings modulate nanoparticle behavior. XPS and ToF-SIMS analysis confirmed the presence of organic coatings dependent on water composition.

Our results demonstrate the potential of our approach to investigate the surface properties of nanoparticles in natural waters while accounting for the complexity of the environmental medium. The concept could be applied to other nanoparticles, including natural ones, and to investigate other physico-chemical properties of the coatings such as composition, thickness or stability. It could also be applied to produce environmentally coated nanoparticles which could serve as more realistic test items in ecotoxicological studies, for instance.

Disclaimer/Disclosure: This study has been financed by the DFG: Determination and prediction of surface coating composition, surface properties, and colloidal stability of nanoparticles after in situ exposure to natural waters (PH 277/4-1 and LE 3784/8-1).

3.08.P-Th134 Variation in Horizontal Distribution of Microplastic Polymers Exceeding 20 Microns in Tokyo Bay Sediments: Effects of Density and Particle Size

Yutaka Kameda *and Emiko Fujita, Chiba Institute of Technology, Japan*

Understanding the behavior of microplastics (MPs) in aquatic environments is essential for reducing their contamination levels in the future. Large quantities of MPs can enter bays near densely populated urban areas and ultimately settle into sediments. However, there are currently no comprehensive reports on the horizontal distribution of smaller MP polymers in bay sediments over a wide range.

In this study, we investigated the concentrations and size distributions of MPs greater than 20 microns in sediment samples from 10 sites in the northern region of Tokyo Bay, one of the most heavily contaminated bays in Japan. Sediment matrices were removed using a hydroperoxide-based Fenton reaction and density separation with sodium iodide. Extracted samples containing MPs were filtered onto a silicon membrane, and all MPs across the entire membrane area were automatically analyzed using micro-FTIR imaging techniques and our custom identification program, YCALOS, for accurate identification and quantification. MP concentrations in sediments ranged from 38.2 to 242.5 pieces per gram (dry weight), with 14 different polymers identified, including ABS, alkyd resin, AS resin, ethylene vinyl acetate (EVA), polyamide, polyethylene (PE), PET, PMMA, polypropylene (PP), polystyrene, polyurethane, polyvinyl acetate, and polyvinyl chloride.

Using the Kriging interpolation method, we generated contour diagrams for each polymer, revealing distinct sedimentation patterns that varied by MP size distribution and density. Polyethylene terephthalate particles and fibers, as high-density MPs, tended to settle close to river mouths, forming smaller hotspot areas. In contrast, low-density MPs like PE and PP were widely dispersed in the bay s central area, with hotspots for particles smaller than 100 microns. These findings suggest that high-density MPs (greater than 1.0 g/cm^3) settle rapidly, while low-density, smaller-sized MPs disperse widely within the bay, settling only when their density increases above 1.0 g/cm^3 through aggregation with biofilms, algae, or other mineral particles.

These insights enhance our understanding of the mechanisms driving MP sedimentation in coastal environments, providing crucial information for managing and mitigating MP pollution in aquatic systems.

3.08.P-Th135 Distribution Characteristics and Risk Assessment of Microplastics in Surface Water and Groundwater from Hetao Irrigation District

Gaofeng Zhao*, Institute of Environment and Sustainable Development in Agriculture, Chinese Academy of Agricultural Sciences, China (Mainland)*

Hetao Irrigation District is a major grain and oil seed production region and one of the top three largest irrigation districts in China, which is facing complex challenges for green development of agriculture. The large-scale use of agricultural mulch film in the irrigation district have been more than 30 years, while pollution in the surface water and groundwater caused by microplastics from agricultural mulch film was lack of systematic research. In order to investigate the distribution characteristics and risk of microplastics in surface water and groundwater from the irrigation district. Wuyuan County was selected as the objective area, which was one of the first pilot areas of agricultural non-point source pollution control and supervision guidance in China, surface water and groundwater samples were collected. Thermoextraction and desorption-gas chromatography/ mass spectrometry were used to determine five types of microplastic polymers including Polyvinyl chloride, Polyethylene terephthalate, Polyethylene, Polystyrene, and Polythene in these water samples. The results showed that the concentrations of microplastics in surface water samples from each drainage ranged from ND to 317.1±2.1 μg L-1, Polyvinyl chloride was the most predominant polymer in these surface water samples, accounting for 44.19%. The concentrations of microplastics in the groundwater samples ranged in ND ~ 44.8 ± 7.9 μg L-1; Polythene was the most predominant polymer in the groundwater samples. Polymer hazard index was used to evaluate polymer-specific risks, Polyvinyl chloride was found to be the high risk polymer. These results will provide a cutting-edge research basis for preventing and controlling microplastics pollution in the irrigation district.

3.08.P-Th136 Adsorption of Benzophenone-3 and Octocrylene UV Filters on Polyethylene: Analysis by HPLC-MS/MS and Voltammetry with Screen-Printed Electrodes

Albert Contreras Llin *and Silvia Diaz-Cruz, IDAEA-CSIC, Spain*

Microplastics (MPs) are pollutants of global concern, posing a persistent threat due to their accumulation and low degradation rates in the environment. Acting as transport vehicles, MPs adsorb various contaminants, facilitating their accumulation in aquatic ecosystems. This issue is exacerbated by emerging contaminants such as UV filters (UVFs), particularly in coastal areas, where combined exposure poses significant environmental risks. This study focuses on determining the adsorption capacity of polyethylene

(PE) for benzophenone-3 (BP3) and octocrylene (OC), evaluating the influence of parameters such as pH, temperature, and exposure time. A central composite design (CCD) was employed to optimize resource efficiency during experimentation. Controlled experiments were conducted in both pure water and synthetic seawater. High-performance liquid chromatography coupled to tandem mass spectrometry (HPLC-MS/MS) was applied to accurately quantify UVF concentrations, providing high sensitivity and specificity in chemical detection. In parallel, differential pulse adsorption stripping voltammetry (DPAdSV) using screen-printed electrodes (SPE) was applied for electrochemical analysis, offering a rapid and cost-effective approach to monitor adsorption dynamics.
The findings revealed that OC exhibited a stronger affinity for PE than BP3, attributed to its higher octanol-water partition coefficient (log Kow 6.88 vs. 3.79), indicating greater compatibility with non-polar environments. Among the variables studied, exposure time emerged as the most significant factor influencing adsorption in aqueous solutions. In contrast, pH and temperature had minimal impact in pure water but were significant in synthetic seawater, particularly for BP3, due to electrostatic and solubility effects (data for OC in synthetic seawater is currently being processed). The dominant interactions driving adsorption were hydrophobic in nature. Notably, the results from electrochemical analyses using differential pulse adsorption stripping voltammetry (DPAdSV) closely aligned with those obtained via HPLC-MS/MS, establishing SPE as a reliable and efficient method for in situ BP3 detection. This study highlights the utility of CCD in identifying critical variables and optimizing experimental designs to better understand the adsorption behavior of UVFs on MPs.

3.08.P-Th137 Indicators and Impacts of Microplastics Released from Traffic Paints and Paved Roads into Surface Waters, Detected Using an Automated Microplastic Preparation System
Yutaka Kameda *and Emiko Fujita, Chiba Institute of Technology, Japan*
Despite the widespread use of traffic paints and polymer-modified asphalt containing various microplastics (MPs) in road markings and pavement worldwide, accurately detecting and quantifying their release into surface waters including rivers, lakes, and seas remains a considerable challenge. This study employed both an Automated Microplastic Preparation device (AMP) and a General Manual Preparation method (GMP) to measure the concentrations and size distributions of 20 polymer types of MPs larger than 300 µm in 17 surface water samples from rivers and a lake affected by road dust, as well as 6 samples from Tokyo Bay. Observed MP concentrations across all sampling sites ranged from 0.06 to 25.8 pieces/m³. Notably, polyethylene-ethyl acrylate (PEA) copolymer and urethane alkyd (UA), commonly used as additives in asphalt and traffic paints, were detected only via AMP, particularly in river waters, while GMP failed to detect these polymers. Their maximum concentrations reached 4.2 pieces/m³. Combined, PEA and UA accounted for between 5.9% and 45.2% of total MPs in river water contaminated by road dust under dry weather conditions.
Principal component analysis of polymeric composition data revealed three primary groups: the first consisting of additive polymers like PEA and ethylene vinyl acetate, the second of traffic paint polymers such as UA and alkyd resin, and the third of common sea water MPs like polyethylene and polypropylene. Additionally, annual loads of PEA and UA into Tokyo Bay showed a significant positive correlation with road areas in the catchment areas of sampling sites. These findings indicate that PEA and UA may serve as reliable indicators of MP contamination arising from road markings and pavement.

3.08.P-Th138 Microplastics in Elbe River Sediments Analyzed by Thermal Extraction-Desorption Gas Chromatography-Mass Spectrometry (TED-GCMS)
Siqi Wu[1]*, Alexander Bohme*[1]*, Mara Romerscheid*[1]*, Martin Simoneit*[1]*, Andreas Schaffer*[2]*, Martin Krauss*[1]*, Norbert Kamjunke*[3]*, Anna Matousu*[4]*, Tina Sanders*[5]*, Ingeborg Bussmann*[6]*, Bjorn Raupers*[7]*, Holger Brix*[5] *and Annika Jahnke*[1]*, (1)UFZ - Helmholtz Centre for Environmental Research, Department of Exposure Science, Germany, (2)Institute for Environmental Research (IFER), RWTH Aachen University, Germany, (3)UFZ - Helmholtz Centre for Environmental Research, Department of River Ecology, Germany, (4)Biology Centre, Czech Academy of Sciences, Institute of Hydrobiology, Ceske Budejovice, Czech Republic, (5)Institute for Carbon Cycles, Helmholtz Centre Hereon GmbH, Germany, (6)Departments of Shelf Sea System Ecology, Alfred-Wegener-Institut, Helmholtz Zentrum fur Polar- und Meeresforschung, Germany, (7)GEOMAR Helmholtz Centre for Ocean Research, Germany*
Microplastic pollution is a globally emerging environmental concern, with sediments serving as major sinks for certain polymers in aquatic systems. Traditional environmental analysis of microplastics typically involves spectroscopic methods, such as Fourier Transform Infrared and Raman spectroscopy. While effective for identifying microplastic morphology, these methods are time-consuming and may overlook quantitative (mass) data. In contrast, methods like Thermal Extraction-Desorption Gas Chromatography-Mass Spectrometry (TED-GCMS) can provide valuable mass-based measurements of microplastics. In this study, we applied this thermal method to investigate microplastic pollution in

sediments from the Elbe River. Twenty-seven sediment samples were collected along the river, covering the Czech Elbe, the free-flowing inland Elbe, the tidal Elbe, and the North Sea. After density separation and digestion, sediment samples were analyzed. Microplastic patterns covering seven common polymers, i.e., polyethylene (PE), polypropylene (PP), polystyrene (PS), polyethylene terephthalate (PET), polyamide (PA), polylactic acid (PLA), and polymethyl methacrylate (PMMA), will be presented.

3.08.P-Th139 Development of an Analytical Method for Measuring Fine Rubber Particles Exceeding 20 Microns in Sediment Using Micro-FTIR Imaging Techniques

Yutaka Kameda *and Emiko Fujita, Chiba Institute of Technology, Japan*

Synthetic rubbers present in atmospheric, aquatic, and terrestrial environments are of increasing concern due to their ecological impacts on wildlife and potential health risks to humans. Tire wear particles, in particular, have been widely studied and are typically analyzed using ICP-MS, Py-GCMS, and vibrational spectroscopy. Although vibrational spectroscopy provides non-destructive and rapid analysis, measuring fine rubber particles smaller than 1 mm remains challenging due to weak spectral signals and limited effective pretreatment methods for environmental samples, making it difficult to isolate and analyze such particles without physical handling limitations.

In this study, we developed a simultaneous analytical method to detect nine types of elastomer particles larger than 20 microns in sediment using micro-FTIR imaging. The elastomers analyzed included Styrene-Butadiene Rubber, Tetrafluoroethylene-Propylene Elastomer, Ethylene-Propylene Rubber, Chloroprene Rubber, Chloro-Sulfonated Polyethylene Rubber, Isobutylene-Isoprene Rubber, Silicone Rubber, Acrylonitrile Butadiene Rubber, and Ethylene-Propylene-Diene Terpolymer Rubber all common on road surfaces in Japan. A novel pretreatment procedure was established to digest sediment samples from Tokyo Bay without hydroperoxide, as hydroperoxide could dissolve the elastomers. Following digestion, density separation was performed similarly to the method for microplastics reported by Kameda et al. The separated samples were then filtered onto a silicone membrane, and the spectral data for all particles across the membrane were automatically collected using micro-FTIR imaging.

For identification, we employed a newly developed software, YCALOS, which accurately identified the nine elastomers, overcoming the limitations of existing software in handling small particles due to interference from sample matrix peaks and noise. This advanced analytical method for detecting elastomers in sediment could also be applied to surface water, wastewater, and atmospheric samples, broadening its potential environmental applications.

3.08.P-Th140 Automatic Sample Preparation Device for Microplastics Analysis

Markus Sillanpaa[1]*, Ilse Heiskanen*[1]*, Yuki Nakagawa*[2]*, Outi Setala*[1] *and Yoshio Ikezawa*[3]*, (1)Finnish Environment Institute (Syke), Finland, (2)European Innovation Center, Shimadzu Europa GmbH, Germany, (3)Shimadzu Corporation, Japan*

Microplastics have been found in every environmental compartment in urban and remote areas wherever they have been studied. Even though the omnipresence of microplastics in the environment is acknowledged, different approaches in sampling, sample preparation, and particle identification/quantification hamper comparison between studies. Since the environmental samples have a complex particulate matrix, the several laborious treatments must be performed to remove interfering particles prior to chemical analysis.

To lighten the workload and improve the process repeatability, Shimadzu Corporation has developed an automatic sample preparation device (MAP-100) for the isolation of microplastics from environmental samples. The MAP-100 automatically performs a multistep preparation including chemical oxidation, serial (1 to 3) density separation, and final filtration. The efficiency of sample preparation can be enhanced with an integrated magnetic stirrer and temperature control. The lower size limit of MAP-100 is 300 µm. In this study, the performance of the novel sample preparation device was explored.

For a performance test, three types of surface water samples were collected with a manta trawl (mesh size 300 µm) from Lake Saimaa, the Gulf of Finland and the River Vantaa. Hydrogen peroxide (30%) was used for the oxidation of organic material in samples, whereas mineral particles were separated in a saturated sodium iodide solution (density 1.8 g/cm3). The collected samples were spiked with the reference plastics that represented different sizes and densities: 355-425 µm polyethylene and poly(methyl methacrylate), 3 mm polyoxymethylene and 4 mm polypropene. Laboratory blanks were analyzed along with the field samples. The unknown particles were analyzed with a Fourier Transform Infrared spectrometer equipped with an attenuated Total Reflectance measurement unit.

The performance of the MAP-100 was evaluated in terms of recovery rate, sample contamination, and the removal efficiency of sample matrix. The recovery rates were derived for microplastics close to the lower cutoff size of the MAP-100 and to the upper size limit of microplastics. If the performance is satisfactory, the MAP-100 is a very appealing tool for monitoring microplastics in surface water.

3.08.P-Th141 Development of a Portable and Cost-Effective Sampling Device for Microplastics in Water, Utilizing Household Water Filtration Systems

Yutaka Kameda[1]*, Emiko Fujita*[1]*, Yukio Kobayashi*[2] *and Mikiko Nakayama*[3]*, (1)Chiba Institute of Technology, Japan, (2)Chemical Cleansui Corporation, Japan, (3)Mitsubishi Chemical Cleansui Corporation, Japan*

Sampling microplastics (MPs) in surface waters such as rivers, lakes, bays, oceans, and even tap water typically requires large and heavy equipment, including neuston nets, plankton nets, and large pumps. This is due to the substantial water volumes needed for analysis: for instance, European guidelines recommend sampling 1000 L of tap water, while hundreds of liters are often necessary to collect MPs larger than 20 µm in environmental waters. These methods are labor-intensive, time-consuming, and challenging to deploy widely. Specialized filtration systems employing pumps and disc membranes have been developed, but these systems are often expensive, custom-made, and inaccessible for broad application.
Furthermore, detecting MPs smaller than 10 µm, critical for assessing ecological and human health risks, presents additional challenges. Conventional methods, such as neuston and plankton nets, are unsuitable for capturing MPs in this size range.
To address these issues, this study aimed to develop a portable, cost-effective sampling device for MPs in water samples. We utilized a commercially available household water filtration system (Mitsubishi Chemical Cleansui Corporation), which is easily accessible via online platforms such as Amazon and Yahoo. The system employs hollow fiber membranes capable of concentrating MPs larger than 0.2 µm into a collection vessel. Its compact size and lightweight design make it suitable for use in diverse environments, including research vessels, riversides, kitchens, and bathrooms.
Our investigations demonstrated that the system could filter 300 L of river water, seawater, or tap water in just 30 minutes without requiring membrane replacement during the filtration process. Contamination from the filtration system itself was minimal, with MP concentrations from the household membranes significantly lower than the concentrations of MPs collected in the samples. Additionally, we developed an efficient extraction method to recover MPs from the membranes while minimizing contamination during the procedure.

3.08.P-Th142 Small Microplastics (<100 µm) in Wet Depositions: First Micro-FTIR-NIR Analysis and Creation of NIR Libraries

Beatrice Rosso[1]*, Barbara Bravo*[2]*, Carlo Barbante*[3]*, Andrea Gambaro*[3] *and Fabiana Corami*[1]*, (1)CNR ISP, Italy, (2)Thermo Fisher Italy, Italy, (3)Ca Foscari University of Venice, Italy*

SMPs (small microplastics <100 µm) have become a significant environmental concern due to their widespread presence and, due to their smallest size, they are posing a significant threat to the biota and human health. However, SMPs are still often overlooked, , and, due to different pretreatment and analytical methods, the results of the few studies on SMPs can be challenging to compare, leading to discrepancies in data quality and reliability. Besides, it is crucial to cross-validate different analytical methods for assessing SMPs, to ensure consistent and reliable results, and enable more robust evaluations of environmental impact and potential negative implications for human health. In scientific literature, a very low number of MP studies employed the NIR spectroscopy technique and there is more lack of knowledge in the use of this technique for the smallest size (SMPs) analysis and the removal procedures for the interferences assessment (organic, inorganic and biological compounds) from real environmental samples. In our study, SMPs in different size ranges were analyzed employing two analytical supports (e.g., BaF_2 support and ANODISC filter, respectively) with Micro-FT-NIR spectroscopy to create new libraries. Then, a comparison with a real environmental sample (e.g., a wet deposition from the urban area of Mestre, Venice, Italy) filtered after an oleoextraction and purification procedure previously developed (Corami et al., 2021) on ANODISC filter was analyzed using the same libraries. Different SMP typologies were confirmed using FT-NIR spectroscopy in wet depositions with high matches (<90%). Hence, ANODISC filters were confirmed to be a suitable support for SMP analysis in FT-NIR spectroscopy, opening possibilities for expanding the cross-validation techniques approach for SMP detection providing reproducible and reliable data in real environmental samples. Further, FTI-NIR spectroscopy is confirmed to be fast for real-time SMP analysis, allowing the polymer characterization of a wide range of polymers with an appropriate pretreatment methodology for real environmental samples.

3.09.A Future of Suspect and Non-Target Screening to Monitor Emerging Contaminants in the Environment

3.09.A.T-01 Integrating TIMS-PASEF with LC-HRMS and Biotransformation-Driven Suspect and Non-Target Screening Workflows to Address Key Challenges in Xenometabolome Analysis

Dimitrios E. Damalas[1]*, Carsten Baessmann*[2] *and Nikolaos S. Thomaidis*[1]*, (1)Laboratory of Analytical*

Chemistry, Department of Chemistry, National and Kapodistrian University of Athens (NKUA), Greece, (2)Bruker Daltonics GmbH & Co KG, Germany

The impact of xenobiotics in the aquatic ecosystem is evaluated in more depth when the whole xeno-metabolome (xenobiotics and their biotransformation products (bio-TPs)) of aquatic organisms is studied. Despite the technological advancements in LC-HRMS, the identification of bio-TPs remains challenging. This study addresses the analytical (e.g., isomeric bio-TPs, low-intensity bio-TPs, and absence of MS/MS data) and data processing (complex unknown bio-TPs) challenges of comprehensive xenometabolome assessment. Using ZFE exposed to benzotriazoles (BTs) and triclosan as complex case studies we aim to answer the following research questions: (1) How can we generate extensive, multi-dimensional analytical evidence to support challenging identification cases, and (2) How can we best leverage the produced analytical evidence, along with the inherent biotransformation context (known structure of the parent compound and biotransformation reactions), to prioritize and annotate unknown bio-TPs with high confidence.

To achieve this, we combined complementary analytical dimensions (RPLC, HILIC, TIMS) to extend the available analytical space. The potential of Trapped Ion Mobility Spectrometry (TIMS) combined with Parallel Accumulation Serial Fragmentation (PASEF) and HRMS to overcome limitations regarding isomer separation, spectral complexity, sensitivity, and MS/MS coverage was evaluated. Finally, a biotransformation-oriented data processing workflow was established, integrating suspect screening, non-target screening and the inherent characteristics of biotransformation experiments to identify bio-TPs with high confidence.

Our results demonstrate that TIMS effectively separated isomeric bio-TPs (OH-sulfate-4MeBT) and enhanced S/N ratios for improved detection of low intensity features. PASEF delivered comprehensive MS/MS coverage (>70% of precursors) without compromising sensitivity, enabling confident identification even for low-intensity bio-TPs (OH-glucuronide-4MeBT). The developed data processing workflow, combining suspect and non-target screening within silico tools, facilitated the annotation of complex bio-TPs, including those formed through multiple sequential biotransformation reactions. Overall, this approach significantly enhances our ability to characterize the xenometabolome with confidence, and ultimately improve xenobiotic risk assessment.

3.09.A.T-02 Identification of Novel Highly Polar Sulfonated Disinfection By-Products in Drinking Water using Supercritical Fluid Chromatography-High Resolution Mass Spectrometry

Maolida Nihemaiti[1], *Bettina Seiwert*[1], *Maik Icker*[2], *Andreu Fargas-Marques*[3], *Josepa Fabregas Serra*[3], *Noem Benavente Calderon*[3] *and Thorsten Reemtsma*[1], *(1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Institute of Organic Chemistry, University of Leipzig, Germany, (3)Consorci d'Aigues de Tarragona, Spain*

The generic methods to characterize disinfection by-products (DBPs), gas chromatography or reversed-phase liquid chromatography coupled to high resolution mass spectrometry (HRMS), can result in significant analytical gaps by overlooking the very polar fractions of DBPs. For the first time in this study, we applied an alternative method, supercritical fluid chromatography-HRMS, to revisit DBPs in drinking water treatment plants and distribution networks. In total 15 novel highly polar DBPs were identified as the sulfonated derivatives of haloacetonitriles, haloacetamides, and haloacetaldehydes. Regardless of the lack of analytical standards, we were able to conduct the structural confirmation and quantification of these newly identified DBPs by preparing their mixture via chlorination of a precursor compound and by combining nuclear magnetic resonance spectroscopy analysis with SFC-HRMS analysis. The concentrations of total haloacetonitrilesulfonic acids and haloacetaldehydesulfonic acids in drinking water were estimated to be up to 50 and 800 ng/L, respectively. Considering the stronger toxicity of haloacetonitriles, haloacetamides, and haloacetaldehydes than that of the regulated DBPs, these newly found sulfonic acid derivatives may also pose a health risk.

3.09.A.T-03 Extensive Chromatographic Platform Comparison (LC-, HILIC-, IC-, SFC-HRMS) for Polar Contaminants in Groundwater

Jonathan Zweigle[1], *Selina Tisler*[1], *Michael Schluesener*[2], *Joanna Flottmann*[3], *Tobias Bader*[3], *Nanna Hjort Vidkjær*[4], *Ulla Bollmann*[5] *and Jan H. Christensen*[1], *(1)Analytical Chemistry Group, Department of Plant and Environmental Science, University of Copenhagen, Denmark, (2)Federal Institute of Hydrology (BfG), Germany, (3)Laboratory for Operation Control and Research, Zweckverband Landeswasserversorgung, Germany, (4)Geological Survey of Denmark and Greenland (GEUS), Denmark, (5)Geochemistry, Geological Survey of Denmark and Greenland (GEUS), Denmark*

The analysis of emerging contaminants and their transformation products (TPs) in the aqueous environment is a major challenge due to the wide chemical space that needs to be captured analytically. While most studies focus on established liquid chromatography coupled with high-resolution mass

spectrometry (LC-HRMS) for non-target and suspect screening, there is an increasing need for the addition of complementary chromatography. In particular, the inclusion of very polar compounds due to their high mobility and threat to drinking water resources is needed.
Our study aims for a comparison of a wide range of separation methods (LC-, HILIC-, IC-, and SFC-HRMS) for improved chemical space coverage in groundwater. Aliquots from a standard mixture (>100 compounds) and a groundwater sample from Denmark enriched by multiphase SPE were distributed between 4 laboratories and measured with 10 different chromatographic methods all coupled to HRMS. Data was acquired both in positive and negative polarity with data-dependent (DDA) and data-independent (DIA) acquisition to maximize fragmentation information.
After feature detection and several filtering steps, the detected features were aligned across platforms by accurate mass and MS/MS spectral similarity to be able to compare detections across platforms and investigate similarities and complementarities. Furthermore, identified compounds from every individual method were compared to investigate the amenability of certain compound classes to certain platforms (e.g., which compounds are unique to SFC-HRMS). While LC-HRMS was able to cover only half of the standards, the addition of the other platforms increased the compound coverage by an additional 40%. SFC-HRMS was able to cover the most compounds due to its ability to retain both very polar compounds but also more hydrophobic ones. IC-HRMS could also detect several unique compounds (e.g., Ethephon) not covered by other platforms. Our approach highlights both advantages and challenges arising when combining HRMS data from many complementary chromatographic methods.

Disclaimer/Disclosure: This study is a contribution to the AQUAPLEXUS project which is funded by the Innovation Fund Denmark under grant agreement no. 2079-00037B.

3.09.A.T-04 Chemical Profiling and Toxicity of the Airborne Exposome in Indoor and Outdoor Environments using Polydimethylsiloxane (PDMS) Foam Passive Samplers

Adrià Sunyer-Caldú[1]*, Hongyu Xie*[1]*, Benilde Bonnefille*[1]*, Ji Eun Lee*[2]*, Seung-Bok Lee*[2]*, Stefano Papazian*[1] *and Jonathan W Martin*[1]*, (1)Department of Environmental Science, Exposure and Effects Unit, Science for Life Laboratory, Stockholm University, Sweden, (2)Chemical & Biological integrative Research Center, Biomedical Research Division, Korea Institute of Science and Technology, Republic of Korea*

The chemical exposome encompasses all environmental chemical exposures an individual encounters from conception to death. The air we breathe is a key pathway of exposure, and contributes to chronic disease and premature mortality around the world, yet its chemical composition is largely unexplored in most human environments. To advance airborne exposomics and broaden the chemical space examined, we developed and tested polydimethylsiloxane (PDMS) foam for passive air sampling in indoor and outdoor environments. This material captures both (semi-)volatile organic compounds and particulate matter and can be compatible with toxicity assays, facilitating molecular discovery, quantification, and toxicity assessment for a broad spectrum of airborne chemicals and their mixtures. We specifically optimized and validated GC-HRMS and LC-HRMS sample preparation methodologies for using over 200 prioritized substances from 20 different chemical classes, and demonstrate a method to assess the cytotoxicity of extracts in primary human lung fibroblasts. Together, these methods allow for comprehensive chemical analysis and toxicity assessment for the same passive air samples. Application to an indoor pilot study, with samples collected over eight-weeks, allowed to detection of 21 LC and 46 GC target analytes with concentrations in sampler ranging between 0.003 297.7 ng/cm2, including the presence of 23 PCBs. LC- and GC- amenable chemicals such as DEET, tris(2-butoxyethyl) phosphate, or tributyl phosphate, were detected in both modes at similar concentrations, adding a confidence layer to the reported results. Additionally, suspect screening using MS-Dial software and public libraries (e.g., Mass Bank North America, or GNPS) allowed for the tentative identification of 39 (LC) and 62 (GC) chemicals at level 2. Finally, nontarget approaches such as feature-based molecular networking and network annotation propagation are being applied to further identify features of interest that can be linked with high cytotoxicity in human lung cells. PDMS foam disks have been deployed in over 200 homes across eight European countries as part of the Horizon Europe INQUIRE project. We will present novel results and preliminary data from this extensive sampling effort, highlighting the samplers' effectiveness in airborne exposure assessment, and toxicity evaluation to supports studies of the exposome and future chemical regulation.

3.09.A.T-05 Connecting Contamination Fingerprints and Toxicity Patterns in Source-Related Effluents using Non-Target Screening

Iker Alvarez-Mora[1]*, Alain Hoyek*[1]*, Melis Muz Massei*[1]*, Carolin Huber*[1]*, Martin Krauss*[2] *and Werner Brack*[2]*, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

The SOURCES project of the European NORMAN network aims to explore the contamination patterns, toxicity profiles and identify effect drivers in different micropollutant sources discharging into the water cycle across Europe. Conventional chemical analysis offers only a partial view of these complex mixtures, making effect-based methods and non-target screening (NTS) essential to enable a more thorough chemical and effect evaluation. This study applies two prioritization strategies to link features detected in over 100 samples from sources-related effluents to their bioactivity in nine in vitro bioassays. The tested endpoints include: androgenic activity, estrogenic activity, neurotoxicity, thyroid hormone receptor activity, mutagenicity (two YG strains), oxidative stress, PXR activity and AhR activity. Following SPE extraction and analysis by HPLC-Exploris Orbitrap, the data was processed using MZmine 3 prior to feature prioritization. First, the MLinvitroTox toxicity prediction tool, based on MS/MS data, was used to filter relevant candidates for each bioassay endpoint. These candidates were then analyzed using PLS and Random Forest (RF) models to correlate chemical features with bioassay data, identifying the primary effect drivers. In total, 154,572 features were detected after intensity filtering and blank subtraction, with 997 and 251 features prioritized for androgenicity and oxidative stress, respectively. The RF models, with R^2 values of 0.67 and 0.30, helped identify the top 20 features linked to androgenic activity, primarily steroids and their derivatives, along with some anti-androgenic coumarins. For oxidative stress, O-glycosides were notably present in the top 20, though structural searches did not yield strong candidates. Preliminary results suggest that the observed effects are related to the prioritized compounds, particularly for androgenicity, while oxidative stress may be driven by the overall chemical mixture. The proposed approach enables significant prioritization and focuses identification efforts on a small group of candidates, thereby improving the efficiency of effect driver detection in monitoring studies. Further work will extend this approach to other endpoints and confirm candidates through spectral library searches and target screening.

3.09.B Future of Suspect and Non-Target Screening to Monitor Emerging Contaminants in the Environment

3.09.B.T-01 Non-Target Screening of Water Samples and Application of Different Prioritization Strategies

Nienke Meekel[1]*, Anneli Kruve*[2]*, Dennis Vughs*[3]*, Audrey Biesmans*[4]*, Margo van der Kooi*[4]*, Marja Lamoree*[5] *and Frederic Been*[5]*, (1)KWR Water Research Institute | Vrije Universiteit Amsterdam, Netherlands, (2)Stockholm University, Sweden, (3)KWR Water Research Institute, Nieuwegein, Netherlands, (4)KWR Water Research Institute, Netherlands, (5)Vrije Universiteit, Netherlands*

Municipal wastewater treatment plants (WWTPs) are known sources of organic micropollutants in surface waters. Originally designed to treat biological waste, such as human urine and feces, WWTPs now face increasing challenges due to the widespread use of pharmaceuticals, personal care products, and household chemicals. These products introduce a diverse array of chemicals into wastewater. However, WWTPs are not yet fully optimized for the removal of these anthropogenic chemicals or their transformation products, resulting in their emission to the environment. In this study, we carried out an extensive sampling campaign collecting 60 consecutive 24h composite samples at one of the largest WWTPs in the Netherlands. We analysed these samples along with surface water samples using suspect- and non-target screening with reversed-phase liquid chromatography (RPLC) coupled to high-resolution mass spectrometry (HRMS). In order to be able to focus on the most relevant features and samples, we applied different prioritization strategies. A combination of multivariate statistics and a recently developed prioritisation model based on the prediction of structural alerts from tandem mass spectra (MS2) were used to prioritize features of interest for further investigation. The approach developed here using the combination of different prioritization strategies can be utilized in both environmental, exposomics, and human (bio)monitoring studies. They can rapidly highlight potentially significant features or samples that require further investigation, either by applying other in silico tools or through additional experimental work like targeted analysis. Additionally, findings from this study show that based on raw and unfiltered MS2 spectra, it is possible to predict whether detected features potentially contain specific structural alerts associated with toxic effects.

3.09.B.T-02 Prioritization of Unknown Features Based on Predicted Toxicity Categories

Viktoriia Turkina[1]*, Jelle T. Gringhuis*[1]*, Sanne Boot*[1]*, Jake O'Brien*[2]*, Antonia Praetorius*[3] *and Saer Samanipour*[1]*, (1)University of Amsterdam, Netherlands, (2)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (3)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands*

Environmental samples are highly complex, containing a wide range of both known and unknown components. Liquid Chromatography coupled with High-Resolution Mass Spectrometry (LC-HRMS)

Non-Targeted Analysis (NTA) has become a critical method for studying these samples comprehensively. However, identifying the detected constituents poses a significant challenge due to the large number of features revealed by the analysis. To overcome this, prioritization strategies are often used to focus on the most relevant features for further investigation.
In this research, we developed an alternative prioritization approach that connects fragmentation and chromatographic data directly to aquatic toxicity categories, eliminating the need for individual compound identification. Recognizing that fragmentation data is not always available or well-characterized, we introduced two predictive models: a Random Forest Classification (RFC) model and a Kernel Density Estimation (KDE) model. The RFC model uses MS1 data, retention time, and cumulative neutral losses (CNLs) derived from fragmentation to classify fish toxicity categories when fragmentation data is available. In contrast, the KDE model relies solely on retention time and MS1 data for cases without fragmentation information.
Both models achieved accuracy levels comparable to structure-based prediction methods. We further validated their performance using an LC-HRMS pesticide mixture in a tea extract, where the CNL-based RFC model achieved an accuracy of 0.76 and the KDE model reached 0.61. These results highlight the models robustness and potential for real-world applications.

3.09.B.T-03 PubChemLite plus Collision Cross Section (CCS) Values for Enhanced Interpretation of Non-Target Environmental Data

***Emma Schymanski*[1]**, *Anjana Elapavalore[1], Dylan Ross[2], Valentin Groues[1], Dagny Aurich[1], Allison Krinsky[3], Sunghwan Kim[4], Paul Thiessen[4], Jian Zhang[4], James Dodds[5], Erin Baker[5] and Evan Bolton[4], (1)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (2)PNNL, United States, (3)Department of Medicinal Chemistry, University of Washington, United States, (4)NCBI/NLM/NIH, United States, (5)Department of Chemistry, University of North Carolina, United States*
Finding relevant chemicals in the vast (known) chemical space is a major challenge for environmental and exposomics studies leveraging non-target high resolution mass spectrometry (NT-HRMS) methods. Chemical databases now contain hundreds of millions of chemicals, yet many are not relevant - and many relevant chemicals are missing. PubChemLite for Exposomics is an extensive collaborative, open science effort to provide a dynamic collection of chemicals for environmental, metabolomics and exposomics research, along with supporting information about their relevance to assist researchers in the interpretation of candidate hits. The PubChemLite for Exposomics collection is compiled from ten sections of PubChem, enhanced with patent, literature and annotation counts and predicted partitioning coefficient (logP) values, as well as predicted collision cross section (CCS) values using CCSbase to support ion mobility experiments. Predicted CCS are currently provided for 8 adducts ([M+H]+, [M+Na]+, [M+NH4]+, [M+K]+, [M-H]-, [M+Na-2H]-, [M]+, [M]-). Monthly versions are archived on Zenodo under a CC-BY license, supporting reproducible research. A new interface has been developed for researchers to browse the collection, including several search functions and a per-chemical overview of chemical identifiers, the annotation content, chemical stripes on patent and literature data as well as tables of the predicted CCS values for the 8 adducts. In order to provide additional experimental CCS values to improve the coverage of CCS predictions for environmentally relevant chemicals, a collection of open experimental collision cross section values were compiled and added to PubChem, along with pipelines to add new data as received and update the corresponding compiled dataset. This contribution will describe the collaborative efforts to build the PubChemLite with CCS (PCL-CCS) versions, how this can support researchers in environmental/exposomics studies and explore known limitations and potential for future developments. The code (GitLab) and data behind these efforts are openly available (DOI: 10.5281/zenodo.4081056 and DOI: 10.5281/zenodo.6800138 redirect to the latest version of PCL-CCS and experimental CCS collection, respectively). Experimental CCS values can be browsed on PubChem (https://pubchem.ncbi.nlm.nih.gov/classification/#hid=106), while PubChemLite content can be explored at https://pubchemlite.lcsb.uni.lu.

3.09.B.T-04 Enhancing Regulatory Environmental Monitoring: Expanding Chemical Domain in HRMS Non-Target Screening

***Eric Rosenheinrich*[1]**, *Thomas Backhaus[2], Nicole Bandow[1], Kevin S. Jewell[3], Anna Lena Kronsbein[1], Tobias Schulze[1], Emma Schymanski[4], Ronya Mona Wallis[1] and Jan Koschorreck[1], (1)German Environment Agency (UBA), Germany, (2)RWTH Aachen University, Aachen, Germany, (3)German Federal Institute of Hydrology (BfG), Germany, (4)LCSB, University of Luxembourg, Luxembourg*
The assessment of complex chemical mixtures in the environment requires robust and comprehensive quantification methods. Non-target screening (NTS) using liquid or gas chromatography coupled with high-resolution mass spectrometry (LC/GC-HRMS) and cheminformatics workflows provides a

comprehensive overview of chemical exposure, but regulatory monitoring often focuses on a limited number of prioritised compounds. The NORMAN Substance Database (SusDat), with over 100,000 substances of environmental concern, serves as a reference for chemical market emissions. This study, part of the UBA project "Water Monitoring of the Future", integrates data from the German NTS portal and publicly available target data. The NTS portal uses three approaches: database-assisted screening (DBAS) with MS^2 spectra and retention times for unambiguous identification, suspect screening of known chemicals and their transformation products, and broader non-target analysis to assess chemical exposure in German rivers.
Efforts will focus on expanding the Collective Spectral Library (CSL) to improve overlap between target and NTS data, increase chemical domain coverage and ensure quantification quality. Missing functional groups will be evaluated for ionisation efficiency using electrospray ionisation (ESI) to allow systematic CSL expansion. PubChem fingerprinting and UMAP analysis were used to identify under-represented functional groups, highlighting specific clusters such as phthalates, steroid derivatives and oxazoles. Nitrogen-containing compounds show higher ionisation efficiencies in ESI+ and ESI- modes. These findings improve predictions of ionisation efficiency, reduce uncertainties in LC-ESI-HRMS quantification and provide reliable data for regulatory decision-making. By filling gaps in chemical domain, this study establishes a robust framework for evaluating complex chemical mixtures and advancing environmental monitoring.

3.09.B.T-05 Target-Decoy Strategy for Controlling False Discovery Rates in Structure Annotation of Small Organic Molecules in Environmental Non-Targeted Analysis by Computational Mass Spectrometry

*Gordon Getzinger[1] and **Lee Ferguson**[2], (1)Loyola University Chicago, United States, (2)Duke University, United States*

Structure annotation of small molecules by high-resolution mass spectrometry (HRMS) provides insights into the occurrence and fate of unknown organic contaminants in environmental samples. There are now many algorithms based on rule-based, combinatorial, or machine-learning-based methods to rank molecule spectrum matches (MSMs) by correlating molecular fragmentation in tandem mass spectrometry to candidate structures, but such approaches generally have unknown error rates and are thus difficult to use systematically to annotate unknown compounds in practice. Therefore, approaches are needed for estimating false discovery rates (FDR) in MSMs. We have developed an approach for controlling error rates in MSMs using a target-decoy strategy. Target-decoy strategies compare score distributions of candidate molecules (i.e., targets) with those derived from molecules known to be incorrect (i.e., decoys). The target-decoy strategy is common to HRMS-based proteomics, in which reversed peptide sequences are used to construct decoy databases. However, few approaches are available for generating small molecule decoy databases. Here, we describe an approach to generating small molecule structure decoys based on the RDKit cheminformatics software and a custom Python library (SMdecoy). Our approach defines the target database as the set of known molecules for a given molecular formula present in the PubChem database. Next, decoys are generated by mutating and rearranging molecules. Mutation generates new molecules by swapping substructures in candidate molecules with isomeric substructures from the set of all target and decoy molecules. Rearrangement swaps moieties within a molecule to generate new structures. After mutating and rearranging the non-redundant set of target and decoy molecules are combined and the algorithm recurses until a pre-defined number of decoys are generated. Finally, the distribution of MSM scores for target and decoy structures are evaluated based on a pre-defined FDR. Here we will present evaluation of the described target-decoy strategy using MSMs for tandem mass spectra from >400 unique structures using the computational MS tools MetFrag, MAGMa, and CFM-ID. Results demonstrate how FDR control can increase confidence for high-throughput structure annotation of small molecules in environmental samples by HRMS.

3.09.P Future of Suspect and Non-Target Screening to Monitor Emerging Contaminants in the Environment

3.09.P-Tu215 First Steps in the Non-Targeted Identification of Poly- and Perfluorinated Substances using Two-Dimensional Liquid Chromatography Coupled with High-Resolution Tandem Mass Spectrometry (LC×LC-HRMS/MS)

***Lapo Renai**[1], Massimo Del Bubba[2], Andrea Gargano[1] and Saer Samanipour[1], (1)Van t Hoff Institute for Molecular Sciences (HIMS), University of Amsterdam, Netherlands, (2)Department of Chemistry, University of Florence, Italy*

Poly- and perfluoroalkyl substances (PFAS) represent a real threat due to their environmental persistence and toxicity. The widespread production and various uses of PFAS have resulted in significant

physicochemical variability in the synthesized products and their precursors, leaving many of these chemicals structurally unknown. Therefore, these chemicals require the implementation of complex non-targeted analysis (NTA) workflows using liquid chromatography coupled with high-resolution mass spectrometry (LC-HRMS) generating high-quality data for their comprehensive identification. However, PFAS chemical space often experiences co-elution of homologs, which can compromise the quality of MS1 and MS2 data, thereby affecting identification confidence.
To this extent, comprehensive two-dimensional LC (LC×LC) provides unparalleled resolving power towards complex PFAS mixtures (e.g., aqueous film-forming foams, AFFFs). Additionally, we hypothesized that the optimized orthogonal separation not only improves PFAS detection in the mass domain but also could increase the quality of tandem spectra (MS/MS) for PFAS identification by resolving chromatographic overlap that occurs in mono-dimensional LC within and among PFAS homologs.
For these reasons, we validated an LC×LC HRMS/MS NTA workflow exploiting mass defect analysis (e.g., remainder of Kendrick mass , RKM) for both the detection and identification of PFAS homolog series (HS) to acquire high-resolution data-dependent (DDA) and independent (DIA) experiments generating high-quality and comprehensive structural MS data.
Results evidenced that LC×LC and RKM prioritization successfully enhanced the quality of PFAS fragmentation patterns allowing for their accurate NTA identification and HS grouping in AFFF complex mixtures. In more details, 12 PFAS HS were successfully categorized, including confirmed compounds and tentative candidates belonging to the HS of perfluoroalkyl carboxylic acids, perfluoroalkyl sulfonic acids, (N-pentafluoro(5)sulfide)-perfluoroalkane sulfonates, N-sulfopropyldimethylammoniopropyl perfluoroalkane sulfonamides, and N-carbox ymethyldimethylammoniopropyl perfluoroalkane sulfonamide.

3.09.P-Tu216 Non-Targeted Analysis of PFAS in Drinking and Source Water using Liquid Chromatography High-Resolution Mass Spectrometry and QSRR Retention Time Prediction
***Yong-Lai Feng**, Anca Baesu, Joan Hnatiw, Anca-Maria Tugulea and France Lemieux, Health Canada, Canada*
Per- and polyfluoroalkyl substances (PFAS) are categorized within a class that comprises thousands of synthetic chemicals, many of which have been used worldwide to fabricate products resistant to water, heat, and stains since the 1950s. Studies show that exposure to even trace amounts of some PFAS is associated with harmful health effects. The current monitoring program in Canada targets only the most commonly researched PFASand the number of PFAS characterized in exposure assessments is still relatively small in comparison to the total number registered for commercial use, not withstanding their transformation products and metabolites in the environment. Non-targeted analysis (NTA) has emerged as a tool that is used to identify and prioritize chemicals for human exposure assessment. While the sample preparation step determines those chemicals that are extracted, it is the data acquisition and analysis stages that ultimately determine chemical identification. Therefore the goals of this study were to develop an NTA method that can provide reproducible identification results. Three data analysis approaches, including FluoroMatch, Compound Discoverer, and FreeStyle were compared with respect to identification reproducibility, all using the same data acquired by liquid chromatography Q-Exactive Orbitrap mass spectrometry. In contrast to FreeStyle, isotopic labelled standards typically cannot be identified with the Fluoromatch and Compound Discoverer methods, meaning the data analysis using these tools is not compatible with the QC protocol in place (which includes spiked internal standards). Therefore, manual searching of isotopic standards, via complementary targeted software such as TraceFinder, is necessary when FluoroMatch/Compound Discoverer are employed. A QSRR retention time model was used to predict the retention times of the tentatively annotated structures to increase identification confidence levels. With this approach, more than ten new PFAS and previously unreported PFAS were identified with a Level 2 degree of confidence in drinking and source water. The results of this study also highlight the importance of reproducible data acquisition. In addition, the practices covered and discussed in this study will benefit and support the advancement of the field of NTA of PFAS.

Disclaimer/Disclosure: This project was financially supported by the Canadian Federal Government under the Chemicals Management Plan (CMP).

3.09.P-Tu217 Detecting PFAS Beyond the Current Regulative Request: A Comprehensive Overview of the Contamination in Dutch Water by UPHLC-Ion Mobility-HRMS
*David Liwara[1], **Carsten Baessmann**[2], Arnd Ingendoh[2], Birgit Schneider[2], Ilona Nordhorn[2], Sicco Brandsma[1] and Pim Leonards[1], (1)VU Amsterdam, Netherlands, (2)Bruker Daltonics GmbH & Co KG, Germany*

The US EPA estimates 15,000 PFAS as manufactured compounds, precursors, and degradation products. With this high number and the lack of reference standards or spectral libraries and plenty of isomers, a systematic and comprehensive monitoring becomes an extremely challenging task. Here, the intention was to sample and analyze wastewater and surface water at 30 sites in the Netherlands to create a map of the PFAS distribution by a non-target, unbiased analysis. UHPLC-HRMS combined with trapped ion mobility (TIMS) was used to identify the PFAS compounds with 4-dimensions of criteria: mass accuracy, isotope pattern fit, MS/MS, CCS (collisional cross sections).
Samples were prepared by SPE according to EPA 1633 with a 2000x preconcentration for surface water and 500x for wastewater. Data acquisition was done with timsTOF Pro 2 (Bruker) in PASEF and bbCID modes. Kendrick mass defect (KMD) filters PFAS compounds from background, based on the fluorine content (repeating CF2 units). The identification workflow comprised of several steps using library searches, suspect list screening and denovo determination.
In total more than 20,000 features were detected from all effluents and surface water samples of the 30 sampling sites. About 500 potential PFAS candidates were left after the KMD filtering. For the wastewater, in total 188 features could be annotated as PFAS, and for the surface water samples, 137 features could be annotated. The number of detected PFAs varied at the different sampling sites, as expected from their local conditions and infrastructure. A couple of PFAS precursors and degradation products have been found which are not screened yet in any legal directives. These would have been overlooked in a targeted approach. I.e., while the targeted compounds may have been quantified then at actual low levels, the non-targeted degradation products would be present at high levels still posing potential hazard and health risks. An example is H2-U-PFOS which was identified by denovo determination. This unsaturated PFOS has already been found before in the environment, but a standard is not commercially available yet. Compounds like this one cannot be found with any current target or library search approach. In the presented non-targeted approach, the PFAS analysis is clearly extended beyond those limits since it enables the detection of a virtually unlimited number of PFAS incl. isomers in complex matrices.

3.09.P-Tu218 Identifying Hidden Trends in PFAS Exposure: A Retrospective Suspect Screening Study of High-Resolution Mass Spectrometry Data

Federica Calabrò, *Lapo Renai, Saer Samanipour and Andrea Gargano, University of Amsterdam - Van 't Hoff Institute for Molecular Sciences, Netherlands*

Per- and Polyfluoroalkyl Substances (PFAS) are chemicals known for their water-repellent and flame-retardant properties, widely used in consumer and industrial products.
Water consumption and dietary exposure are the primary pathways for PFAS human exposure. These substances are persistent, prone to accumulate in organisms, and have a half-life in humans of 4 to 8 years, thus raising global health concerns.
Legacy PFAS have been listed as toxic to human and wildlife. Studies have linked PFAS exposure to endocrine disrupting activity and other health issues such as cancer, decreased fertility, abnormal neurodevelopment, and immune system deficiency.
Untargeted lipidomics and metabolomics analysis is increasingly applied to evaluate the impacts of PFAS exposures in epidemiological studies. Despite the high exposure rate, these have mainly focused on metabolic responses to the limited EU-regulated PFAS, likely underestimating the actual extent of exposure to these chemicals.
To tackle this problem, this research aimed at extending proofs of a wider PFAS exposure impacting human health. Retrospective high-resolution mass spectrometry (HRMS) suspect screening analysis allowed us for retrieving PFAS-related spectral patterns in public untargeted lipidomics datasets, expanding the knowledge of PFAS exposure beyond the former targets.
Human lipidomics and metabolomics raw data were sourced from public MS repositories (e.g., Metabolomic Workbench) and previous literature, according to the following criteria: published epidemiological original articles, minimum one event of PFAS detection in study samples, with untargeted metabolomics applied in participants biofluid samples.
A suspect list of commonly detected PFAS and their precursors guided the untargeted screening of the selected HRMS data. Furtherly, this included C4-C14 perfluoro carboxylic (PFCAs) and sulfonic acids (PFSAs), ether PFAS, fluorotelomers, and alternative Emerging PFAS precursors.
Negative mode HRMS (both DIA and DDA) datasets were processed using the suspect list, applying the jHRMS toolbox workflow for feature detection, data alignment, clustering, and visualization. The method was validated with recorded PFAS standards spectra. Lastly, investigation of any hidden exposure trends was conducted.

3.09.P-Tu219 Identification of Transformation Products of Pharmaceutical Compounds Generated by Photodegradation by Suspect and Non-Target Screenings

***Marie-Hel ne Devier**, Solenne Reverbel, Valentin Dupraz, Ian Vedeau, Oriane Yvin, Emmanuel Geneste, Karyn Le Menach, Marwa Brahim, Aurelien Trivella, Patrick Mazellier and Helene BUDZINSKI, Univ. Bordeaux, CNRS, Bordeaux INP, EPOC, France*

Pharmaceutical compounds together with their transformation products (TPs) are released into waters from different sources, in particular via the discharge from wastewater treatment plants (WWTPs), and their pseudo-persistence in the aqueous environment may pose potential risks to human health and ecosystems [1]. During wastewater treatment, degradation of pharmaceutical compounds into TPs can take place via biotic and abiotic reactions. Once introduced in the receiving waters, they can be further submitted to solar photodegradation [2]. Moreover, it is now well admitted that some TPs could be more mobile, persistent and/or more toxic than their parent compound [3].

In this context, this study aimed to (1) assess the degradation of some pharmaceutical compounds after simulated solar irradiation (7 model compounds) and irradiation at 254 nm (carbamazepine and atenolol) in spiked pure water and WWTP effluent, and (2) identify the TPs generated by high-resolution mass spectrometry coupled to liquid chromatography (LC-HRMS) in suspect and non-target modes. Pharmaceutical compounds and some of their known TPs were quantified by target LC-MS/MS by isotopic dilution. TPs were tentatively identified by LC-MS/QTOF using fullscan mode and two DDA acquisition modes: (1) fragmentation of the most abundant entities (DDA abundance), and (2) fragmentation of a list of predefined masses (DDA list ; 371 potential PTs identified in the scientific literature and generated in silico [4]). For both simulated solar irradiation and 254 nm irradiation experiments, the workflow was focused on the filtering of the molecular entities present only in the irradiated samples and still present at the end of the experiment (48h or 50% conversion rates), thus corresponding to persistent potential TPs, using the Agilent MPP statistical tool (hierarchical clustering and fold change). Then, TP identification was performed by searching for matches in databases and librairies (DBLs) (Agilent, MassBank, mzCloud and internal library), and an identification level was assigned to each TP [5]. The MetFrag tool [6] and R software were used to assign one or more candidate structures to fragmented entities with no match in the DBLs. All the results will be synthetized and presented to the meeting, also suggesting a list of potential TPs to be monitored in rivers.

Disclaimer/Disclosure: This work was carried out within the framework of the TRANSPRO project, funded by the ANR (ANR-18-CE04-0006) and the ETRAC project, funded by the Région New Aquitaine. The work also benefited from the PLATINE platform (environmental organic analytical chemistry platform) afiliated with the team and accredited by the university of Bordeaux and the CNRS (REGEF network). The authors also thank the New Aquitaine Region and the CPER A2E, a project co-financed by the European Union and the New Aquitaine Region, for their financial support.

3.09.P-Tu220 Rapid Screening using an Electronic Nose for Evaluating Odor Compound Removal in Reverse Osmosis of Oil Sands Process-Affected Water

***Eun Ju Kim**, Sook Hyun Nam, Jae Wuk Koo and Tae-Mun Hwang, Korea Institute of Civil Engineering and Building Technology, Republic of Korea*

In this study, we propose a monitoring method using an electronic nose to predict and evaluate the performance of the reverse osmosis (RO) according to the pretreatment process in the treatment of oil sands process-affected water (OSPW). The pretreatment process was ultrafiltration (UF) using a ceramic membrane. This study aims to develop and improve analytical methods for the rapid identification of odor-causing substances in treated water OSPW. OSPW contains complex and environmentally persistent dissolved organic mixtures that can be toxic. OSPW always includes several major contaminants, such as naphthenic acids (NA), polycyclic aromatic hydrocarbons (PAH), BTEX (benzene, toluene, ethylbenzene, and xylene), phenols, heavy metals, and ions. These substances have toxicity, and due to the complexity of OSPW, it is challenging to specifically assess the impact of chemical compounds. This study proposes a method to rapidly screen chemical compounds that cause odors in treated OSPW using an electronic nose to quickly identify changes in the treated water. The analytical conditions for the E-nose (HERACLES NEO, Alpha MOS, Toulouse, France) are as follows. Columns used was MXT-1701 (10 m × 0.18 mm i.d., 0.4 µm film thickness). Incubation was conducted at two temperature conditions, 50°C and 70°C, for 20 minutes. The oven temperature program was as follows: hold at 50°C for 25 seconds, raise to 80°C (1°C per second), raise to 250°C (3°C per second), and final hold at 250°C for 21 seconds. The analyzed substances were scored by process using multivariate analysis and utilized to develop a theoretical model for performance prediction in the RO process. For prediction, we used the solution diffusion model (SDM), a widely accepted framework that describes the mechanism by which solutes move across membranes. The data analyzed by the electronic nose were analyzed by applying the SDM that considers concentration polarization to analyze the experimental results and predict the removal performance under various operating conditions. The prediction model based on the solution-diffusion framework shows a good correlation with experimental data, suggesting its potential usefulness for large-scale system applications. Electronic nose analysis provides a promising solution for monitoring OSPW treated water, as this study confirms that it is a rapid monitoring method for identifying toxic substances in OSPW process treated water

Disclaimer/Disclosure: This work was supported by the Korea Agency for Infrastructure Technology Advancement (KAIA) grant funded by Ministry of Land, Infrastructure and Transport (Grant RS-2022-00144137).

3.09.P-Tu221 Assessment of Emerging Contaminants in Irrigation Canal Waters: A Suspected Non-Target Screening Approach

Igor Antic[1], *Jelena ivancev*[1], *Maja Buljovcic*[1], *Dusan Rakic*[1], *Andras Szekeres*[2], *Monika Varga*[2], *Csaba Vagvolgyi*[2] *and Natasa Durisic-Mladenovic*[1], *(1)University of Novi Sad, Faculty of Technology, Serbia, (2)University of Szeged, Faculty of Science and Technology, Department of Biotechnology and Microbiology, Hungary*

Everyday anthropogenic activities release vast amounts of toxic organic compounds into the environment, including pharmaceuticals, pesticides, industrial chemicals (e.g., per- and polyfluoroalkyl substances), personal care products, and their biotic and abiotic transformation products. Not all of these compounds are regulated under current environmental frameworks as priority contaminants. Instead, many are classified as emerging pollutants-contaminants of emerging concern (CECs)-with limited or no regulatory status. These substances have suspected or fully unknown long-term effects on ecosystems and human health. In Serbia, where wastewater management systems are underdeveloped, the majority of urban and industrial wastewater is directly discharged into surface water without prior treatment. This is particularly concerning in the agricultural region of Vojvodina in northern Serbia, where surface water serves as a critical resource for irrigation.

This study aims to chemically characterize emerging contaminants in the surface water of the Great Bačka Canal, known as one of the most polluted waterways in Europe, employing a suspect screening approach combined with a semi-quantification tool. A total of 40 composite surface water samples were collected along the Canal. Sample preparation involved multi-layer SPE to encompass a wide range of contaminants with varying physicochemical properties. Liquid chromatography coupled with high-resolution mass spectrometry (LC-HRMS) was used to analyze the extracts. A dedicated data processing software (Compound Discoverer) was employed to detect several thousand chemical features in the water samples. These features were narrowed down to a more focused list of several hundred chemical entities through a stepwise filtering strategy, allowing the identification of compounds with a high level of confidence. The analysis revealed that pharmaceuticals, pesticides, and industrial compounds with multiple applications dominated among the identified contaminants. Sites near urban areas exhibited significantly higher contamination levels, both in terms of the number of detected compounds and their estimated concentrations. The main objective of this work is to advance the understanding of the distribution, diversity, and concentration of emerging contaminants in heavily impacted surface water systems, thereby contributing to future regulatory frameworks and mitigation strategies to protect environmental and human health.

Disclaimer/Disclosure: This research was supported by the Science Fund of the Republic of Serbia, # grant no. 7335, Sustainable environmental monitoring and prediction of pollutants spread EnviLife.

3.09.P-Tu222 Natural Wetlands: Challenging the Conventional Perspective on Wastewater Treatment Processes

Markus Brinkmann[1], ***Blake Hunnie***[1], *Zi Yang*[1] *and Rayen Morales Urrutia*[2], *(1)Toxicology Centre, University of Saskatchewan, SK, Canada, (2)Department of Biological Sciences, University of Lethbridge, Canada*

Current global declines in freshwater quality and quantity are pivotal issues being worsened by rising human populations, heightening agricultural, industrial, and urban water demands. These anthropogenic pressures increase the exposure of natural ecosystems to organic contaminants via wastewater, posing risks to both humans and the environment. While effective at remediating chemical contamination, wastewater treatment plants (WWTPs) are costly and in many cases require unrealistic development to mitigate the release of all types of chemicals from entering freshwater sources. Wetlands offer a promising, low-cost alternative for terminal wastewater treatment, being termed nature s kidneys. This study examines the ability of the Frank Lake (FL), AB, Canda, an agro-industrial and municipal effluent-driven wetland complex to remediate organic contaminants, while assessing the potential toxicity of the combined effluent. To begin addressing these points, non-targeted analyses were performed via ultra-high performance liquid chromatography high resolution mass spectrometry to identify and semi-quantify organic chemicals in both sediment and water extracts. The toxicological properties of all annotated compounds were assessed by the USEPA ToxCast program. In vitro and 21-day in vivo examinations of endocrine disruption to the T47D-KBluc human breast cancer cell line using estrogen receptor assays, and Fathead Minnows (Pimephales promelas) were also conducted. To date, 773 unique compounds were identified in FL samples; 202 of which exhibit toxicological effects. The relative abundance of pharmaceuticals, one of the most prevalent use classes of chemicals in this mixture, was shown to decrease as water flows through the wetland; highlighting its potential as a remediative alternative to terminal WWTP processes. Similarly, the contamination at the combined site of municipal and agro-industrial effluent release resulted in endocrine-disrupting impacts including estrogen receptor transactivation during in vitro assessments, decreased male P. promelas fertility, and increased tubercle scores, with reduced to undetectable effects downstream. The results herein showcase the potential for natural wetlands to minimize contaminant loads that enter downstream water supplies, and thus their related toxicological impacts on freshwater ecosystems; providing an alternative solution towards sustainable water pollution management.

3.09.P-Tu223 Prioritizing Organic Toxicants in Hydraulic Fracturing Flowback and Produced Water from Shale Gas Sites using Integrative Effect-Directed Analysis and Non-Target Screening
*Leiwei He[1], Fei Cheng[2], Fan Wu[1] and **Jing You**[1], (1)Jinan University, China (Mainland), (2)Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, China (Mainland)*
The use of hydraulic fracturing in shale gas exploitation has generated substantial amount of flowback and produced water (FPW), and ecological risk of these highly complex chemical mixtures has raised worldwide concern. Herein, an integrative effect-directed analysis (EDA) and nontarget screening (NTS) workflow was developed to identify and prioritize main toxicants in treated FPW (T-FPW). The workflow included sample extraction and fractionation, zebrafish embryo toxicity tests, target and nontarget chemical analyses, and toxicity prioritization and confirmation using toxicological priority index (ToxPi). Results showed that less hydrophobic compounds which were used in fracturing fluid and their degradation products were the potentially high-risk toxicants in T-FPW. Thirty-nine target compounds identified in toxic fraction explained 4.82% of the mortality. Additional 584 nontarget contaminants were annotated by NTS. Risk prioritization was achieved for 470 identified contaminants with ecotoxicity data available using a ToxPi method. Six nontarget toxicants were identified with higher ecological risks than all target contaminants, and their presence in FPW were confirmed using reference standards. A principal component analysis of NTS features revealed that EDA fractionation reduced mixture complexity and focused toxicant screening, which significantly improved NTS efficiency, highlighting advantages of integrative EDA and NTS for mixture risk assessment.

3.09.P-Tu224 Combining Advanced Analytical and Effect-Based Approaches for Characterization of Wastewater
***Kevin Rocco**[1], Erica Selin[1], Kevin Ugwu Hernandez[2], Maria Larsson[1] and Anna Maria Rotander[1], (1)Örebro University, Man-Technology-Environment (MTM) Research Center, Sweden, (2)Örebro University, Man-Technology-Environment (MTM) Research Center, Denmark*
Over the past 15 years, advances in analytical screening techniques, particularly with suspect and non-target screening, have significantly improved the characterization of wastewater. These approaches allowed the identification of various contaminants, highlighting the potential of wastewater-based epidemiology to serve as an early warning system for environmental hazards. However, many compounds in this complex matrix remain undetected and uncharacterized, thereby presenting potential threats to the environmental ecosystems. To address these challenges, we implemented an integrative approach combining advanced analytical techniques, suspect and non-target screening, with effect-based in vitro assays to comprehensively characterize and assess contaminants present in wastewater. Samples were collected from seven locations within Örebro, representing residential, industrial, and mixed-use areas, with global influent and effluents samples. Sampling was conducted in 2023, in May and September. Two extractions protocols were used on the collected samples, generating extracts for an apolar and a polar fraction. Each fraction was split for organic contaminants analysis, using liquid and gas chromatography coupled with high resolution mass spectrometry (LC- and GC-HRMS), and effect-based in vitro assessment, consisting of the aryl hydrocarbon receptor (AhR; DR CALUX), androgen receptor antagonism (AR CALUX) as well as estrogen receptor ? (ER? CALUX) activities. Our analysis revealed site-specific differences in contamination profiles, with pharmaceuticals such as lidocaine being

predominantly detected in the residential areas, whereas plasticizers such as triphenyl phosphate were more prevalent in the industrial samples. The results from the effect-based methods showed variability in receptor activity between the different fractions and sampling areas. Specifically regarding ER? activity, apolar extracts displayed higher bioactivity compared to the polar extracts, with all samples being bioactive in September and bioequivalent concentrations reaching up to 31.9 ?g/mL in the residential area. Further research is necessary to elucidate the relationship existing between the detection of chemical contaminants and their biological effects. This study demonstrates the value of integrating innovative analytical strategies with effect-based methods for evaluating wastewater, providing comprehensive insights for improving environmental monitoring strategies in the future.

3.09.P-Tu225 An Extensive Pollutant Characterization Method for Organic Fertilizers Combining Accelerated Solvent Extraction, Chemical Analysis and Cell-based Bioassays

***Rhayn Werz**[1], Kevin Rocco[2], Maria Larsson[1], Anna Maria Rotander[3], Magnus Engwall[4] and Anna Karrman[1], (1)Örebro University, Sweden, (2)Örebro University, Sweden, (3)Örebro University, Sweden, (4)School of Science and Technology, Örebro University, Örebro, Sweden*

Increasing the circularity of nutrients essential for crop growth is a vital part of the Circular Economy Action Plan designed by the European Union. In Sweden, sewage sludge, cow manure, and fermented foodwaste are the prevalent types of organic fertilizers (OF), mainly acting as fertilizers for phosphorus and organic matter.

However, the presence of a diverse range of emerging micropollutants has raised concerns around the use of OF. While optimized methods for extraction and chemical analysis exist for individual pollutant groups, there is a pressing need for a more comprehensive method to streamline the pollution assessment of such fertilizers.

This study aims to fill this gap by combining an Accelerated Solvent Extraction(ASE) method with GC- and LC-HRMS analyses as well as CALUX® bioassays. Combining chemical analysis with bioassays gives insight into pollutant groups present as well as resulting mixture and toxicity effects. Sewage sludge samples were acquired from 9 wastewater treatment plants with differently sized catchment areas (cities, towns, rural) across Sweden. Additionally, 5 cow manure samples and 5 food waste fermentate samples were included in the study.

Extraction was performed both with apolar (n-hexane and dichloromethane mix) and polar (methanol) solvents. Using a spike-addition approach, recoveries of apolar contaminant groups such as polychlorinated biphenyls, dioxins and furans, polybrominated diphenyl ethers, polycyclic aromatic hydrocarbons, and siloxanes were tested. The recoveries for polar contaminant groups, including per- and polyfluoroalkyl substances, phthalates, bisphenols, phosphorus flame retardants and a mix representing widely used pharmaceutical classes were also evaluated. Unspiked extracts were assessed with an array of CALUX® bioassays, testing for estrogenic, anti-androgenic, xenobiotic effects as well as for oxidative stress (ER?, anti-AR, DR, Nrf2 CALUX®).

Our results show that performing both an apolar and polar extraction is necessary to capture the different pollutant groups present. For example, the bio-EEQ values differed greatly between the apolar and polar extracts in the ER assay but to a much lesser extent in the DR assay (bio-TEQ values).

ASE combined with GC- and LC-HRMS analysis seems to be promising to extract and characterize a wide range of pollutants present in OF. Bioassays like ER?, anti-AR, DR, Nrf2 CALUX® can give further insights into extraction efficiencies of bioactive compound classes.

3.09.P-Tu226 Identification of Major AhR and ER Agonists in Freshwater Fish from the Gapcheon River in Korea Using Effect-Directed Analysis and Nontarget Screening

***Jihyun Cha**[1], Jiyun Gwak[1], Mungi Kim[1], Dokyun Kim[2], Junghyun Lee[3], Kyung-Hoon Shin[4], Hyo-Bang Moon[4], Jong Seong Kim[5] and Seongjin Hong[1], (1)Chungnam National University, Republic of Korea, (2)Korea Institute of Ocean Science & Technology (KIOST), Republic of Korea, (3)Kongju National University, Republic of Korea, (4)Hanyang University, Republic of Korea, (5)Seoul National University, Republic of Korea*

This study aimed to identify major aryl hydrocarbon receptor (AhR) and estrogen receptor (ER) agonists in freshwater fish collected near the sewage treatment plant (STP) outfall in the Gapcheon River using effect-directed analysis (EDA) and nontarget screening (NTS). Target species included common carp (Cyprinus carpio, S1), crucian carp (Carassius carassius, S2), Far Eastern catfish (Silurus asotus, S3), barbel steed (Hemibarbus labeo, S4), and skygager (Erythroculter erythropterus, S5). The accurate trophic positions of fish, calculated from δ15N values of amino acids, were 2.2 for S1 and S2, 3.0 for S3, and 3.2 for S4 and S5. The H4IIE-luc bioassay revealed elevated AhR-mediated potencies in the mid-polar fractions of S2 egg, S2 muscle, S3 fillet, and S5 liver. The T47D-kbluc bioassay identified significant ER-mediated activities in the polar fractions of the S2 egg and S2 muscle. Twenty-one targeted AhR agonists, including 7 traditional polycyclic aromatic hydrocarbons (PAHs) and 14 emerging PAHs, accounted for 49%, 94%, 83%, and 20% of AhR-mediated potencies in the S2 egg, S2 muscle, S3 fillet and S5 liver, respectively. Among these, benzo[b]anthracene was the dominant contributor, explaining 18% to 68% (mean = 44%) of AhR-mediated potencies. In contrast, 4 known ER agonists, such as estrone, 17β-estradiol (E2), estriol, and 17β-ethinylestradiol, explained only 7.7% and 18% of ER-mediated potencies in polar fractions of S2 eggs and muscle, respectively, with E2 contributing 7.6% in eggs and 17% in muscle. To identify unknown ER agonists, NTS using LC-QTOFMS was conducted on the highly potent polar fraction of the S2 eggs. A four-tier selection criteria identified 15 and 12 candidates in positive and negative ionization modes, respectively. Toxicological confirmation using the T47D-kbluc bioassay revealed significant ER efficacies for mestanolone, mesterolone, and methandrostenolone in positive mode, and alfatradiol, 2-hydroxyestradiol, 17-epiestriol, and epiestriol in negative mode. The inclusion of these novel ER agonists increased the explanation rates of ER-mediated potencies to 27% in eggs and 21% in muscle, with 17-epiestriol (18%) dominating in eggs and epiestriol (2.7%) in muscle. The findings highlight the need for further studies on the sources of these AhR and ER agonists, particularly their association with STP effluents, environmental pathways, ecotoxicity, and accumulation across trophic levels in aquatic organisms.

3.09.P-Tu227 Efficient Identification of Chemical Indicators for Enhanced Pollution Management in Industrialized Coastal Regions

***Mangong Shin**, Sori Mok and Hyo-Bang Moon, Department of Marine Science and Convergence Technology, College of Science and Convergence Technology, Hanyang University, Republic of Korea*

Marine sediments are crucial indicators of anthropogenic pollution, yet traditional analytical approaches often fall short in capturing the full complexity of non-targeted contaminants in intensively industrialized coastal environments. To address these challenges, this study introduces a refined workflow and software tool tailored for non-target screening (NTS) using a gas chromatography coupled to a time-of-flight mass spectrometry (GC-TOF/MS). By incorporating retention index (RI) filtering, the developed tool effectively improved data processing and enhanced the identification of diagnostic chemical indicators in marine sediments.

Sediment samples from Okpo and Onsan Bays, which are close to big-sized industrialized complexes, were analyzed using the developed software including the automated extraction process of reliable chemical features with reduction of low-quality data. The workflow narrowed over 2,000 detected features to 60 diagnostic compounds through systematic filtering and validation processes. The software demonstrated strong validation accuracy (87%) and significantly reduced the manual effort required for data analysis, offering practical improvements to current NTS workflows. Key compounds identified include cyclic siloxanes, n-alkanes, and polycyclic aromatic hydrocarbons (PAHs), which were linked to distinct pollution sources via Partial Least Squares-Discriminant Analysis (PLS-DA). The PLS-DA model exhibited robust predictive performance ($Q^2 = 0.938$) and statistical significance ($p < 0.0005$), demonstrating the tool s reliability for diagnostic applications.

This study highlights the potential of the software to improve environmental monitoring practices, offering a scalable and efficient tool for analyzing complex contamination profiles. By refining NTS workflows, the developed methodology presents a practical approach for tracing pollution sources, with meaningful implications for enhancing pollution management strategies and informing regulatory frameworks in industrial coastal areas. This provides a foundation for additional studies to expand the application of this tool across diverse environments and contamination scenarios, contributing to broader efforts in environmental conservation.

Disclaimer/Disclosure: This research was supported by Korea Institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries, Korea (RS-2021-KS211535).

3.09.P-Tu228 Non-Targeted Microplastic Leachate Analysis Using Dual Electron Ionization/Chemical Ionization Gas Chromatography-High Resolution Mass Spectrometry

***Pegah Mousazadehfazeli**[1], Sonja Klee[2], Nikiforos Alygizakis[3], Jaroslav Slobodnik[4], Jorg Roosma[5], Andrea Mizzi Brunner[5], Arnd Ingendoh[6], Christina Troyer[1], Stephan Hann[1] and Teresa Steininger-Mairinger[1], (1)BOKU University, Institute of Analytical Chemistry, Austria, (2)TOFWERK AG, Switzerland, (3)National and Kapodistrian University of Athens, Department of Chemistry, Laboratory of Analytical Chemistry, Greece, (4)Environmental Institute, Slovakia, (5)TNO, Environmental Modelling,*

Sensing and Analysis (EMSA), Netherlands, (6)Bruker Daltonics GmbH & Co KG, Germany
The production of synthetic polymers has created an environmental threat due to plastic pollution. Microplastics; plastic particles under 5 millimeters, degrade chemically and physically in the environment, forming secondary microplastics and low molecular weight compounds that can leach into ecosystems. Gas chromatography (GC) combined with electron ionization (EI) mass spectrometry (MS) has been used for analyzing volatile and semi-volatile compounds, with fragmentation patterns easily matched to databases such as NIST. However, identifying the molecular formula of the intact compound is challenging due to the extensive EI fragmentation. Chemical ionization (CI) preserves intact molecular ions, however, to provide both, EI fragment and exact molecular mass information of the sample, two separate GC runs are usually required. This approach increases analysis time, demands for complex data alignment, and poses the risk of sample degradation/changes between the two individual runs. To address these limitations, a dual-source setup capable of obtaining EI and CI information within a single chromatographic run was used in this work.
Samples were obtained from NORMAN network s joint program activity Microplastics-leaching of additives and non-intentionally added substances . They were extracted using 1-propanol as an extraction solvent and analyzed using a consistent GC method across high-resolution and low-resolution mass spectrometry setups. The employed ecTOF system (Bruker, Bremen, Germany) allowed quasi-simultaneous EI and CI data acquisition. Data processing included peak picking, deconvolution, and alignment, with multivariate analysis such as orthogonal partial least squares discriminant analysis, identifying significant variables. Features were prioritized based on Variable Importance in Projection ranking, with retention indices and mass spectra compared against NIST spectral databases and open-source libraries.
Comparative analysis of microplastic leachates across GC-MS platforms showed differences in sensitivity and confidence levels in compound identification. This study highlights the advantages of CI spectra, particularly for compound classes like hydrocarbons, where fragmentation patterns are similar regardless of chain length and molecular ion data is missing. The number of detected compounds and confidence levels are compared, and the importance of high-resolution EI spectral libraries is demonstrated, showcasing specific examples.

3.09.P-Tu229 Development of a GC-HRMS Spectral Database for Photolytic Degradation Byproducts of Common Organic Pollutants

Thanh Wang[1] *and Vanessa Cajes*[2]*, (1)Linkoping University, Sweden, (2)Örebro University, Sweden*
Photodegradation is a significant degradation mechanism for many environmental organic contaminants, both indoors and outdoors. Many of these contaminants are persistent and toxic, but the exact degradation processes for many of these are not well understood. It is crucial to monitor and study commonly found environmental contaminants and identify their degradation products. However, the lack of standards makes identification difficult. Some of the most common mass spectral libraries are for gas chromatography coupled with mass spectrometry (GC-MS) that are recorded at low resolution. However, this makes it challenging to identify compounds with spectral peaks that differ only slightly in their mass-to-charge ratio (m/z). However, new GC-MS instruments with high mass resolution are more and more common.
The aim of this project was to determine potential degradation products from various compounds commonly found in indoor environments and add these findings to a spectral library for high-resolution mass spectrometry (HRMS). The study involved exposing standards to ultraviolet (UV) light and performing chemical analysis using GC-HRMS. The data was processed using MS-DIAL to identify potential products, and a workflow to generate spectral library was developed to enable suspect screening in environmental samples. Many compounds did not show any degradation under the experimental conditions. This showcases some challenges in the current experimental setup. However, four potential degradation products were found: penta-, tetra-, and tribromobenzene from hexabromobenzene (HBB), and one potential degradation product from 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (EHTBB).

3.09.P-Tu230 High-Resolution Mass Spectrometry Screening of Quaternary Ammonium Compounds (QACs) in Dust from Homes and Various Micro-environments in South China

Guomao Zheng*, Southern University of Science and Technology, China (Mainland)*
Despite their ubiquitous use, information regarding the presence of Quaternary ammonium compounds (QACs) in various micro-environments remains scarce and only a small subset of QACs have been monitored using targeted chemical analysis. In this study, a total of 111 dust samples were collected in homes and various public settings from South China during the COVID-19 pandemic, and were analyzed for traditional and emerging QACs using high-resolution mass spectrometry. The total traditional QAC concentrations in residential dust (?traditional QAC, sum of 18 traditional QACs) ranged from 13.8 150

?g/g with a median con-centration of 42.2 ?g/g. Twenty-eight emerging QACs were identified in these samples and the composition of ?emerging QAC (sum of emerging QACs) to ?QAC (sum of traditional and emerging QACs) ranged from 19 to 42% across various micro-environments, indicating the widespread existence of emerging QACs in indoor environments. Additionally, dust samples from cinemas exhibited higher ?QACs concentrations compared to homes (medians 65.9 vs. 58.3 ?g/g, respectively), indicating heavier emission sources of QACs in these places. Inter-estingly, significantly higher ?QAC concentrations were observed in dust from the rooms with carpets than those without (medians 65.6 vs. 32.6 ?g/g, $p < 0.05$, respectively). Overall, this study shed light on the ubiquitous occurrence of QACs in indoor environments from South China.

3.09.P-Tu231 Development and Validation of an Open Access High Resolution Mass Spectral Library for Detection of Food Toxicants

***Serena Rizzo**, Ivan Aloisi, Federico Padilla Gonzalez, Sjors Rasker and Wout Bergkamp, Wageningen Food Safety Research (WFSR), Netherlands*

Food represent one of the most difficult sample in trace analysis. Due to the high chemical complexity (sugars, lipids, amino acids, etc.) and to the high concentration of major components (such as fatty acids in cereals), searching for low-abundance contaminants or residues in food can be considered a very complex and challenging task.

Nowadays, quali-quantitative analysis of food contaminants mainly relies on the use of hyphenated techniques, such us liquid or gas chromatography coupled to low or high resolution mass spectrometry (namely LRMS and HRMS). The combination with LRMS is often considered the best choice for the targeted strategies. Although this approach is a highly sensitive and selective, it requires prior knowledge of the analytes of interest (e.g., their precursor and product ions), and is not suited for retrospective analysis of extra compounds.

Contrarily, HRMS is the state-of-the-art detection technique for semi-targeted or non-targeted analysis and can be considered as a powerful tool for the detection and identification of known and unknown chemicals. The use of high resolution tandem mass spectra library (HRMS2) helps in the identification of compounds. Nevertheless, most of the them cover natural products and only a few contaminants. Moreover, most of the HRMS2 libraries repositories focus on total number of spectra more than on the quality, for example combining data acquired from different instruments and at nominal and accurate mass.

The aim of the study was to develop and validate a HRMS2 library containing well-known food hazard chemicals, among which veterinary drugs, contaminants, pesticides and natural toxins (including metabolites). The library was built acquiring standards in solvent using ultra high-pressure liquid chromatography (UHPLC) coupled to an Orbitrap IQ-X Tribrid, with positive ESI as the ionization interface. Each compound was acquired using 7 different collision energies generating more than 7,000 mass spectra in total. All the information related to the strategies used for built the library are included here.

Overall, integrating this library into routine testing workflows has the potential to improve food safety monitoring and support more robust regulatory oversight, ultimately benefiting public health and safety.

3.09.P-Tu232 Analysis of Pesticide Residue Using High-Resolution Mass Spectrometry in Korea Herbal Medicines

***Hyeongwook Jo**[1], Jung-Hun Sun[2] and Joon-Kwan Moon[3], (1)HKNU IACF, Republic of Korea, (2)HKNU IACK, Republic of Korea, (3)HKNU, Republic of Korea*

As rapid industrialization and people`s living standards have improved, people have become more interested in quality and safety in food. In particular, direct hazards that impede food safety can be broadly divided into contaminants and residual substances. This has always been present in food production sites, processing industry, distribution processes, or sales processes, and is known to contaminate food in various ways. To solve this problem, developed countries have been investing large amounts of budget to develop and operate hygiene programs such as HACCP for a long time, and Korea has also been operating them under the management and supervision of MFDS. In addition, we are continuously developing residual material analysis methods and residual material testing programs and utilizing them in the field. Among these, looking at the development status of Korea`s simultaneous multi-component residue analysis methods, MFDS about 510 types of pesticides and NAQS about 463 types of pesticides is conducting safety management of pesticide residues in agricultural products. Testing was conducted using HPLC and GC as analysis equipment for safety management of pesticides residues, but recently, testing has been conducted using MS/MS. MS/MS has the advantage of high selectivity and sensitivity, but has disadvantage of being able to analyze only the compounds we designate. Howerer, HRMS has the great advantage of not only being able to identify the exact compound due to its high resolution, but also being able to track when the problem began by extraction specific ions from the total ion chromatogram. Therefore, pesticide residue analysis using HRMS can track not only pesticide residues but also other contaminants or residues, and has excellent selectivity, making it possible to accuratelty determine compounds. If an analysis method using HRMS is developed, it can be used to determine the compounds in food and it is expected that safety management of contaminants and residual substances will be further strengthened

3.09.P-Tu233 Development of an Optimized Workflow for Suspect Screening of Persistent, Mobile, and Toxic (PMT) Substances in Circular Food Systems

Serena Rizzo*, Ivan Aloisi, Federico Padilla Gonzalez, Kyara Jacobs and Kerstin Kratschmer, Wageningen Food Safety Research (WFSR), Netherlands*

The transition to circular food systems introduces food safety challenges arising from chemical contaminants with persistent, mobile, and toxic (PMT) properties, including pesticides, pharmaceuticals, industrial chemicals, and environmental pollutants. These substances, numbering over 15,000 in international databases, are particularly concerning in recycled materials like sewage sludge. Conventional methods for PMT identification, reliant on reference standards, are limited in scope and applicability to complex matrices. To address these gaps, we developed a high-resolution mass spectrometry (HRMS)-based workflow for comprehensive suspect screening of PMTs across a broad polarity spectrum in sewage sludge.

The workflow includes a UHPLC-HRMS analysis, employing Data-Dependent (DDA) and Data-Independent Acquisition (DIA) for enhanced scan data collection, alongside a spectral library and inclusion lists derived from the NORMAN database. Two sample preparation methods, SPE-based and QuEChERS-based, were evaluated, with the latter optimized for sensitivity and reproducibility. Suspect PMTs were screened using Compound Discoverer software and matched against the NORMAN database to identify novel compounds. Targeted analysis of reference standards enabled accurate quantification, while suspect screening expanded the detection scope. Testing on 22 sewage sludge samples revealed known and suspect PMTs across diverse sources, including municipal, plant-based, and animal-based residuals.

This workflow provides a robust, transferable method for identifying PMTs in complex matrices without dependence on reference standards. By bridging critical analytical gaps, it supports improved monitoring and risk assessment of chemical contaminants in circular food systems.

3.09.P-Tu234 Combining Retention Factor and Retention Index: A New Approach for Enhancing Retention Prediction Using Chemometrics

Jasmin Schwarte*, Sanne Boot, Tijmen Bos, Bob Pirok and Saer Samanipour, University of Amsterdam, Netherlands*

Liquid chromatography is among the most widely employed techniques across numerous analytical fields, including the analysis of pharmaceuticals, environmental samples, proteins, and polymers. Unfortunately, method development in liquid chromatography can be very time-consuming and challenging due to the high number of variables that need to be optimized such as the mobile and stationary phase selection, the establishment of a fitting solvent gradient, choosing an appropriate flow rate, etc. This is especially true for complex samples. Therefore, efficient optimization techniques such as retention modeling are needed to support the method development.

In the past, two very useful parameters, namely retention factor and retention index, were explored in order to develop an accurate model for retention prediction. A novel machine learning algorithm, for example, was developed to predict the retention indices for structurally unknown chemicals based on cumulative neutral losses. On the other hand, multiple retention models exist that are based on the retention factor such as the linear solvent strength model or the Neue-Kuss model. While the retention factor is directly influenced by the chromatographic conditions it requires multiple measurements to determine the retention model accurately. The retention index depends on the relative retention compared to that of reference substances and can be used to more easily compare different systems and conditions. As of yet, no attempt has been made to combine the retention factor and the retention index for additional information to train the machine learning model. Although the results of individual models look promising, combining both retention parameters could give new insights and lead to more accurate predictions. Therefore, in this project, the retention factor and retention index will be combined into a new parameter, namely the retention score. This new parameter will allow accurate prediction of substances and give a first estimate of whether two substances can be separated by using a certain method.

3.09.P-Tu235 Refining Molecular Networks: The Power of Distance Metrics in Spectral Differentiation

Quinten van Erp[1] *and Saer Samanipour*[2], *(1)University of Amsterdam, Netherlands, (2)University of Amsterdam, Netherlands*
Molecular networks are a visualization that compares every molecule to one another based on their mass spectra, enabling the clustering of similar species based on a similarity score and a specific threshold. These networks are utilized in a wide spectrum of bio and chemistry fields, including the likes of environmental sciences, biomedical, and forensics, to name a few. Since mass spectra are directly related to molecular structures, similar structures will be linked within the network, enabling the identification and exploration of structural similarities and, therefore, related molecules.
For this study, we utilized electrospray ionization (ESI) MS2 spectra, which enables the comparison of molecule fragments within the networks. ESI spectra can deviate between instruments and experimental conditions, making the matter more complex that is observed experimentally and recorded in mass spectrometry databases such as MassBank EU, GNPS (The Global Natural Product Social Molecular Networking), MoNa (MassBank of North America), or NIST (National Institute of Standards and Technology).
Algorithms used to build such networks tend to utilize the cosine score for similarity testing. However, there are a vast majority of different metrics to calculate such scores, i.e., Euclidian Distance, Jaccard Index, Manhattan, Minkowski, and Sørensen-Dice coefficient. We investigated these five different similarity algorithms and their influence on the network thereof. Since different values are obtained from each algorithm, we observed direct influence within the molecular networks. Utilizing different visualization strategies in combination with the varying similarity algorithms was also found to be significant for the formation of molecular networks.
The utilized data contained multiple spectra for each molecule with, i.e., different ionization energies. Therefore, the results were further investigated and connected to the conditions used for the data acquisition. The spectra not used to build the model were used as a test set, which allowed us to evaluate how these similarity metrics influence the level of confidence during the chemical identification via spectral matching.

3.10.A Analysis, Assessment and Management of Contaminants of Emerging Concern and Their Transformation Products

3.10.A.T-01 Keep it Cool in Your Lab! Why "Cold" OECD TG 309 Degradation Tests are the New Hot Trend for Assessing Chemical Persistence

Michael Neumann[1] *and Karsten Nodler*[2], *(1)IV 2.3 Chemicals, German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)German Water Centre (TZW: DVGW-Technologiezentrum Wasser), Germany*
The threat to drinking water resources posed by persistent and mobile substances has been scientifically highlighted for decades and the occurrence of polar chemicals in the aquatic environment has been known since the 1980s. ECHA recommends that the OECD TG 309 degradation test should be performed first as a standard. The goal of the OECD TG 309 degradation test is to demonstrate intrinsic aerobic biodegradability and to derive a valid half-life for aerobic biodegradation (degradation half-life, DegT50) in surface water.
When assessing whether the result is valid two cases must be distinguished: Case 1: A pronounced and significant decrease in the concentration of the test substance in the aqueous phase is observed during the test. This case most likely needs a 14C-labeling of the test substance for a valid test result. Case 2: No pronounced and significant decrease in the concentration of the test substance in the aqueous phase is observed during the test. For a valid test result it is only necessary to demonstrate that a sufficiently high aerobic biodegradation potential (i. e. a vital inoculum) was present in the test system. This is ensured using a reference substance. In case 2, a valid result of the degradation test according to OECD TG 309 can always be obtained without 14C-labeling of the test substance. Case 2 is expected especially for persistent and mobile chemicals.
Criteria were defined to assess if a test substance is suitable for a "cold" degradation test according to OECD TG 309. The criteria were applied to assess a list of 1250 known water contaminants. The list of 832 contaminants prioritized for a "cold" degradation testing according to OECD TG 309 has been divided into two priority levels: contaminants that have already been detected in drinking water, groundwater, raw water or bank filtrate (category A, 422 contaminants) and contaminants that have only been detected in wastewater treatment plant effluent and/or sur-face water (category B, 410 contaminants).
23 Recommendations for a simple, cost-effective and efficient implementation of a valid "cold" degradation test according to OECD TG 309 were developed. The recommendations apply only to those test substances for which no pronounced and significant decrease in concentration in the aqueous phase is

expected during the test. Our work will support drinking water suppliers and water monitoring authorities to carry out OECD TG 309 degradation tests in their own analytical laboratories

Disclaimer/Disclosure: This research project was funded by the German Environmental Agency as project no 179154 and will be published as UBA TEXTE xx/2024

3.10.A.T-02 Sulfamethoxazole Transformation by Heat-Activated Persulfate: Linking Transformation Products Patterns with Compound-Specific Isotope Analysis

Xiao Liu[1]*, Jimmy Kopke*[2]*, Caglar Akay*[2]*, Steffen Kummel*[3] *and Gwenael Imfeld*[1]*, (1)Institut Terre et Environnement de Strasbourg (ITES), Universite de Strasbourg/EOST/ENGEES, France, (2)Department of Molecular Environmental Biotechnology, Helmholtz Centre for Environmental Research-UFZ, Germany, (3)Department of Technical Biogeochemistry, Helmholtz Centre for Environmental Research GmbH UFZ, Germany*

Sulfamethoxazole (SMX) is a frequently detected sulfonamide antibiotic in surface and groundwater, raising environmental concerns about its fate. Oxidative treatments, such as persulfate application, are commonly used for micropollutant removal. To investigate and differentiate SMX transformation by various radicals from other SMX dissipation processes using multi-element compound specific isotope and transformation products (TP) analysis, SMX transformation experiments were conducted using heat-activated persulfate at pH 3, 7, and 10. SMX hydroxylamine (TP269a) and TP178 were identified as the dominant transformation products across all pH levels. The exclusive formation of 4-nitroso-SMX, 4-nitro-SMX, and TP518 at pH 3 highlighted the role of SO? in attacking the amino group. At pH 7 and pH 10, 3A5MI emerged as the dominant TP. Normal carbon isotope fractionation (??^{13}C from 1.9 to 2.3), with consistent isotopic values across pH levels, was attributed to the formation of TP178, which involves C-S bond cleavage. An inverse nitrogen isotope fractionation at pH 3 (?N = +0.68 ± 0.11) was linked to SO? -induced single-electron transfer, leading to the formation of N-centered SMX radicals. Conversely, normal nitrogen isotope fractionation at pH 10 (?N = ?0.27 ± 0.04), was associated with multiple bond cleavages, including N-H bond cleavage initiated by H abstraction through HO and N-S bond cleavage leading to the formation of 3A5MI. The inverse nitrogen isotope fractionation observed at pH 7 indicated that the dominant pathway involved SO? reactions, accounting for 76% of the overall transformation. Overall, the results highlight the potential of CSIA to elucidate SMX persulfate oxidation pathways and evaluating the natural attenuation of SMX through radical reactions in aquatic systems.

3.10.A.T-03 Towards Predicting Persistent Transformation Products in Different Environments

Jasmin Hafner*, Jose Andres Cordero Solano and Kathrin Fenner, Swiss Federal Institute of Aquatic Science and Technology (Eawag), University of Zurich, Switzerland*

Transformation products (TPs) are gaining attention in the scientific community and chemical regulation, in particular if they are persistent, mobile, or toxic. Observed TPs and degradation rates differ between environments, highlighting the necessity to better understand environment-specific biodegradation processes. For regulation dealing with long lists of chemicals and for industry trying to integrate Safe-and-Sustainable-by-Design principles early in the development of new chemicals, tools for fast and reliabe prediction of biodegradation processes are direly needed. We believe that in silico identification of persistent TPs in a given environment from chemical structure alone can be achieved by combining pathway- with persistence prediction.

The pathway prediction engine of the online platform enviPath is commonly applied to generate suspect lists for analytical screening of TPs. We have recently increased the scope of enviPath databases by adding biodegradation data on micropollutants in activated sludge and water-sediment systems. The enviPath database provides training data for new machine learning models developed in our group that can predict persistence endpoints (e.g., primary biotransformation half-lives, breakthrough in wastewater treatment plants), of complex chemicals and provide a reliable uncertainty estimate for each prediction. Here, we apply a model trained on soil half-lives of pesticides to predict persistence of experimentally observed transformation products in soil and activated sludge for which no kinetic data is available. We show that the model can point towards TPs that, although classified as minor, may be be persistent in soil. We believe that the combination of data collection efforts and new approaches to persistence prediction will help achieving a comprehensive understanding of biodegradation processes, and pave the way towards the integrated, environment-specific prediction of persistent TPs.

3.10.A.T-04 Identifying Potentially Hazardous Transformation Products from Compounds on the Global Chemical Inventory

Emma Helena Palm[1]*, Hesam Korki*[2]*, Moustapha Cheikh*[2]*, Siyang Tian*[3]*, David Wishart*[3] *and Emma*

Schymanski[4], (1)University of Luxembourg, Luxembourg, (2)University of Luxembourg, Luxembourg, (3)University of Alberta, Canada, (4)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg
Identifying persistent, mobile, and toxic (PMT) chemicals and their transformation products (TPs) is essential for assessing environmental and health risks. However, public data on TPs is limited: of over 140,000 compounds in the global inventory, only 0.9% have TP data in PubChem. Due to high computational time and numbers, on the fly predictions often cover only 1-2 generations. A comprehensive database with multi-generation TPs is therefore needed to track potentially harmful TPs from longer reaction pathways.
As a proof of concept, 5 generations of environmental TPs were predicted for 321 pesticides using the "env" and abio model in BioTransformer 4.0 (version 2024-11-06). The results were stored in a Neo4j database for fast querying via a web interface that was built with Python, JavaScript, Cypher, and HTML. Dead-end TPs (TPs to which no reaction rules apply) were identified and assessed for mobility, persistence, and toxicity using OPERA predictions.
Starting from 321 initial pesticides, the BioTransformer predictions yielded 752,262 predicted TPs from 1,794,271 unique reactions. However, only 280 of these TPs are predicted to be dead-end products, i.e., TPs with potentially greater environmental persistence concerns. Out of the 280 predicted dead-end TPs, 201 were predicted to be mobile, of which 172 were also very mobile based on the EU CLP criteria. As for persistence, only 149 of the TPs fell inside the model applicability domain, of which 46 were predicted to not be readily biodegradable. One of these vPvM TPs, pyridine N-oxide, had 6 different precursors among the 321 input compounds, all of which shared the pyridine substructure. Thus, similar patterns may be useful for grouping efforts in combination with experimental confirmation of the TPs and their properties. Only 11,198 (0.15%) of the TPs in the GCI-TPs database were found in the PubChem database based on a full InChIKey match. This is concerning from a non-target analysis point of view as structure databases such as PubChem are typically used for annotation. This shows that GCI-TPs can potentially help fill an important gap in annotation workflows. The GCI-TPs web interface has several different search options to facilitate querying, including finding all precursors or TPs of a compound, reaction display and batch searches. The predictions mentioned above are now being scaled to the complete 140,000 compound global chemical inventory.

Disclaimer/Disclosure: Emma H. Palm and Emma L. Schymanski acknowledge funding support from the European Union Horizon 2020 research and innovation programme under Grant Agreement No 101036756 for ZeroPM and from the Luxembourg National Research Fund (FNR) for project A18/BM/12341006.

3.10.P-Th148 Seasonal Variation of Contaminants of Emerging Concern in Swedish Landfill Leachate and its Recipient: A Case Study

***Tsz Yung Wong**[1], Alberto Celma[2] and Oksana Golovko[3], (1)Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Swedish University of Agricultural Sciences (SLU), Sweden*
Landfill leachate is an important point source of contaminants of emerging concerns (CECs) in fresh water systems. There are over 350 active landfills in Sweden, producing 8 ~12 million m3 of leachate each year. This study conducted non-target screening (NTS) and suspect screening (SS) using ultra high-performance liquid chromatography coupled with high resolution mass spectrometry (UHPLC-HRMS) to identify the CECs in Swedish landfill leachate. The aim of this research is to map the occurrence of CECs in Swedish landfill leachate and provide insights into their seasonal changes.
In our study, 24-hour composite samples of untreated, treated leachate and recipient upstream, and downstream (named UL, TL, RU, and RD) were collected from a municipal landfill in Sweden in September 2023, January, March, and June 2024 by time-integrated autosamplers. Extraction was performed on multi-layer solid phase extraction (SPE) cartridges in order to capture a wide spectrum of CECs. Preliminarily, 74 CECs were identified in all the landfill leachate samples, including 35 industrial chemicals, 21 pharmaceuticals, 10 PFASs, and 9 pesticides. Winter had the highest number of detected CECs and the highest detection frequency among all seasons. 49 CECs were detected in UL, TL, and RD across all seasons, and 16 of them were also detected in RU in either or all seasons. Some industrial chemicals (e.g., tripropyl phosphate and dibutyl phthalate) showed lower detection frequencies in warmer seasons (summer and/or autumn), while some pharmaceuticals, such as bicalutamide, losartan, and lamotrigine, had lower detection frequency in spring and summer. Possible reasons for the seasonal change in the occurrence of CECs can be: (1) increased removal efficiency at higher temperature; (2) the amount of produced leachate and the concentration of CECs can be influenced by precipitation; (3) the reception of external waste may vary depending on time. These findings highlight the need for seasonal

monitoring of CECs and adjustments of leachate treatment strategies to manage the diverse presence of CECs in landfill leachate throughout the year.

3.10.P-Th149 Synthetic Musks: From Wastewaters to Surface Water Ecosystems

Stefano Tasselli *and Licia Guzzella, CNR-IRSA, Italy*

Synthetic musks are compounds incorporated in detergents, perfumes, and house-cleaning products. Within them there are Galaxolide, its metabolite Galaxolidone, Tonalide, Celestolide and Phantolide. They are released every day in large amounts into sewage systems and discharged in aquatic ecosystems through wastewater treatment plant (WWTP) effluents. The prolonged exposure of aquatic environments to the continuous discharge of PMFs is raising many concerns about their possible chronic toxicity and future impacts. Data regarding PMFs in Italy are very scarce even if this is the EU-Member State with the highest consumption of these chemicals. In this study, we sampled wastewater in four different stations of a conventional WWTP with activated sludges to understand fate and behaviour of PMFs during treatments. PMFs were measured in all stations up to the µg/L order of magnitude. Biotransformation and adsorption were the two processes driving the fate of these contaminants during treatments. High and stable musk concentrations were measured in activated sludges. Only a slight reduction of the main PMFs, Galaxolide (-20%) and Tonalide (-30%), was evidenced during treatments, together with the increase of the Galaxolide metabolite (+70%). This leads to discharges of these compounds in receiving water bodies which can be degraded by WWTP effluents. PMF presence was then assessed in an anthropized surface water ecosystem, Lake Maggiore, considering both water and sediments of the main tributaries to investigate concentrations entering the lake but also two freshwater bivalves to assess possible bioaccumulation. In waters, characterized also in terms of pH, conductivity, alkalinity, major ions and nutrients, PMFs were detected up to hundreds of ng/L especially in small rivers in which the highest values of N and P were measured. Sediment analyses followed the same degree of pollution with concentration peaks detected during summer seasons. Molluscs analysis reflected the degree of anthropic pressure present on the lake shores, highlighting two different bioaccumulation patterns in the two considered species. In all matrices, Galaxolide, its metabolite Galaxolidone and Tonalide were the most abundant compounds. From these evidences, it is clear that additional wastewaters treatments are needed to reduce discharges of synthetic compounds in aquatic systems in order to prevent aquatic ecosystems degradation from prolonged and continuous exposure to these substances.

3.10.P-Th150 The Contribution of Microflow Liquid Chromatography to the Analysis of Micropollutants and their Transformation Products in Sediments

Louise Durand, *CNRS, France*

Analytical chemistry for environmental monitoring constitutes a paradox. Indeed, it is involved in environmental protection through the monitoring of substances in a variety of matrices, such as wastewaters or sediments, while impacting the environment and human health due to toxic reagents, solvents, and energy-intensive instruments like liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). This technique is widely used in environmental analysis due to its ability to separate, identify, and quantify a wide range of micropollutants in complex matrices, even at very low concentrations. This paradox gave birth in 2013 to a new concept, called Green Analytical Chemistry (GAC) which is defined by 12 principles such as minimizing energy consumption, reducing the quantity of solvents and reagents used or miniaturizing methods.
In this context, our goal is to study the contribution of micro-flow liquid chromatography coupled with tandem mass spectrometry (µLC-MS/MS) for the analysis of ultra-traces of micropollutants (pharmaceuticals and pesticides) and their transformation products in river sediments. On the one hand, the comparison of µLC and LC concerning analytical performances will be studied. Sensitivities and matrix effects obtained with two similar methods (geometric transfer) will be compared for this purpose. On the other hand, its contribution regarding the reduction of environmental impact will be discussed and quantified with a Life Cycle Assessment (LCA).
This work represents a pioneering step towards the adoption of GAC principles by integrating miniaturized fluidic systems into analytical instrumentation. It aims to show the feasibility and relevance of using µLC-MS/MS in environmental analyses, which is marginal, to reduce the environmental impact of methods while maintaining satisfactory analytical performances. Nevertheless, initial environmental assessments indicate that solely reducing instrumental solvent usage is insufficient to significantly lower the overall environmental impact of analysis. Prioritizing sample preparation is crucial.

Disclaimer/Disclosure: This work is part of the BIOSYSMO project, funded by the European Union under the GA n°101060211. Views and opinions expressed are however those of the author(s) only and do

and not after the SUDS. Several compounds such as caffeine, scopoletin, N,N'-Diphenylguanidine, imidacloprid, tris(2-butoxyethyl)phosphate showed the same behavior. Other compounds such as N-butylbenzenesulfonamide and benzoguanamine were significantly reduced by SUDS but were detected in the SUDS samples. On the other hand, compounds such as citroflex A-4, tributyl phosphate, guanylurea and lidocaine N-oxide showed the same intensity in both sample groups. Also interesting was the finding of fenuron, a herbicide.

3.10.B.T-03 Occurrence of Organic Micropollutants and Transformation Products in Managed Groundwater Aquifer Recharge: from Surface Water Infiltration to Produced Drinking Water

Alessia Ore[1]*, Merijn Schriks*[2]*, Annemarie van Wezel*[3] *and Nora B. Sutton*[1]*, (1)Wageningen University, Netherlands, (2)Vitens N.V. Water Expertise Centrum, Netherlands, (3)University of Amsterdam, Netherlands*

Freshwater scarcity is of growing concern in industrialized countries, including the Netherlands, where groundwater is the primary source of drinking water. Recent droughts and intensive drainage have lowered Dutch groundwater tables, prompting drinking water companies and water authorities to explore reuse solutions to replenish aquifers, aiming at alleviating the pressure on natural water sources while maintaining good drinking water quantity and quality.

Managed aquifer recharge (MAR) is widely applied but concerns remain about its effect on natural groundwater quality due to the presence of organic micropollutants (OMPs) and transformation products (TPs) in the infiltrated water, as well as their fate in the environment. This study investigates the impact of MAR with surface water on a Dutch drinking water production area.

Our study assesses water quality changes along the soil passage from infiltration ponds to drinking water production by analyzing water samples of the infiltration pond, surface water, monitoring wells, and extraction wells. Using both target LC-MS and non-target UHPLC-HR-TIMS-MS analysis methods we ensure a comprehensive water quality assessment of known and unknown OMPs and TPs. Additionally, information on the environmental conditions and samples for microbial community analyses were collected.

Preliminary target analysis results indicate significant water quality improvements along the infiltration path from the pond to the closest groundwater extraction well, with removal efficiency of up to 78% of the 25 OMPs detected in the infiltrated water. A few OMPs, including pharmaceuticals (e.g., gabapentin) and pesticide TPs (e.g., dimethenamide-ESA/OA and metolachlor-ESA/OA), remain in extracted water at concentrations around or above 0.1 µg/L. Further treatment at the drinking water production plant further improved water quality. Nonetheless, some OMPs (e.g., TFA, dimethenamide- and metolachlor-ESA) remained in the finished drinking water. The NTA data treatment and interpretation (currently work in progress) will provide additional elucidation on (unknown) TPs and water quality changes along the infiltration path, also in correlation with environmental parameters.

Our research will provide novel findings for a comprehensive exposure assessment of OMPs' (including TPs) presence in water reuse scenarios. These insights can support improved decision-making, regulations, and environmental risk assessment for safer water reuse.

3.10.B.T-04 Pesticides as a Source of Trifluoroacetate (TFA) to the Environment

Finnian Freeling[1]*, Hanna Joerss*[2]*, Stefan P. J. van Leeuwen*[3]*, Juliane Hollender*[4]*, Xingang Liu*[5]*, Karsten Nodler*[1]*, Zhanyun Wang*[6]*, Daniel Zahn*[7] *and Gabriel Sigmund*[3]*, (1)TZW: DVGW-Technologiezentrum Wasser (German Water Centre), Germany, (2)Organic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (3)Environmental Technology, Wageningen University & Research (WUR), Netherlands, (4)Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (5)State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China (Mainland), (6)EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (7)Department of Environmental Analytical Chemistry, Helmholtz-Centre for Environmental Research, Germany*

Compounds containing at least one carbon-bound trifluoromethyl moiety (C-CF3) are potential precursors of the very persistent and very mobile substance trifluoroacetate (TFA). Despite their broad and increasing application, there are no comprehensive studies that have focused on the role of pesticide as a source of TFA to the (aquatic) environment. To address this research gap, the TFA formation potential from agricultural pesticide use was calculated for Europe and the contiguous USA using sales volume estimates of C-CF3-containing pesticides. In addition, spatially resolved monitoring data were used to correlate groundwater TFA concentrations with land use categories and nitrate concentrations in Germany to elucidate the influence of pesticide application on groundwater TFA concentrations. Finally, historical (1940s-2000s) and recent wine samples from Europe were analyzed to determine long-term temporal trends of TFA in wine. Pesticides with TFA formation potential were found to vary in type and use profile between regions, with the estimated maximum TFA emissions ranging from 0 to 83?kg/(km² × year). Based on a molar TFA yield of 100%, a total of 3,200 t and 5,000 t of TFA could be emitted from agricultural pesticide use in Europe and the USA, respectively. Compound-specific TFA formation rates and field studies are needed to characterize the formation of TFA from precursors under environmental conditions and to rank and prioritize pesticides of concern for potential (regulatory) action. Our evaluations revealed a significantly ($p < 0.001$) higher average TFA concentration in the samples of groundwater bodies located in agricultural areas (mean = 1.59 µg/L; median = 1.1 µg/L; n = 411; proportion of agricultural land use >50%) than in areas with lower degrees of agricultural activity. Moreover, the average TFA concentration in the groundwater samples containing nitrate concentrations >25 mg/L (mean:?1.84 µg/L; median:?1.30 µg/L; n = 556) was significantly ($p < 0.0001$) higher than in samples containing ?25 mg/L of nitrate (mean = 0.92 µg/L; median = 0.53 µg/L; n = 1021). This strongly suggests that agricultural land use is associated with elevated TFA concentrations in the aquatic system. The preliminary analysis of wine samples showed a strong positive temporal trend in TFA concentration. This is another indication of the substantial increase of anthropogenic emissions of various TFA precursors, including C-CF3 containing pesticides, over the last decades.

3.10.P-Th145 PMTfocus: Tracing Persistent, Mobile, and Toxic Substances from Water Resources to Human Exposure – An Emerging Environmental and Public Health Challenge

Julieta Sturla Lompre[1], *Geoffroy Duporte*[1], *Clementine Gavalon*[1], *Teo Ferreux*[1], *Eleonore Resongles*[1], *Chirstelle Batiot-Guilhe*[1], *Nassim Ait Mouheb*[2], *Fethi Lachaal*[3], *Helene Fenet*[1], *Frederique Courant*[1] *and Elena Gomez*[1], *(1)HydroSciences Montpellier, IRD, CNRS, University of Montpellier, France, (2)UMR G-EAU - Gestion de l'Eau, Acteurs, Usages; INRAE - Institut National de Recherche pour l Agriculture, l Alimentation et l Environnement, France, (3)Georesources Laboratory, Water Research and Technology Centre of Borj Cedria, Tunisia*

Persistent, mobile, and toxic (PMT) substances in water systems represent a significant environmental and public health challenge. Their chemical properties (resistance to natural degradation and conventional treatment methods) enable their accumulation and dispersion in groundwater, surface water, and drinking water. Recognizing their threat, the European Union classified PMT and vPvM substances as hazard classes under the Classification, Labelling and Packaging of Chemicals Regulation in 2021, in alignment with the EU Drinking Water and Groundwater Directives. The interdisciplinary PMTfocus project investigates PMTs across diverse environments, assessing their occurrence, behavior, and pathways to human exposure.

Samples were collected from four strategic locations: Lez Spring, France (low urban pressure reference); Gherdaïa, Algeria (wastewater-impacted aquifers); Tunisia (artificial recharge with treated wastewater); and Oruro, Bolivia (urban and mining pollution). Analytical methods combined targeted LC-HRMS and non-targeted screening using Solid Phase Extraction (HLB and WAX cartridges). Targeted analyses quantified 51 PM/PMT compounds, including carbamazepine, detected in Tunisia (up to 409.1 ng/L), Bolivia (70.7 ng/L), and Algeria (119.5 ng/L), but below detection limits in Lez Spring. Non-targeted screening identified hundreds of compounds in Tunisian groundwater, 35 of which were confirmed (with analytical standards) as PM/PMTs, including carbamazepine metabolites.

PM/PMTs, including pharmaceuticals, pesticides, industrial chemicals, and personal care products, were detected at all sites. Anthropogenic pressures, particularly urbanization and inadequate wastewater management in Bolivia and Algeria, rise water contamination. The dual approach of targeted and non-targeted analyses ensures comprehensive monitoring of known and emerging contaminants, providing insights into their persistence, behavior, and risks in aquatic systems.

Correlating water analysis with urinary biomarkers will evaluate human exposure, linking environmental contamination to health risks. Results underscore the urgent need for regulatory improvements to mitigate PMT impacts, particularly in regions practicing water reuse or relying on untreated sources. The PMTfocus project contributes to advancing sustainable water management practices, protecting ecosystems and public health globally.

3.10.P-Th146 From Wastewater to Rivers and Soils – Particle-Associated Emissions of Quaternary Ammonium Compounds

Sophie Lennartz[1], *Jan Koschorreck*[2], *Collin Weber*[3], *Bernd Gockener*[4], *Karlheinz Weinfurtner*[4], *Andrea Frohbose-Korner*[2], *Jan Siemens*[5], *Sanjana Balachandran*[6], *Stefanie P. Glaeser*[6] *and Ines Mulder*[7], *(1)Institute of Soil Science and Soil Conservation, Justus-Liebig University Giessen, Germany, (2)German Environment Agency (UBA), Germany, (3)Institute of Applied Geoscience, Technical University of Darmstadt, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Institute of Soil Science and Soil Conservation, Justus-Liebig-University Giessen, Germany, (6)Institute of Applied Microbiology, Justus-Liebig-University Giessen, Germany, (7)Institute of*

Geography, Ruhr-University Bochum, Germany
Quaternary ammonium compounds (QACs) are antimicrobials and cationic surfactants discharged into the environment via municipal, industrial or livestock wastewater. Recently, concerns about their aquatic ecotoxicity and potential contribution to selection and spread antimicrobial resistance have increased, especially since the SARS-CoV-2 pandemic. Although wastewater treatment plants (WWTPs) largely remove QACs from the aqueous wastewater phase, we hypothesized that due to their strong surface affinity, QACs will partition primarily to suspended solids and enter the downstream environment associated with discharged particles. In wastewater-impacted rivers, QACs are expected to be transported in the suspended particulate matter (SPM) a vector for their sedimentation and accumulation in floodplain soils. Moreover, we hypothesized that the concentrations and ecotoxicological risks of QACs in SPM increased during the SARS-CoV-2 pandemic due to the drastic surge in disinfectant use.
We measured the distribution of QACs between the solid and liquid phases of activated sludge and wastewater of three German WWTPs. Concentrations of QACs were determined in SPM collected by the German Environmental Specimen Bank from three German rivers with varying wastewater shares between 2006-2021, and across different depths of floodplain soils. Using targeted multi-residue HPLC-MS/MS analysis, 30 different QACs were quantified including alkyltrimethyl, benzylalkyl and dialkyldimethyl ammonium compounds of varying chain lengths. Ecotoxicological risks in SPM and soil were estimated based on predicted no-effect concentrations and minimal inhibitory concentrations.
Increasing with their hydrophobicity, QACs showed preferential particle-association in WWTPs and were found in all analyzed SPM samples with concentrations up to mg kg-1. High spatiotemporal variability suggests the wastewater share of rivers and seasonal dynamics as important drivers of QAC concentrations in SPM, exceeding the presumed imprint of the pandemic. QAC homologue distributions in the upper layers of floodplain soils closely resembled those in SPM, confirming the importance of particle-associated transport in determining the environmental distribution of QACs. For both SPM and soils, ecotoxicological risks cannot be excluded. This highlights QACs as contaminants of emerging concerns at the aquatic-terrestrial interface.

3.10.P-Th173 Water Treatment Processes: Identification and Quantitation of Transformation Products Formed in Test Systems

***Peter Crick**, Ivan Strepponi and Neil Robinson, Innovative Environmental Services (IES) Ltd, Switzerland*
A recent European Food Safety Authority (EFSA) guidance document describes experimental methods for the identification of transformation products of active substances and their metabolites formed during water treatment processes. These processes include chlorination, chloramination, oxidation, ozonolysis, and ultraviolet light (UV) treatment. Here, we present results of experimental implementation of these processes carried out with a series of test substances.
Experiments were carried out in a standard water with addition of organic carbon obtained from the Suwannee River as defined in the guidance document. Chlorination with sodium hypochlorite was carried out at three different pH levels (6.5, 7.5, and 8.5). Monochloramine was prepared from sodium hypochlorite and ammonium chloride to carry out the chloramination experiments. For the oxidation process, an aqueous chlorine dioxide solution was obtained by addition of sulfuric acid to a solution of sodium chlorite.
In all of these experiments, the concentration of reagent in the test system was determined using the colorimetric N,N-diethyl-p-phenylenediamine (DPD) method to ensure that the requirements of the guidance document were met.
Ozonolysis was carried out by treating the test substances with a freshly prepared solution of ozone in water, while the UV process was performed in an irradiation chamber fitted with a medium pressure UV lamp allowing control of the UV dose to the test solution.
Liquid chromatography coupled with mass spectrometry (LC/MS) was used to analyse the test substances and transformation products formed in these processes. Identification of the transformation products was carried out using high resolution-accurate mass spectrometry (HRAM) with data analysis performed using a non-target screening workflow, while quantitative analysis was performed by HRAM or multiple reaction monitoring (MRM) on a triple quadrupole mass spectrometer.
The results of these experiments are presented, with a discussion of challenges and suggested approaches to fulfilling the requirements of the guidance document.

3.10.P Analysis, Assessment and Management of Contaminants of Emerging Concern and Their Transformation Products

3.10.P-Th143 The Effect of Lignin Derivative Addition as Co-Substrate on DOC Dynamics and OMP Biodegradation in Drinking Water Aquifers

Silvana Quiton-Tapia, *Giulia Kleijwegt and Nora B. Sutton, Environmental Technology, Wageningen University & Research (WUR), Netherlands*

This research explores the effects of adding a lignin derivative, 4-HBA, on DOC dynamics and OMP biodegradation in drinking water aquifers. Conducted at five different aquifer locations with varied water residence times (WRTs), the study involved two sets of batch experiments per location one with natural DOC and another with added 4-HBA over a 90-day aerobic incubation period. Although initial DOC quality showed no spatial differences, temporal EEM analyses indicated a decline in DOC fluorescence, suggesting a long-term biodegradation of humic substances.

While the addition of 4-HBA initially boosted microbial activity, marked by significant changes in the fluorescence of microbial byproducts, this enhancement did not lead to improved OMP biodegradation. Instead, the presence of 4-HBA appeared to inhibit biodegradation relative to batches with only natural DOC. This inhibitory effect could be attributed to several factors, including potential carbon catabolite repression, alterations in microbial community composition, and diauxic growth patterns that might extend the time needed for microbes to adapt to new substrates. These findings indicate that although 4-HBA serves as an easily consumable carbon source, its incorporation may complicate the microbial processing of OMPs.

In summary, the addition of 4-HBA, while stimulating initial microbial activity, has an inhibitory impact on OMP biodegradation. This underscores the complexities of introducing external carbon sources into aquifer systems and emphasizes the importance of a nuanced understanding of microbial and chemical dynamics for effective bioremediation strategies.

Disclaimer/Disclosure: Dutch Research Council (NOWO) Talent Programme Vidi scheme Grant Number 18901.

3.10.P-Th144 Investigating the Presence of Emerging Contaminants in GB Honey

John Nightingale[1], *Laura Carter*[2], *Narmin Garazade*[2], *Ben Woodcock*[3] *and Jennifer Shelton*[3], *(1)University of Leeds, Leeds, United Kingdom, (2)The University of Leeds, United Kingdom, (3)CEH, United Kingdom*

The application of animal manures and biosolids is a well-established practice for waste disposal and soil fertility improvement. However, these practices can inadvertently release emerging contaminants into terrestrial and aquatic environments. Some of these contaminants, including human and veterinary pharmaceuticals, can persist in soils and accumulate in crops, although plant uptake is influenced by environmental parameters and the physiochemical properties of the chemical. Research on the translocation of these contaminants to pollen and nectar, and ultimately to beehives, is limited. It remains unclear whether emerging contaminants, such as human and veterinary pharmaceuticals, are accumulating in hives and potentially exerting toxicological effects as a result of these practices, this gap in our knowledge is surprising, especially given the increasing use of biosolids, which are well-known to be contaminated with a range of pharmaceuticals. Therefore a pilot study was conducted on honey samples collected from sites with ?70% arable land use within a 2 km radius (n = 30 sites). A modified QuEChERS extraction technique coupled with Non-target screening (HRMS) was employed and was capable of identifying four main contaminant groups, these were human pharmaceuticals (50%), industrial contaminants (33.3%), agri-chemicals (16.7%), and veterinary pharmaceuticals (0.8%) in an array of the samples. The presence of the fungicide azoxystrobin was expected, but, to the best of our knowledge, this is the first report of pharmaceuticals such as ibuprofen, flurandrenolide, alprenolol, propranolol, and aspirin in honey samples. Semi-quantitative analysis revealed concentrations of human pharmaceuticals ranging from 0.015 to 0.91 µg/g (dw). The toxicological effects of these concentrations on human and forager health remain unclear. Therefore this research demonstrates an appropriate means to target chemicals of concern in agri-ecosystems but also to provide assessments of risk to bee health. These findings are substantial and reiterate the need for a better understanding of the risks and factors contributing to declining bee populations. They warrant urgent attention and further investigation.

3.10.P-Th145 PMTfocus: Tracing Persistent, Mobile, and Toxic Substances from Water Resources to Human Exposure – An Emerging Environmental and Public Health Challenge

Julieta Sturla Lompre[1], *Geoffroy Duporte*[1], *Clementine Gavalon*[1], *Teo Ferreux*[1], *Eleonore Resongles*[1], *Chirstelle Batiot-Guilhe*[1], *Nassim Ait Mouheb*[2], *Fethi Lachaal*[3], *Helene Fenet*[1], *Frederique Courant*[1] *and Elena Gomez*[1], *(1)HydroSciences Montpellier, IRD, CNRS, University of Montpellier, France, (2)UMR G-EAU - Gestion de l'Eau, Acteurs, Usages; INRAE - Institut National de Recherche pour l Agriculture, l Alimentation et l Environnement, France, (3)Georesources Laboratory, Water Research and Technology*

Centre of Borj Cedria, Tunisia
Persistent, mobile, and toxic (PMT) substances in water systems represent a significant environmental and public health challenge. Their chemical properties (resistance to natural degradation and conventional treatment methods) enable their accumulation and dispersion in groundwater, surface water, and drinking water. Recognizing their threat, the European Union classified PMT and vPvM substances as hazard classes under the Classification, Labelling and Packaging of Chemicals Regulation in 2021, in alignment with the EU Drinking Water and Groundwater Directives. The interdisciplinary PMTfocus project investigates PMTs across diverse environments, assessing their occurrence, behavior, and pathways to human exposure.
Samples were collected from four strategic locations: Lez Spring, France (low urban pressure reference); Gherdaïa, Algeria (wastewater-impacted aquifers); Tunisia (artificial recharge with treated wastewater); and Oruro, Bolivia (urban and mining pollution). Analytical methods combined targeted LC-HRMS and non-targeted screening using Solid Phase Extraction (HLB and WAX cartridges). Targeted analyses quantified 51 PM/PMT compounds, including carbamazepine, detected in Tunisia (up to 409.1 ng/L), Bolivia (70.7 ng/L), and Algeria (119.5 ng/L), but below detection limits in Lez Spring. Non-targeted screening identified hundreds of compounds in Tunisian groundwater, 35 of which were confirmed (with analytical standards) as PM/PMTs, including carbamazepine metabolites.
PM/PMTs, including pharmaceuticals, pesticides, industrial chemicals, and personal care products, were detected at all sites. Anthropogenic pressures, particularly urbanization and inadequate wastewater management in Bolivia and Algeria, rise water contamination. The dual approach of targeted and non-targeted analyses ensures comprehensive monitoring of known and emerging contaminants, providing insights into their persistence, behavior, and risks in aquatic systems.
Correlating water analysis with urinary biomarkers will evaluate human exposure, linking environmental contamination to health risks. Results underscore the urgent need for regulatory improvements to mitigate PMT impacts, particularly in regions practicing water reuse or relying on untreated sources. The PMTfocus project contributes to advancing sustainable water management practices, protecting ecosystems and public health globally.

3.10.P-Th146 From Wastewater to Rivers and Soils – Particle-Associated Emissions of Quaternary Ammonium Compounds

Sophie Lennartz[1], *Jan Koschorreck*[2], *Collin Weber*[3], *Bernd Gockener*[4], *Karlheinz Weinfurtner*[4], *Andrea Frohbose-Korner*[2], *Jan Siemens*[5], *Sanjana Balachandran*[6], *Stefanie P. Glaeser*[6] *and Ines Mulder*[7], *(1)Institute of Soil Science and Soil Conservation, Justus-Liebig University Giessen, Germany, (2)German Environment Agency (UBA), Germany, (3)Institute of Applied Geoscience, Technical University of Darmstadt, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Institute of Soil Science and Soil Conservation, Justus-Liebig-University Giessen, Germany, (6)Institute of Applied Microbiology, Justus-Liebig-University Giessen, Germany, (7)Institute of Geography, Ruhr-University Bochum, Germany*
Quaternary ammonium compounds (QACs) are antimicrobials and cationic surfactants discharged into the environment via municipal, industrial or livestock wastewater. Recently, concerns about their aquatic ecotoxicity and potential contribution to selection and spread antimicrobial resistance have increased, especially since the SARS-CoV-2 pandemic. Although wastewater treatment plants (WWTPs) largely remove QACs from the aqueous wastewater phase, we hypothesized that due to their strong surface affinity, QACs will partition primarily to suspended solids and enter the downstream environment associated with discharged particles. In wastewater-impacted rivers, QACs are expected to be transported in the suspended particulate matter (SPM) a vector for their sedimentation and accumulation in floodplain soils. Moreover, we hypothesized that the concentrations and ecotoxicological risks of QACs in SPM increased during the SARS-CoV-2 pandemic due to the drastic surge in disinfectant use.
We measured the distribution of QACs between the solid and liquid phases of activated sludge and wastewater of three German WWTPs. Concentrations of QACs were determined in SPM collected by the German Environmental Specimen Bank from three German rivers with varying wastewater shares between 2006-2021, and across different depths of floodplain soils. Using targeted multi-residue HPLC-MS/MS analysis, 30 different QACs were quantified including alkyltrimethyl, benzylalkyl and dialkyldimethyl ammonium compounds of varying chain lengths. Ecotoxicological risks in SPM and soil were estimated based on predicted no-effect concentrations and minimal inhibitory concentrations. Increasing with their hydrophobicity, QACs showed preferential particle-association in WWTPs and were found in all analyzed SPM samples with concentrations up to mg kg-1. High spatiotemporal variability suggests the wastewater share of rivers and seasonal dynamics as important drivers of QAC concentrations in SPM, exceeding the presumed imprint of the pandemic. QAC homologue distributions in the upper layers of floodplain soils closely resembled those in SPM, confirming the importance of particle-

associated transport in determining the environmental distribution of QACs. For both SPM and soils, ecotoxicological risks cannot be excluded. This highlights QACs as contaminants of emerging concerns at the aquatic-terrestrial interface.

Disclaimer/Disclosure: This study was funded by the German Research Foundation (DFG) project number 458460392.

3.10.P-Th147 Effect-Based Strategy for Identification and Assessment of Potential Health Effects of Hazardous Organic Chemicals in Vehicles

Nathalie Struwe[1]*, Ulrika Eriksson*[2]*, Maria Bernander*[3] *and Maria Larsson*[4]*, (1)Örebro University, Örebro, Sweden, (2)Örebro University, Sweden, (3)Volvo Cars AB, Sweden, (4)Örebro University, Sweden*

The car cabin is an indoor environment of interest due to the high material-to-space ratio and the high temperatures that can be reached, especially during a sunny summer s day. Plastic materials of various sources and composition is the predominant material inside vehicles, which is concerning due to the lack of information about what potential hazardous chemicals may contain. In this project, active air sampling was performed in a stand-still car at 25°C vs 65°C in a climate chamber. In addition, solvent and heat extraction of plastic materials, used in vehicles, was performed separately to investigate the sources of the chemicals and biological effects seen in the air samples.

The air samples were chemically and biologically characterised using GC/LRMS and different in vitro Chemical Activated LUciferase gene Expression (CALUX®) bioreporter assays. The chemical target method included different groups of polycyclic aromatic hydrocarbons e.g., native PAHs, alkyl-PAHs and oxy-PAHs. To further identify chemicals in the air and materials, suspect screening using high-resolution GC/HRMS and LC/HRMS will be performed on the samples. Pesticides, flame retardants, plasticisers and other plastic associated chemicals will be a part of the suspect list. The in vitro bioassays used for analysing air and material samples are ER-, anti-AR, DR- and Nrf2-CALUX®. Additionally, the plastic materials will be analysed for the presence of PFAS compounds using a LC/MS method targeting PFAS compounds, and CIC measuring extractable organic fluorine.

Preliminary results from the climate chamber shows that the highest activities can be seen in the bioassays when the temperature is increased to 65°C, and that a decrease in activity can be seen over the following days when heating up the same car repeatedly. This suggests that the release of semi-volatile compounds from materials will decrease over time when the vehicle is being heated. Only a few extractions of plastic materials have been performed at this time. Results from these show that the materials contain compounds which are active in both DR- and ER-CALUX.

The results from this study will increase the knowledge about the identity, sources and the combination effects of chemicals present in the car cabin environment as well as appropriate methods to screen for the chemicals.

3.10.P-Th148 Seasonal Variation of Contaminants of Emerging Concern in Swedish Landfill Leachate and its Recipient: A Case Study

Tsz Yung Wong[1]*, Alberto Celma*[2] *and Oksana Golovko*[3]*, (1)Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Swedish University of Agricultural Sciences (SLU), Sweden*

Landfill leachate is an important point source of contaminants of emerging concerns (CECs) in fresh water systems. There are over 350 active landfills in Sweden, producing 8 ~12 million m3 of leachate each year. This study conducted non-target screening (NTS) and suspect screening (SS) using ultra high-performance liquid chromatography coupled with high resolution mass spectrometry (UHPLC-HRMS) to identify the CECs in Swedish landfill leachate. The aim of this research is to map the occurrence of CECs in Swedish landfill leachate and provide insights into their seasonal changes.

In our study, 24-hour composite samples of untreated, treated leachate and recipient upstream, and downstream (named UL, TL, RU, and RD) were collected from a municipal landfill in Sweden in September 2023, January, March, and June 2024 by time-integrated autosamplers. Extraction was performed on multi-layer solid phase extraction (SPE) cartridges in order to capture a wide spectrum of CECs. Preliminarily, 74 CECs were identified in all the landfill leachate samples, including 35 industrial chemicals, 21 pharmaceuticals, 10 PFASs, and 9 pesticides. Winter had the highest number of detected CECs and the highest detection frequency among all seasons. 49 CECs were detected in UL, TL, and RD across all seasons, and 16 of them were also detected in RU in either or all seasons. Some industrial chemicals (e.g., tripropyl phosphate and dibutyl phthalate) showed lower detection frequencies in warmer seasons (summer and/or autumn), while some pharmaceuticals, such as bicalutamide, losartan, and lamotrigine, had lower detection frequency in spring and summer. Possible reasons for the seasonal change in the occurrence of CECs can be: (1) increased removal efficiency at higher temperature; (2) the amount of produced leachate and the concentration of CECs can be influenced by precipitation; (3) the reception of external waste may vary depending on time. These findings highlight the need for seasonal monitoring of CECs and adjustments of leachate treatment strategies to manage the diverse presence of CECs in landfill leachate throughout the year.

3.10.P-Th149 Synthetic Musks: From Wastewaters to Surface Water Ecosystems

Stefano Tasselli *and Licia Guzzella, CNR-IRSA, Italy*

Synthetic musks are compounds incorporated in detergents, perfumes, and house-cleaning products. Within them there are Galaxolide, its metabolite Galaxolidone, Tonalide, Celestolide and Phantolide. They are released every day in large amounts into sewage systems and discharged in aquatic ecosystems through wastewater treatment plant (WWTP) effluents. The prolonged exposure of aquatic environments to the continuous discharge of PMFs is raising many concerns about their possible chronic toxicity and future impacts. Data regarding PMFs in Italy are very scarce even if this is the EU-Member State with the highest consumption of these chemicals. In this study, we sampled wastewater in four different stations of a conventional WWTP with activated sludges to understand fate and behaviour of PMFs during treatments. PMFs were measured in all stations up to the µg/L order of magnitude. Biotransformation and adsorption were the two processes driving the fate of these contaminants during treatments. High and stable musk concentrations were measured in activated sludges. Only a slight reduction of the main PMFs, Galaxolide (-20%) and Tonalide (-30%), was evidenced during treatments, together with the increase of the Galaxolide metabolite (+70%). This leads to discharges of these compounds in receiving water bodies which can be degraded by WWTP effluents. PMF presence was then assessed in an anthropized surface water ecosystem, Lake Maggiore, considering both water and sediments of the main tributaries to investigate concentrations entering the lake but also two freshwater bivalves to assess possible bioaccumulation. In waters, characterized also in terms of pH, conductivity, alkalinity, major ions and nutrients, PMFs were detected up to hundreds of ng/L especially in small rivers in which the highest values of N and P were measured. Sediment analyses followed the same degree of pollution with concentration peaks detected during summer seasons. Molluscs analysis reflected the degree of anthropic pressure present on the lake shores, highlighting two different bioaccumulation patterns in the two considered species. In all matrices, Galaxolide, its metabolite Galaxolidone and Tonalide were the most abundant compounds. From these evidences, it is clear that additional wastewaters treatments are needed to reduce discharges of synthetic compounds in aquatic systems in order to prevent aquatic ecosystems degradation from prolonged and continuous exposure to these substances.

3.10.P-Th150 The Contribution of Microflow Liquid Chromatography to the Analysis of Micropollutants and their Transformation Products in Sediments

Louise Durand*, CNRS, France*

Analytical chemistry for environmental monitoring constitutes a paradox. Indeed, it is involved in environmental protection through the monitoring of substances in a variety of matrices, such as wastewaters or sediments, while impacting the environment and human health due to toxic reagents, solvents, and energy-intensive instruments like liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). This technique is widely used in environmental analysis due to its ability to separate, identify, and quantify a wide range of micropollutants in complex matrices, even at very low concentrations. This paradox gave birth in 2013 to a new concept, called Green Analytical Chemistry (GAC) which is defined by 12 principles such as minimizing energy consumption, reducing the quantity of solvents and reagents used or miniaturizing methods.

In this context, our goal is to study the contribution of micro-flow liquid chromatography coupled with tandem mass spectrometry (µLC-MS/MS) for the analysis of ultra-traces of micropollutants (pharmaceuticals and pesticides) and their transformation products in river sediments. On the one hand, the comparison of µLC and LC concerning analytical performances will be studied. Sensitivities and matrix effects obtained with two similar methods (geometric transfer) will be compared for this purpose. On the other hand, its contribution regarding the reduction of environmental impact will be discussed and quantified with a Life Cycle Assessment (LCA).

This work represents a pioneering step towards the adoption of GAC principles by integrating miniaturized fluidic systems into analytical instrumentation. It aims to show the feasibility and relevance of using µLC-MS/MS in environmental analyses, which is marginal, to reduce the environmental impact of methods while maintaining satisfactory analytical performances. Nevertheless, initial environmental assessments indicate that solely reducing instrumental solvent usage is insufficient to significantly lower the overall environmental impact of analysis. Prioritizing sample preparation is crucial.

Disclaimer/Disclosure: This work is part of the BIOSYSMO project, funded by the European Union under the GA n°101060211. 3.10.P-Th151 In Silico Tentative Identification of Pharmaceutical Biotransformation Products in Receiving Water

Olukemi Oloyede[1]*, Leon Barron*[1]*, Russell Davenport*[2] *and Irene Bramke*[3]*, (1)Environmental Research Group, Imperial College London, United Kingdom, (2)Newcastle University, United Kingdom, (3)AstraZeneca, United Kingdom*

Pharmaceuticals and their biotransformation products (BPs) are not monitored routinely in river water. A European Commission report in 2020 details a shortlist of several anti-microbial pharmaceuticals in the next EU Water Framework Directive (WFD) watch list to be closely monitored in surface waters. Antimicrobials such as sulfamethoxazole and clotrimazole are pharmaceuticals that are of particular concern, increasingly being detected in surface water and soils across Europe and are toxic and mobile in the aquatic environment.

This work aims to fill a research gap in the lack of predictive understanding of pharmaceutical biotransformation (BT) and degradation; high resolution analytical methods have been developed for in silico ID of pharmaceuticals and their BPs but do not provide information about the mechanisms of BT. It will determine the BT rate of prioritised compounds (including those in the EU WFD watch list) and investigate their BT pathways in river water. The microbial and chemical data derived from these studies will be used to create a model that can help predict the BT of pharmaceuticals in river water.

Suspect screening in HRMS analysis has been used to detect and identify APIs and their BPs in wastewater impacted rivers and the use of online predictive tools such as BioTransformer 3.0 (BT 3.0) and EAWAG BBD/PPS have been used to predict BPs that could be formed in environmental microbial transformation (EMT). Structures of these predicted BPs are compared with spectral libraries and machine learning based retention time (tR) prediction models to shortlist suspect pharmaceuticals. 36 out of 900 BPs predicted using BT 3.0 and EAWAG-BBD/PPS were found in HRMS data at the most wastewater impacted site, as well as 22 BPs in unspiked riverwater and 66 BPs in spiked riverwater at that same site. Trimethoprim, sulfamethoxazole, citalopram, propranolol and venlafaxine (observed in WFD watchlist) have BPs that have lower PNEC values than their parent compounds in freshwater, which may allude to higher environmental risk in water.

Future work includes the application of the tR model to BPs of these compounds in HRMS data, as well as assessing identified BPs in terms of environmental risk e.g., PNEC. Biological analytical methods, e.g., qPCR and biological predictive databases e.g., PathPred, BRENDA will also be conducted to observe resident enzymes and/or microbial communities that may be involved in the observed BTs of these specific compounds.

3.10.P-Th152 Temporal Characterization of Progestins Accumulation in Three Different Estuarine Systems Along the Portuguese Coast

Patricia Cardoso[1]*, Hugo Morais*[1]*, Vania Encarnacao Amorim*[1]*, Antonio Silva Ferreira*[2]*, Miguel A. Pardal*[3] *and Catarina Cruzeiro*[4]*, (1)CIIMAR, Portugal, (2)Universidade Catolica Portuguesa, Portugal, (3)CFE Centre for Functional Ecology, University of Coimbra, Portugal, (4)FEUP, University of Porto, Portugal*

Synthetic progestins are micropollutants of special concern, due to their growing use in human and veterinary therapies and their risks to aquatic life. Currently, there is a lack of environmental information on these compounds, worldwide. The main objective of this work was to characterize the levels of the most consumed progestins in Portugal. For that, Ria de Aveiro, Tagus estuary and Ria Formosa were sampled in a temporal perspective to evaluate levels of drospirenone (DRO), desogestrel (DSG), gestodene (GST) and levonorgestrel (LNG) in surface water samples and macrobenthic organisms (bivalve, polychaete, and crustacean). Regarding surface waters, drospirenone and desogestrel were the most abundant progestins. In the North of Portugal, DSG was the most abundant (Aveiro: 193.9 ng L-1, summer), while DRO was more representative in the South (Tagus: 178.9 ng L-1; Formosa: 125.7 ng L-1), also in summer. These spatial differences can be associated with the hydrodynamics of each estuarine system as well as the distinct population and tourist levels associated with each site.

Concerning the biological matrices, progestins were only quantifiable for the crustacean. Values were generally low, peaking with drospirenone values in Ria de Aveiro (1.33 ± 0.26 ng/g ww) and Tagus estuary (1.42 ± 0.55 ng/g ww), while Ria Formosa exhibited the lowest progestin concentrations (< 1 ng/g ww).

In conclusion, it is essential to maintain ongoing monitoring of aquatic systems, particularly regarding progestin levels, not only in surface waters but also in other matrices such as sediments and biota. This will enhance our understanding of the true impact of these compounds and provide critical information to support the development of regulations aimed at controlling hormone levels in the environment.

PG Cardoso (IF/01506/2014) was supported by FCT investigator contract, subsidized by the European Social Fund and MCTES (Portuguese Ministry of Science, Technology and Higher Education), through the POPH (Human Potential Operational Program) and Hugo Morais by a FCT PhD grant (SFRH/BD/139762/2018). This research was also supported by national funds through FCT Foundation for Science and Technology within the scope of UIDB/ 04423/2020 and UIDP/04423/2020. We would like to thank all the colleagues that helped during the experiment.

3.10.P-Th153 Pharmaceutical Removal in Batch Anaerobic Wastewater Treatment: Ecotoxicological Impacts on Cladocerans as Bioindicators

Allan Pretti Ogura[1]*, Vinicius Silveira Leite*[2]*, Matheus Dias Rezende*[2]*, Matheus Neves de Araujo*[1]*, Elis Watanabe Nogueira*[1] *and Marcelo Zaiat*[1]*, (1)Laboratory of Biological Processes, University of São Paulo, Brazil, (2)University of São Paulo, Brazil*

Pharmaceuticals can cause toxic effects on various aquatic organisms and, therefore, they must be removed in wastewater treatment plants. Anaerobic bioreactors have shown promise in degrading these compounds, particularly during the acidogenic phase. This study aimed to evaluate the ecotoxicity of synthetic effluents before and after treatment in batch anaerobic bioreactors. The treatment process involved two scenarios: one with and one without the inoculation of eight target compounds (acetaminophen, atenolol, caffeine, carbamazepine, diclofenac, ibuprofen, naproxen, and propranolol). Treatment efficiency was assessed using two species of cladocerans, namely Ceriodaphnia silvestrii and Daphnia similis. Both species were cultured following Brazilian standards (ABNT NBR 13373/2022 and 12713/2022). Acute ecotoxicity assays were performed with effluent samples at 100% and 50% concentrations (10 mL for C. silvestrii and 15 mL for D. similis), using four replicates with five neonate organisms per test. The assays lasted 48 h at 25°C for C. silvestrii and 20°C for D. similis, under artificial light (100 lx) and controlled photoperiods (12h: 12 h for C. silvestrii and 16h: 8 h for D. similis). Validation was achieved when control samples exhibited less than 20% immobility, and data was compared by Analysis of Variance (ANOVA, with 95% confidence level). Despite the reduction in pharmaceuticals concentrations in effluents, C. silvestrii had significant immobility when exposed to 50% and 100% samples, likely due to the high salinity of synthetic wastewater, reflecting this species' sensitivity to such conditions. For D. similis, organisms remained mostly mobile at 50%, with no significant differences observed between effluents with and without pharmaceuticals ($p > 0.05$). However, at 100%, samples with pharmaceuticals were more toxic, with a mobility of 75±5%, compared to 47±3% in samples without these compounds. Despite high effect concentrations reported for individual compounds (generally in the order of mg/L), factors such as compound mixtures and elevated salinity may contribute to the overall toxicity of treated samples. Even after the removal of pharmaceuticals, their transformation products (TPs) may still pose a toxic threat. The results reinforce the necessity of ecotoxicity assessments for wastewater effluents, particularly considering the complexity of wastewater monitoring and the potential risks posed by pharmaceutical mixtures and their by-products.

Disclaimer/Disclosure: This work was supported by the São Paulo Research Foundation (FAPESP) and the Basic Sanitation Company of the State of São Paulo (Sabesp). A.P.O. and E.W.N. have FAPESP postdoctoral grants (Process 2021/14789-1 and 2023/10489-9, respectively). M.N.A. has a FAPESP Ph.D. scholarship (2022/01945-8). V.S.L. and M.D.R. have undergraduate FAPESP scholarships (Process 2023/02569-2 and 2024/01815-2, respectively).

3.10.P-Th154 Quantification and Environmental Fate of Pharmaceuticals and Personal Care Products Across the Soil and Water Systems of Delhi: Insights from Batch Experiments

Dileep Singh *and Smriti Gupta, Indian Institute of Technology, Roorkee, India*

Emerging contaminants such as pharmaceuticals and personal care products (PPCPs) pose significant ecological and health risks due to their persistence, bioactivity, and potential transformation into toxic metabolites. The National Capital Region (NCR) of Delhi, India intersected by the heavily polluted Yamuna River represents a critical case study for understanding the environmental behavior of PPCPs, as the region is impacted by untreated wastewater and industrial effluents.

This study focuses on the analysis and fate of 32 PPCPs spanning diverse classes, including antibiotics, hormones and endocrine disruptors, analgesics and non-steroidal anti-inflammatory drugs(NSAIDs), anti-allergens, anti-epileptics, stimulants, beta-blockers, lipid regulators, antibacterials, and artificial sweeteners. A robust and validated liquid chromatography-mass spectrometry (LC-MS) method has been developed for precise quantification of these compounds in soil, groundwater, and surface water matrices. In addition, transformation products and metabolites of the targeted compounds will be screened using Quadrupole Time-of-Flight (Q-TOF) mass spectrometry.
To understand the environmental behavior of PPCPs, systematic batch experiments will be conducted to investigate sorption and desorption kinetics, as well as isotherms, in soils from the study region. These experiments provide critical insights into the mobility and bioavailability of PPCPs, highlighting their potential for groundwater contamination. Furthermore, aerobic and anaerobic soil incubation studies will be performed to evaluate the degradation behavior of selected PPCPs under different environmental conditions. For compounds exhibiting significant degradation, Q-TOF will be used to identify transformation products generated under these environmental conditions.
The quantification of PPCPs across the NCR region in soil, groundwater, and surface water will provide critical insights into their spatial distribution, persistence, and transformation pathways. This research will advance our understanding of PPCP behavior in aquatic and terrestrial systems and offer actionable insights for mitigating environmental and health risks while contributing to improved pollution management strategies.

3.10.P-Th155 Impact of Variable Parameters on the Formation of Possible Transformation Products during Drinking Water Treatment Simulation

Felix Beyer *and Alexander Roth, Eurofins Agroscience Services EcoChem GmbH, Germany*

Drinking water is prepared form raw water abstracted from environmental sources. Various drinking water treatment techniques need to be applied to achieve a desired level of disinfection. The raw water often contains plant protection products and biocides from various sources such as agriculture and urban infrastructure. Consequently, those chemicals are exposed to disinfection treatments potentially leading to formation of transformation products (TPs), which might not be monitored and could possess toxic properties.
The aim of the Guidance document on the impact of water treatment processes on residues of active substances or their metabolites in water abstracted for the production of drinking water , published by EFSA (2023), is to provide a comprehensive account of experiments that simulate potential drinking water treatments and assess the resulting TPs. The document specifies minimum or maximum values for parameters, e.g., the ratio of the treatment reagent to the active substance or reaction times for the various treatments. On the other hand, the same guideline fixes the volume of water to be used for the experiments very strictly.
The objective of this work is to identify the parameters that are critical for the formation of TPs. The following two hypotheses were tested. Firstly, it was assumed that the significant variation in the ratio of the removal agent and reaction time may exert a considerable impact on the formation of TPs. Secondly, it was hypothesized that the variation in sample volumes has no effect on the formation of TPs.
Terbutryn, a biocide, serves as the model substance for this study. It has already been frequently detected in surface and groundwater, and is, additionally, listed as substance to be monitored in accordance with the Water Framework Directive. The aforementioned propositions are to be conducted by varying the ratio of disinfection agent vs. parent compound, sample volume and reaction time as part of a design of experiment (DOE) and followed by non-target analysis utilizing high resolution mass spectrometry. This is intended to determine the number of features representing possible TPs depending on the parameter variation and to compare them statistically with other variations.
Specifically, this work should provide insight and understanding into whether a careful selection of the precise specification of parameters such as the disinfection agent to parent compound ratio, as well as reaction duration, is necessary.

3.10.P-Th156 In Vitro Dermal Absorption of Key Colour Developers in Thermal Paper: A Focus on Bisphenol A, Bisphenol S, and Pergafast 201

Olha Tsykhotska*, Elodie Person, Marine Valleix, Anne Hillenweck, Sandrine Bruel, Francois Laurent and Daniel Zalko, Toxalim (Research Centre in Food Toxicology), Universite de Toulouse, INRAE, ENVT, INP-Purpan, France*

Thermal papers have been used since the 1970s to print tickets, receipts, but also food packaging labels. Bisphenol A (BPA) has for long been the most common colour developer in thermal papers, but its endocrine-disrupting properties have led to restrict its use in the European Union (it should not exceed 0.02% of thermal printing papers weight). In response, manufacturers have begun to replace BPA with

alternatives such as Bisphenol S (BPS) and other substances, including Pergafast 201 (PF201). BPS was demonstrated to be at least equally as active as BPA, and was classified as an endocrine disruptor in 2023. In contrast, toxicity data for PF201 still lacks. The handling of thermal papers represents the primary route of occupational exposure to colour developers, but also concerns consumers, through receipts and food packaging tags manipulation and storage. Despite the increasing use of BPA alternatives, the percutaneous absorption of these substances remains poorly understood.
We carried out an ex vivo study in accordance with OECD (n428, n28) and EFSA guidelines to evaluate the human dermal absorption of BPA, BPS and PF201. Viable split-thickness abdominal skin samples from women aged 23-48 years (BPS: n = 5 donors; BPA and PF201: n = 7 donors) were mounted on static Franz diffusion cells. Tritium-labelled molecules were topically applied (1.38 nmol/cm2) in phosphate-buffered saline. After 24h, radioactivity distribution was measured in all skin compartments, allowing to establish a mass balance. Mean recoveries were 98.0%, 93.5% and 95.3% of the applied dose, for BPA, BPS and PF201, respectively. The absorbed doses were 4.59 ± 2.18%, 0.56 ± 0.90%, and 0.19 ± 0.10% for BPA, BPS and PF201, respectively. Average PF201 and BPS absorbed doses were significantly lower compared to the average BPA absorbed dose. Furthermore, dermal delivery values were 15.7 ± 3.68% (BPA), 7.03 ± 3.14% (BPS) and 5.31 ± 5.35% (PF201). Our study provides evidence that these three compounds can reside in the deeper layers of the stratum corneum for more than 24 hours, and thus remain potentially bioavailable.
Overall, this study contributes to a better understanding of dermal exposure to BPA alternatives, with this route being suspected to significantly contribute to human exposure for these substances. Our results may help reach a better assessment of associated hazards and risks by public authorities.

3.10.P-Th157 Assessing Biochar's Potential for Long-Term Pharmaceutical Adsorption in Flow-Through Wastewater Systems

*Bent Speksnijder[1], Maximilian Tyka[1], Prithvi Simha[2], Alberto Celma[1] and **Oksana Golovko**[1], (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Energy and Technology, Swedish University of Agricultural Sciences (SLU), Sweden*

Conventional wastewater treatment facilities have low removal efficiencies for pharmaceuticals, which are present globally in groundwater and surface water, including drinking water reservoir. This study investigates the adsorption capacities of five different biochar materials for the removal of pharmaceuticals from effluent from tertiary treatment of municipal wastewater, using a continuous flow column experiment to evaluate breakthrough points and removal efficiencies.
The experiment involved exposing biochar materials in a constant flow column system to spiked wastewater effluent containing selected pharmaceuticals with varied physicochemical properties to assess adsorption effectiveness. Among the biochar materials tested, forest biomass and sewage sludge biochar materials demonstrated superior adsorption capacities, maintaining over 99% removal efficiency beyond 440 bed volumes, attributed to higher packing densities. In contrast, spruce biochar displayed a quicker breakthrough due to lower density, underscoring the critical role of biochar characteristics in adsorption performance. Additionally, sludge biochar exhibited biofilm formation, suggesting enhanced biodegradation potential for prolonged treatment applications.
These findings indicate that biochar s surface properties, particularly density and charge, are significant for pharmaceutical adsorption, with cationic pharmaceuticals showing improved retention. This study advances the understanding of biochar-based quaternary wastewater treatment, though further research, including pilot-scale studies, is recommended to assess biochar's long-term efficacy and cost-effectiveness in environmental applications.

3.10.P-Th158 Screening of Traffic Related Organic Micropollutants in Municipal Stormwater Ponds

***Bent Speksnijder**, Oksana Golovko and Alberto Celma, Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden*

Stormwater ponds are designed to collect water from road runoffs and frequently serve as hot spots for traffic related organic micropollutants (TR-OMP). These pollutants, including their transformation products, can be highly toxic and have a large impact on the environment.
In this study 11 stormwater ponds were investigated around the Uppsala municipality (Sweden). These include potentially impacted sites, remote locations as well as recreational parks. Surface water was collected during three different seasons: spring, summer and fall. Samples were extracted by using a

generic Solid Phase Extraction (SPE) method and analysed by means of ultra-performance liquid chromatographic (UPLC) system coupled to a Q Exactive Focus Orbitrap.
Suspect screening of the collected stormwater samples identified a diverse array of TR-OMP commonly linked to road runoff, including tire wear compounds. This analysis highlights the diversity of the contaminant profiles across different stormwater pond locations, suggesting that factors such as urban density, traffic intensity, and local land use significantly influence the pollutant profiles. The variability in TR-OMP composition underscores the complex interplay between stormwater dynamics and environmental exposure pathways, emphasizing the need for site-specific monitoring and tailored mitigation strategies to manage stormwater quality effectively.

3.10.P-Th159 Pesticide Residues with Hazard Classifications Relevant to Non-Target Species Including Humans are Omnipresent in the Environment and Farmer Residences
Vera Silva[1]*, Lingtong Gai*[1]*, Paula Harkes*[1]*, Gaowei Tan*[1]*, Coen J. Ritsema*[1]*, Francisco Alcon*[2]*, Josefina Contreras*[2]*, Nelson Abrantes*[3]*, Isabel Campos*[3]*, Isabelle Baldi*[4]*, Mathilde Bureau*[4]*, Florian Christ*[5]*, Daniele Mandrioli*[6]*, Daria Sgargi*[6]*, Igor Paskovic*[7]*, Marija Polic Paskovic*[7]*, Matja Glavan*[8]*, Jakub Hofman*[9]*, Esperanza Huerta Lwanga*[1]*, Trine Norgaard*[10]*, Zuzana Bílková*[9]*, Rima Osman*[1]*, Chrow Khurshid*[1]*, Irene Navarro*[11]*, Adrian De La Torre*[12]*, Paloma Sanz*[11]*, María Ángeles Martinez*[11]*, Jonatan Dias*[13]*, Hans Mol*[13]*, Gerrit Gort*[14]*, Daniel M. Figueiredo*[15]*, Paul T. J. Scheepers*[16]*, Vivi Schlunssen*[17]*, Anne Vested Anne Vested*[17]*, Abdallah Alaoui*[5] *and violette geissen*[1]*, (1)Soil Physics and Land Management Group, Wageningen University & Research, Netherlands, (2)Agricultural Engineering School, Universidad Politecnica de Cartagena, Spain, (3)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (4)Univ. Bordeaux, INSERM, BPH, France, (5)Institute of Geography, University of Bern, Switzerland, (6)Cesare Maltoni Cancer Research Center, Ramazzini Institute, Italy, (7)Department of Agriculture and Nutrition, Institute of Agriculture and Tourism, Croatia, (8)Agronomy Department, Biotechnical Faculty, University of Ljubljana, Slovenia, (9)RECETOX, Masaryk University, Czech Republic, (10)Department of Agroecology, Aarhus University, Denmark, (11)Unit of POPs and Emerging Pollutants in the Environment, Department of Environment, CIEMAT, Madrid, Spain, (12)Unit of POPs and Emerging Pollutants in the Environment, Department of Environment, CIEMAT, Spain, (13)Wageningen Food Safety Research (WFSR), part of Wageningen University & Research, Netherlands, (14)Biometris, Wageningen University, Netherlands, (15)Institute for Risk Assessment Sciences (IRAS), Utrecht University, Netherlands, (16)Radboud Institute for Biological and Environmental Sciences, Radboud University Nijmegen, Netherlands, (17)Department of Public Health, Research Unit for Environment, Occupation and Health, Danish Ramazzini Centre, Aarhus University, Denmark*
Intensive and widespread use of pesticides raises serious environmental and human health concerns. The presence and levels of 209 pesticide residues (active substances and transformation products) in 625 environmental samples (201 soil, 193 crop, 20 outdoor air, 115 indoor dust, 58 surface water, and 38 sediment samples) have been studied. The samples were collected during the 2021 growing season, across 10 study sites, covering the main European crops, and conventional and organic farming systems. We profiled the pesticide residues found in the different matrices using existing hazard classifications towards non-target organisms and humans. Combining monitoring data and hazard information, we developed an indicator for the prioritization of pesticides, which can support policy decisions and sustainable pesticide use transitions. Eighty-six percent of the samples had at least one residue above the respective limit of detection. One hundred residues were found in soil, 112 in water, 99 in sediments, 78 in crops, 76 in outdoor air, and 197 in indoor dust. The number, levels, and profile of residues varied between farming systems. Our results show that non-approved compounds still represent a significant part of environmental cocktails and should be accounted for in monitoring programs and risk assessments. The hazard profiles analysis confirms the dominance of compounds of low-moderate hazard and underscores the high hazard of some approved compounds and recurring "no data available" situations. Overall, our results support the idea that risk should be assessed in a mixture context, taking environmentally relevant mixtures into consideration. We have uncovered uncertainties and data gaps that should be addressed, as well as the policy implications at the EU approval status level. Our newly introduced indicator can help identify research priority areas, and act as a reference for targeted scenarios set forth in the Farm to Fork pesticide reduction goals.

3.10.P-Th160 Assessing the Environmental Hazard of Synthetic Phenolic Antioxidants

Cleo Soldini[1]*, Carolin Seller-Brison*[1] *and Kathrin Fenner*[2]*, (1)University of Zurich, Switzerland, (2)University of Zurich, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Synthetic phenolic antioxidants (SPAs) are contaminants of emerging concern due to their extensive use in a wide range of applications, e.g., as preserving agents in plastics, fire retardants, synthetic fibers, fuels, and even foods. As a result, SPAs are now frequently detected in various environmental matrices, including natural water bodies, sediments, air or biota. Although prior studies have shown that certain SPAs and their transformation products can exhibit toxic effects in living organisms, data on their environmental fate and (eco-)toxicity remains sparse for a majority of compounds in this diverse and large class of substances.

This project aims to address this knowledge gap by investigating key environmental hazards of SPAs, namely persistence and (eco-)toxicity. As a first step, we assess the persistence of a broad range of SPAs as well as the formation of transformation products (i.e., ~100 substances), using activated sludge biotransformation assays. In this context, our goal is to streamline biodegradation experiments so that they are rapid yet robustly predictive of the compounds tendency to be biotransformed by complex environmental microbial communities, allowing for more efficient data collection for persistence assessment. Besides screening a large number of substances and developing a targeted LCMS analytical method, we will use these experimental systems to further explore a recently proposed alternative hazard assessment concept i.e., the cumulative and persistent toxicity equivalents (CTE/PTE) concept. The CTE/PTE concept couples biotransformation experiments with animal-free in vitro bioassays to test different cellular toxicity pathways so that key hazards of parent compounds and transformation products can be detected and quantified.

Our findings will provide critical data for environmental hazard assessment of SPAs. In addition, the tested workflows and optimized analytical method may eventually be integrated into the early stages of chemical development process for new emerging SPAs, thus providing essential information for the design of safe and sustainable chemicals.

3.10.P-Th161 Rapid Antimony Speciation in PET Additives Using Frontal Chromatography-ICP-MS: A New Approach for Environmental Risk Assessment

Davide Spanu[1]*, Gilberto Binda*[2]*, Alejandro Ruiz Lopez*[3]*, Gianluca Roncoroni*[1]*, Damiano Monticelli*[1] *and Sandro Recchia*[1]*, (1)University of Insubria, Italy, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)University School for Advanced Studies IUSS Pavia, Italy*

Antimony (Sb), used as a catalyst in polyethylene terephthalate (PET) production, poses significant environmental and health risks due to its potential leaching into water sources. While PET commonly contains hundreds of mg/kg of Sb, current methodologies focus solely on total Sb content, overlooking the critical need for speciation of Sb(III) and Sb(V). This distinction is essential, as Sb(III) is more toxic and carcinogenic than Sb(V). Addressing this gap is vital for accurate risk assessment, especially as PET use continues to grow worldwide.

We present a novel, rapid method for Sb speciation using Frontal Chromatography coupled with Inductively Coupled Plasma Mass Spectrometry (FC-ICP-MS), optimized for analyzing Sb leaching from PET additives. The method utilizes a low-pressure column with a strong cation-exchange resin and nitric acid (HNO3) as the eluent, allowing for efficient separation and detection of Sb(III) and Sb(V). Through systematic multivariate optimization, we achieved an exceptionally fast analysis time of 150 seconds and a detection limit below 1 ng/kg for both Sb species.

The application of this method to a variety of PET samples, including colored, virgin, recycled, and environmental plastics, revealed significant variability in Sb species migration. Aging and manufacturing processes notably influenced leaching behavior, with environmental samples showing the highest rates of Sb release. Across all samples, Sb(V) dominated the leachates, but Sb(III) levels were found to increase in naturally weathered plastics, indicating a shift in speciation over time.

Our FC-ICP-MS approach offers substantial advantages over traditional techniques, including faster analysis times, lower detection limits, and simpler instrumentation. The method s sensitivity and reliability make it a powerful tool for environmental monitoring and regulatory purposes. Additionally, its alignment with green analytical chemistry principles underscores its potential for widespread adoption in environmental health assessments, providing critical insights into Sb contamination and its ecological impacts.

3.10.P-Th162 How Common Oyster Mushroom Can Assist in Pharmaceutical Removal

Oksana Golovko[1]*, Alberto Celma*[1]*, Adrià Sunyer-Caldú*[2] *and Malin Hultberg*[3]*, (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Environmental Science (ACES, Exposure & Effects), Science for Life Laboratory, Stockholm University, Sweden, (3)Department of Biosystems and Technology, Swedish University of Agricultural Sciences, Sweden*

Emerging contaminants (EC), including pharmaceuticals, are insufficiently removed by conventional wastewater treatment processes, posing a significant risk to quality and safety of water resources. Effluents from wastewater treatment plants (WWTPs) are a primary source of EC pollution in inland waters, underscoring the urgent need for efficient removal technologies. White-rot fungi, through a process known as mycoremediation, offer a promising bioremediation strategy due to the broad-spectrum activity of their ligninolytic enzymes, which can degrade a wide array of ECs.
This study explores the use of white-rot fungi, Pleurotus ostreatus M2191, for the bioremediation of pharmaceuticals through mycoremediation in wastewater effluent. Fungal pellets cultivated with Kraft lignin induced significant laccase enzyme production, with activity levels reaching up to 360 U/L. After 48 hours of fungal growth, pharmaceuticals (clarithromycin, sertraline, and venlafaxine) were introduced individually and as a mixture. Following 24 hours of exposure, fungal treatments demonstrated notable reductions in pharmaceutical concentrations, particularly for sertraline. Biosorption and extracellular degradation by laccases and other enzymes were identified as primary mechanisms of pharmaceutical removal, with biosorption favored for hydrophobic compounds. Additionally, the formation of transformation products (TPs) was evaluated using suspect screening, neutral loss, and common mass search, highlighting the role of white-rot fungi in environmental bioremediation and TPs formation. This research supports the potential of fungal treatment for removing pharmaceuticals from water, offering insights into the mechanisms and efficacy of mycoremediation.

3.10.P-Th163 Investigating Quaternary Ammonium Compounds (QACs) Throughout Wastewater Treatment Plants and Receiving Waters

Anna Mahony[1]*, Patrick McNamara*[2] *and* ***William Arnold***[1]*, (1)University of Minnesota, United States, (2)Marquette University, United States*

Quaternary ammonium compounds (QACs) are a group of chemicals used in a wide range of consumer, agricultural, and industrial products, including disinfectants. Due to the COVID-19 pandemic, use of disinfectants has increased significantly since March 2020, increasing loads to wastewater plants and the environment. QACs have been shown to impact the development of antibiotic resistance and may be toxic to aquatic life. Thus, it is important to study the increasing use of disinfectants in the environment. Quarterly influent, effluent and biosolid samples were taken from 10 wastewater treatment plants with varying sizes and treatment methods in Minnesota, Wisconsin and California, USA beginning in June 2021. At two plants, samples were taken along the treatment train to establish a mass balance during treatment. Surface water and surface sediment samples were also collected approximately a kilometer downstream of the wastewater discharge sites. These samples were analyzed for 25 QACs by solid phase extraction followed by analysis by LC-MS/MS. While >90% of QACs are removed during wastewater treatment, these chemicals are present in such high concentrations in influents that low μg/L concentrations are still present in effluents. Additionally, biosolids have high levels of QACs. Because biosolids may be land-applied, this presents a route for the release of QACs to the environment and additional QACs could wind up in surface water and sediments through run off and leaching. QACs were present in high ng/L concentrations in the surface water collected, showing that effluent contributes a substantial amount of QACs to the environment

3.10.P-Th164 Chemical Pollution in Stormwater Ponds. Suspect Screening of Organic Micropollutants in Impacted Reservoirs in a Swedish Context

Alberto Celma[1]*, Victoria Eriksson*[2]*, Oksana Golovko*[1] *and Karin Wiberg*[1]*, (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Physics, Chemistry and Biology (IFM), Linkoping University, Sweden*

Street run-off stormwater is often a hotspot for a wide range of organic pollutants as a result of traffic, pest control, road wear, buildings and other human activities. Although most organic micropollutants occur in low concentrations, many of them are highly toxic and, thus, even low concentrations might threaten the environment by harming aquatic organisms. Also, human health can be affected since, in Sweden, the vast majority of drinking water is produced from surface water.
In this work, we have investigated both influent and effluent water streams from two stormwater ponds impacted by, among others, heavy traffic and residential and industrial areas. Additionally, in case of technical failures, one of the ponds gets impacted by municipal wastewater as a nearby pump station for

sewage water directly discharges untreated wastewater to the pond during such operating conditions. Outlet streams of both stormwater ponds, eventually, mouth in Lake Mälaren (Sweden), which serves source water for drinking water production for 2 million people. Thus, it is of utmost importance to be well informed about the impact from inflowing contaminated water.
To investigate the impact of hydrological events on the fate of organic micropollutants in the ponds, water samples were collected both at dry periods (base flow) and rain events using flow proportional sampling. Mixed-mode solid-phase extraction (SPE) and ultra-high pressure liquid chromatography coupled to high resolution mass spectrometry (UHPLC-HRMS) were used for wide-scope screening of organic micropollutants of the samples permitting to expand the chemical coverage in comparison with conventional sample analysis strategies. Data revealed the presence of a large set of chemicals resulting from different human activities in both the influent and effluent streams from the stormwater pond. In total, near 70 organic micropollutants were identified, being vehicle related compounds and pharmaceuticals the most frequently detected compounds.
In this communication, we aim at shedding light into the pollution of stormwater ponds and its implication to the surrounding water bodies in a Swedish context.

3.10.P-Th165 Assessing Nanocarriers for their Environmental Risks
Anna Pavlicek, *Florian Part, Christian Zafiu, Eva-Kathrin Ehmoser, Sabine Gressler, Bernd Moritz Giese, Marius Koppler and Florian Sitzwohl, BOKU University, Austria*
Nanotechnology is nowadays considered a key technology of the 21st century, representing an umbrella for a multitude of products and processes rather than a single technology or application. It is simultaneously considered an "emerging technology" as well as an "emerging issue of environmental concern. One innovative technology are Nanocarriers or Nanocarrier systems (NCS). These NCS are innovative transport- and encapsulation systems that enable targeted delivery and release of active ingredients (AI) at a designated site. These systems achieve higher efficiency of the AI at the target site and therefore require a lower total amount used compared to conventional products. Despite their potential advantages, NCS might have the potential to become contaminants of emerging concern as there is a lot of uncertainty regarding their possible environmental risks. Their complexity, the variety of NCS formulations, and the missing definition and adequate testing and assessment strategies hamper proper risk assessment. Our project focuses on whether and to what extent existing guidelines like the OECD TG 318 can be adapted to assess the mobility, release and biodegradation of NCS under environmentally relevant conditions. Which analytical methods should be used and combined to assess the mobility and degradability of the nanocarrier and the (un-)intended release of the active ingredient in freshwater systems? As there is currently little information on the mobility of NCS in the environment and no harmonised methods to determine them, our research project aims to investigate appropriate methods for selected types of NCS to test their environmental behaviour at lab scale. We, therefore, developed a working definition and systematic categorisation of NCS based on size and function. Furthermore, three representative nanocarrier types are undergoing tests on their potential mobility under different environmental conditions (electrolyte composition, Suwannee River NOM extract content, pH, and temperature). The NCS are loaded with traceable fluorescent molecules, which may be released under changing environmental conditions. Fluorescence spectroscopy, UV-VIS and dynamic light scattering (DLS) are applied to test the nanocarriers dispersion and colloidal stability. The test protocol is inspired by OECD test guideline No. 318 for testing the dispersion stability of nanomaterials under simulated environmental conditions and is modified towards analysing NCS.

Disclaimer/Disclosure: Project is funded by the German Federal Ministry for the Environment, Nature Conservation, Nuclear Safety and Consumer Protection and commissioned by the German Federal Environment Agency (UBA), grant number 3722 66 4010401 0.

3.10.P-Th166 Analysis of Phthalate Esters, Alternative Plasticizers, and Organic Phosphorus Flame Retardants in 46 Recycled Plastic Pellets
Naohide Shinohara[1], *Naoya Kojima*[2], *Tomoko Oguri*[2], *Kyoko Ono*[2], *Tomoko Oguri*[2] *and Masashi Gamo*[2], *(1)National Institute of Industrial Science and Technology, Japan, (2)National Institute of Advanced Industrial Science and Technology, Japan*
Introduction
In a recycling-focused society, increasing the use of recycled plastics is essential. However, the safety of recycled plastics remains unclear. This study analyzed recycled plastic pellets made from polyethylene and polypropylene for phthalate plasticizers, alternative plasticizers, and organic phosphorus flame retardants.
Methods

The concentrations of these substances were measured in 44 types of recycled plastic pellets from 10 recycling plants in Japan. Approximately 200 mg of recycled plastic pellets were weighed and placed in a high-pressure container with 10 mL of cyclohexane, then heated to 150 ºC for 4 hours to resolve the resin and extract the components. After centrifugation, the supernatant was filtered, and 1 mL of the filtrate was diluted with methanol to 10 mL to reprecipitate the resin. This mixture was then centrifugated and filtered again to remove the reprecipitated resin. The liquid was concentrated to 1.5 mL using nitrogen blowdown at 30 ºC, after which internal standards were added, and the samples were analyzed by gas chromatography-mass spectrometry (GC-MS).
Results
The main plasticizers detected were diethylhexyl phthalate (DEHP) in 75% of the samples (N.D. (<0.1) to 54.5 μg/g), diisononyl phthalate (DINP) in 20% of the samples (N.D. (<0.01) to 33.3 μg/g), diisononyl adipate (DINA) in 41% of the samples (N.D. (<0.01) to 181 μg/g), tributyl acetyl citrate (ATBC) in 75% of the samples (N.D. (<0.02) to 60.8 μg/g), and diethylhexyl terephthalate (DEHT) in 86% of the samples (N.D. (<0.01) to 9.77 μg/g). The main organophosphorus flame retardants detected were tris (2-chloroethyl) phosphate (TCEP) in 39% of the samples (N.D. (<0.002) to 4.23 μg/g) and tris (1-chloro-2-propyl) phosphate (TCPP) in 68% of the samples (N.D. (<0.02) to 0.694 μg/g).
Discussion
In all of the recycled plastic pellets analyzed, the concentrations of the substances were all more than one order below the maximum allowable content (0.1%) of the four phthalates (DEHP, di-n-butyl phthalate (DnBP), benzyl butyl phthalate (BBP), and di-iso-butyl phthalate (DiBP)) specified in the RoHS Directive. In addition, the total concentration of the four phthalates restricted in toys and other products under the REACH regulations was also more than one order below the maximum allowable content (0.1%). Based on these findings, there are little safety concerns regarding these substances in the recycled plastic pellets in the plants measured in this study.

Disclaimer/Disclosure: Part of this study is based on results from the Circular Economy System project of the Cross-ministerial Strategic Innovation Promotion Program, Cabinet Office, Japan commissioned by Environmental Restoration and Conservation Agency.

3.10.P-Th167 Real-time Monitoring of 16 Pharmaceuticals in Wastewater using Automated On-Site SPE and LC-MS/MS Methods

Sook Hyun Nam*, Ho Min Kye and Tae-Mun Hwang, Korea Institute of Civil Engineering and Building Technology, Republic of Korea*

This study aimed to monitor 16 pharmaceuticals in the final effluent of a wastewater treatment plant in South Korea, utilizing automated on-site sampling and solid-phase extraction (SPE) combined with liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis. Automated online solid-phase extraction (SPE) and liquid chromatography-tandem mass spectrometry (LC-MS/MS) methods exist, but the equipment is expensive, and there are no online systems that can be installed in the field for sampling. Pharmaceutical products (16 types) include acetaminophen, atenolol, caffeine, carbamazepine, diclofenac, ibuprofen, iopromide, lincomycin, naproxen, paraxanthine, propranolol, ranitidine, sulfamethoxazole, trimethoprim, and triclosan, and are substances detected in South Korea. In this study, the SPE system consisted of four components (Sampling, SPE, Extraction, and Injection) and was designed to achieve a 500-fold concentration. Considering 500-fold concentration, the lowest detection limit is 2 ng/L, although it varies depending on the substance. Optimization of SPE and LC-MS/MS under a variety of conditions for field samples improved sensitivity and selectivity. SPE cartridges are automatically washed and prepared to remove residual substances and effectively capture the analyte. For samples with complex matrices, such as wastewater, optimizing the SPE process required careful attention to the washing step, which removes interfering matrix components, and the cartridge drying step. Since the optimal pH conditions differ depending on the chemical properties of each pharmaceutical ingredient, the recovery rate and sensitivity for each ingredient were evaluated under various pH conditions. To find the optimal pH conditions, the pretreatment process was analyzed at various pH (3, 7, 10), and the recovery was evaluated using internal standards of carbamazepine-d10, ibuprofen-d3, atenolol-d7, sulfamethazine-13C3, sulfamethoxazole-d4 and trimethoprim-d9. Interestingly, only at pH 10 was the recovery of atenolol high at 85 110%. In this study, we systematically analyzed the effect of various conditions on the extraction efficiency of pharmaceutical ingredients during the SPE pretreatment process. This development enables real-time monitoring of pharmaceutical products in the field, and provides reliable data even from complex matrices of wastewater samples.

Disclaimer/Disclosure: This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Project for developing innovative drinking water and wastewater technologies Program, funded by Korea Ministry of Environment (MOE)(Grant RS-2022-KE002370).

3.10.P-Th168 Analysis of Aromatic Amines and Their Transformation Products in Dust from Five Different Indoor Environments Representing Diverse Source Profiles

Özge Edebali[1]*, Lisa Melymuk*[2]*, Marek Stiborek*[3]*, Anna Goellner*[4]*, Melis Muz Massei*[4]*, Zdenek Simek*[3] *and Branislav Vrana*[3]*, (1)Faculty of Science, RECETOX, Masaryk University, Czech Republic, (2)Masaryk University, Brno, Czech Republic, (3)RECETOX, Masaryk University, Czech Republic, (4)UFZ Helmholtz Centre for Environmental Research, Department of Effect Directed Analysis, Germany*

Aromatic amines (AAs) are found in a wide range of products, including pharmaceuticals, pesticides, rubber, textiles, hair dyes, and plastic products, and are by-products in tobacco smoke and certain cooking activities. Several AAs and their transformation products are classified as substances of very high concern. However, limited data exist regarding the presence and behavior of AAs in indoor environments, where human exposure may be significant, given that people spend over 90% of their time indoors. Indoor dust is a critical environmental matrix in this context for human exposure to various chemicals. Furthermore, indoor environments may contribute to wastewater contamination, as chemicals are potentially transferred to wastewater treatment plants through laundry water and cleaning. This study evaluates the occurrence, composition profiles, and potential sources of emerging AAs and related transformation products within dust across indoor environments with specific AA source profiles.

Dust sampling was conducted in five types of indoor spaces: a hairdresser, a restaurant kitchen, a smoking pub, a smoking home, and a non-smoking home. Repeated samples of settled dust were collected on quartz fiber filters over a six-week period using a vacuum cleaner equipped with a specialized sampling head. Wet wipe samples were also taken from elevated surfaces to complement dust sampling. An ultrasonic extraction method was developed to recover target analytes (primary AAs) from the dust samples, with methyl tert-butyl ether selected as the extraction solvent. AAs were consistently detected across the indoor spaces, with levels and composition profiles driven by the major sources in each type of indoor environment. The findings underscore the importance of indoor dust as a key environmental matrix for assessing exposure to AAs and other emerging contaminants and emphasize the need for further research on indoor sources of AAs, particularly to better evaluate occupational exposures and better characterize their pathways from indoor environments into surface waters via wastewater. The findings contribute to a better understanding of exposure from indoor sources and the tracking of high-concern substances that are important for both human health and environmental safety.

Disclaimer/Disclosure: The results were created with the financial support of the provider Czech Science Foundation within the project Accumulation in textiles and release by laundry as an emission pathway for aromatic amines from indoor environments to waste- and surface water no. GF22-06020K.

3.10.P-Th169 Wastewater Pollution in Yucatan's Karstic Aquifer: Caffeine and Bacteria in Monitoring Wells of the Yucatan Peninsula

Diego Ivan Najera-Perez[1]*, Elsa Norena-Barroso*[2]*, Norma Angelica Marquez-Velazquez*[2]*, Gabriela Rodriguez Fuentes*[2]*, Erick Soto-Garcia*[2]*, Roger Pacheco-Castro*[2] *and Paulo Salles*[2]*, (1)Posgrado en Ciencias del Mar y Limnolog a, UNAM, Mexico, (2)Universidad Nacional Autonoma de Mexico (UNAM), Mexico*

In the Yucatan Peninsula (YP), the karst aquifer is associated with geological formations such as fractures and caverns, which give the soil great porosity and permeability. The aquifer is recharged and groundwater is transported to the coasts through the karst, processes that are fundamental in the water dynamics of the region. However, these same characteristics that allow the retention of large volumes of water also make the aquifer extremely vulnerable to contamination by wastewater. This vulnerability is aggravated by the intensification of human activity and the lack of adequate infrastructure for wastewater treatment, affecting the quality of water available to the population, a situation of great concern because groundwater is the only source of fresh water available to people.

In this study, the presence of caffeine in monitoring wells was evaluated. Caffeine can be used as a chemical tracer of the presence of human-origin wastewater in the aquifer, since the YP does not have a coffee industry, but the population consumes products containing caffeine (drinks, drugs, food); the caffeine consumed is excreted through urine and its final destination is wastewater. Likewise, the presence of fecal coliforms and enterococci was determined, in order to contrast the information provided by both indicators regarding contamination of human origin (non-specific biological tracer vs. chemical tracer). Water samples were collected in May 2024 (dry season) in 16 monitoring wells at two depths in the three states that are part of the YP: three wells in Campeche; one cenote and nine wells located in the northwest area of the state of Yucatán, and three wells in Quintana Roo. Caffeine was determined by solid phase extraction (SPE) and gas chromatography-mass spectrometry (GC-MS). Bacteria were determined by membrane filtration using selective culture media. There was fecal contamination in 14 of the 16 sites analyzed, either by enterococci and/or fecal coliforms. Caffeine ranged from 10.6 to 2381.5 ng/L and it was detected in 100% of the wells at both depths, with higher concentrations at the surface than at mid-depth (except in the cenote); a general trend of increasing caffeine levels was also observed at the sites closest to the coast. The entry of untreated human wastewater was verified by the presence of faecal bacteria and caffeine. Detection of caffeine also indicates that there may be other compounds of emerging concern that can affect humans and biota.

3.10.P-Th170 Dissipation of Organic Micropollutants Originating from Sewage Sludge in Three Soils

***Radka Kodesova**[1], Martin Kocarek[2], Martin Ferencik[3], Ales Klement[4], Miroslav Fer[5] and Antonin Nikodem[2], (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)Czech University of Life Sciences Prague, Czech Republic, (3)Elbe River Basin, State Enterprise, Czech Republic, (4)Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Prague, Czech Republic, (5)Czech University of Life Sciences Prague, Prague, Czech Republic*

Sludge from wastewater treatment plants, which are often supplied to the soil as a source of organic matter and other nutrients, can be contaminated with many micropollutants. These substances can then be taken up by plants, or they can migrate within the vadose zone and subsequently contaminate groundwater. The availability of these compounds for plants and their further spread in the environment depends on their sorption and stability in the soil environment. The persistence of substances in the soil is usually investigated under laboratory conditions, when individual compounds are applied into the soil and then the residual concentrations are analyzed over time. However, the dissipation of substances can be influenced by many factors, such as their initial concentration or the presence of other micropollutants and other substances in the contamination source. Therefore, this study focused on the analysis of the dissipation of selected sixteen micropollutants (including both parent compounds and metabolites), which were presented in sludge from a wastewater treatment plant, after its application into three different soils. In addition, the resulting dissipation trends were compared with the results of standard dissipation experiments for seven individual compounds applied into the same soils and carried out under identical conditions, which were published by Menacherry et al. (2023, https://doi.org/10.1016/j.jhazmat.2023.132143). For some compounds (1-methyl-1H-benzotriazole, lamotrigine, venlafaxine, and sertraline), the dissipation profiles were in both cases similar. On the other hand, in some cases, faster dissipation was found when the compound was applied individually (valsartan and atorvastatin), or when it was applied through sewage sludge (telmisartan).

Disclaimer/Disclosure: The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QL24010384 and QK21020080.

3.10.P-Th171 Biodegradation of Sulfonamides and Fluoroquinolones in Domestic Sewage using an Anaerobic Fixed-Bed Biofilm Reactor

***Rodrigo Braz Carneiro**, Elis Watanabe Nogueira, Mayara Caroline Felipe, Marcelo Zaiat and Álvaro J. Santos-Neto, University of São Paulo, Brazil*

Among emerging contaminants, antibiotics have particular significance, since they can modify the microbial community, promoting antimicrobial resistance. Fluoroquinolones and sulfonamides are two important classes of antibiotics widely used in human and veterinary medicine worldwide. In this work, the removal of 7 antibiotics frequently detected in urban wastewater was evaluated in an anaerobic fixed-bed biofilm reactor (AnFBBR) treating domestic sewage during 60 days. The antibiotics consisted of 3 sulfonamides sulfamethoxazole (SMX), sulfadimethoxine (SDX) and sulfamerazine (SMZ); and 4 fluoroquinolones ciprofloxacin (CIP), pefloxacin (PEF), enrofloxacin (ENR), and ofloxacin (OFL). The domestic sewage was collected directly from the sewer pipes located near the Environmental Engineering campus of University of Sao Paulo (Sao Carlos, SP, Brazil). The bioreactor's performance was monitored through physical-chemical analyses: pH, alkalinity, volatile acids, chemical oxygen demand (COD), biogas composition (methane and carbon dioxide), and antibiotics. The antibiotics concentration was determined by using a column-switching online solid phase extraction coupled to a liquid chromatography/tandem mass spectrometry (SPE-LC-MS/MS) method - Chromatograph Agilent 1200 LC series and hybrid triple quadrupole-linear ion trap mass spectrometer AB SCIEX QTRAP 5500. A mixed solution of internal standards (SMX-C13, SDX-C13, CIP-D8, ENR-D5) was used to quantify the analytes and correct for matrix effects. The sewage had the following physical-chemical characteristics: COD = 525 ± 27 mg L-1; pH = 7.47 ± 0.17; alkalinity = 172 ± 16 mg L-1. The results indicated high performance of the bioreactor in biodegrade organic matter, with COD removal efficiency = 87 ± 3%, and methane content in the biogas > 70%. The antibiotic removals were: SMX = 83 ± 8%, SDX = 22 ± 25%, SMZ = 55 ± 24%, CIP = 56 ± 21%, PEF = 80 ± 10%, ENR = 82 ± 9%, OFL = 73 ± 6%. SMX, PEF, ENR, and OFL were the most easily biodegradable, while SMZ and CIP showed moderate biodegradation, and SDX showed high recalcitrance. AnFBBR proved to be feasible in removing antibiotics from sewage. However, complementary technologies that can be coupled to the AnFBBR should be further implemented in order to mitigate the effects of antibiotics on the environment, especially the spread and development of antimicrobial resistance genes.

Disclaimer/Disclosure: This work was supported by the São Paulo Research Foundation (FAPESP - grant numbers 2022/10615-1, 2019/22532-0, and 2017/02147-0); and the Coordination for the Improvement of Higher Education Personnel (CAPES - Finance Code 001).

3.10.P-Th172 Toxicity of Newly Synthesized Ionic Liquids Based on the Acute *Daphnia magna* Immobilization Test

Tanja Obrad Tomic (Tunic)[1], *Varja Mihajlovic*[1], *Marijana Dunjic*[1], *Dina Tenji*[1], *Jovana Panic*[2] *and Milan Vranes*[2], *(1)Department of Biology and Ecology, University of Novi Sad, Serbia, (2)Department of Chemistry, Biochemistry and Environmental Protection, Faculty of Sciences, University of Novi Sad, Serbia*

Over the past few decades, the scientific community has been turning its attention to the potential widespread use of ionic liquids (ILs). Due to the non-volatility and relatively low toxicity of certain ionic liquids, their potential as a less toxic solvent has been recognized. However, the lack of data on a number of properties of ILs directs current research towards the assessment of their ecotoxicological effects. It has been shown in previous researches that combining different cations and anions affects the toxicity of ILs, and also that protic ILs and aprotic analogues show differences in their toxicity to organisms. Standard toxicity tests are suitable tools for the ecotoxicological characterization of various chemicals and may contribute to the assessment of the toxicity of ionic liquids, as well.

This study includes the analysis on seventeen newly synthesized protic ionic liquids that have 2-hydroxy-1-propylammonium, 1-hydroxy-2-methyl-2-propylammonium or triethanolammonium as cations, while anions are residues of various acids. To contribute to the knowledge about their toxicity, standard acute immobilization tests on *Daphnia magna* were carried out and EC50 values for all ILs were determined. The toxicity of the tested ILs was discussed in the context of experiments done in this study and a comparison of effects of the same ILs on different test models based on previous research. Based on the results of tests with *D. magna*, none of the ionic liquids proved to be toxic, one IL was categorized as harmful, while the other ILs showed no harmful effects. Taking into account the EC50 values from other tests, the *D. magna* tests showed a higher sensitivity to the investigated ionic liquids.

Disclaimer/Disclosure: This research was supported by the Ministry of Science, Technological Development and Innovation of the Republic of Serbia, Grants No. 451-03-137/2025-03/ 200125 & 451-03-136/2025-03/ 200125.

3.10.P-Th173 Water Treatment Processes: Identification and Quantitation of Transformation Products Formed in Test Systems

Peter Crick, *Ivan Strepponi and Neil Robinson, Innovative Environmental Services (IES) Ltd, Switzerland*

A recent European Food Safety Authority (EFSA) guidance document describes experimental methods for the identification of transformation products of active substances and their metabolites formed during water treatment processes. These processes include chlorination, chloramination, oxidation, ozonolysis, and ultraviolet light (UV) treatment. Here, we present results of experimental implementation of these processes carried out with a series of test substances.

Experiments were carried out in a standard water with addition of organic carbon obtained from the Suwannee River as defined in the guidance document. Chlorination with sodium hypochlorite was carried out at three different pH levels (6.5, 7.5, and 8.5). Monochloramine was prepared from sodium hypochlorite and ammonium chloride to carry out the chloramination experiments. For the oxidation process, an aqueous chlorine dioxide solution was obtained by addition of sulfuric acid to a solution of sodium chlorite.

In all of these experiments, the concentration of reagent in the test system was determined using the colorimetric N,N-diethyl-p-phenylenediamine (DPD) method to ensure that the requirements of the guidance document were met.

Ozonolysis was carried out by treating the test substances with a freshly prepared solution of ozone in

water, while the UV process was performed in an irradiation chamber fitted with a medium pressure UV lamp allowing control of the UV dose to the test solution.
Liquid chromatography coupled with mass spectrometry (LC/MS) was used to analyse the test substances and transformation products formed in these processes. Identification of the transformation products was carried out using high resolution-accurate mass spectrometry (HRAM) with data analysis performed using a non-target screening workflow, while quantitative analysis was performed by HRAM or multiple reaction monitoring (MRM) on a triple quadrupole mass spectrometer.
The results of these experiments are presented, with a discussion of challenges and suggested approaches to fulfilling the requirements of the guidance document.

3.10.P-Th175 Biocides in the Environment (BiU) - Advancements of the German Monitoring Database

*Christiane Meier and **Korinna Ziegler**, German Environment Agency (UBA), Dessau-Rosslau, Germany*
The Biocides in the environment (BiU) database was launched in 2023 with about 90,000 data entries, focusing on data from Germany, Austria and Switzerland, with the aim to collect and make biocide monitoring data publicly accessible. Biocidal products have a widespread use especially in urban areas as insecticides, disinfectants and preservatives that can lead to unavoidable emissions into various environmental compartments. Monitoring data can be used to address potential risks and raise awareness of environmental impacts of biocides. In 2024 the German Environment Agency (UBA) started developments to identify further suitable data sources and to establish the framework for a half-automatable extension of the "BiU database so that biocide monitoring data from German-speaking countries can be regularly integrated from various external data sources in future. Potential data sources were checked using respective inclusion criteria such as usage rights as well as the effort of data extraction and were matched with a priority list of 290 biocidal active substances and transformation products. Out of 66 reviewed environmental monitoring data sources, only 8 met the inclusion criteria and were further used. In total measurement data of 98 biocidal substances and transformation products were identified and included in the BiU database predominantly from Germany (96.4 %). Most of the measurement data is available for surface water (61.7 %) and groundwater (36.6 %), whereas data for soil, sediments, suspended particulate matter, or biota is rare. First analyses of the collected data, which comprise around 800,000 identified measured values, were conducted and will be presented. Key questions addressed the most frequently detected substances and the potential relation to specific application areas. Data will be used for further assessments, for example to evaluate temporal trends of specific biocides in environmental compartments or to have a closer look at the occurrence of specific substance groups like highly toxic pyrethroids. However, findings indicate that data for some environmental compartments is insufficient for gaining an appropriate overview of biocide contamination. Further efforts are still necessary to measure and collect environmental data for biocides and to made these data publicly available.

3.10.P-Th176 Environmental Concentrations of Bisphenol A in North American Surface Waters and Sediments Over the Years of 2010 to 2022

*Chesney Swansborough[1], Javier Soto[1], **Simon Gutierrez**[1], Emma Pemberton[1], Margaret E. McArdle[2], Ellen M. Mihaich[3], Evelyn Majoris[4], Christopher B Hughes[1] and Michael Bunge[4], (1)Ricardo, United Kingdom, (2)Exponent International Ltd., United States, (3)ER2 for SABIC, United States, (4)Covestro Deutschland AG, Germany*
Bisphenol A (BPA), a high-volume industrial chemical in widespread commercial use for over five decades, is used in the production of numerous consumer products and materials. Due to increasing regulatory scrutiny on BPA and other bisphenols for their potential endocrine-disrupting effects, various proposals for regulatory measures have emerged.
Extensive reports document the presence of BPA in environmental media, with a primary focus on aquatic ecosystems. This study provides a comprehensive analysis of measured BPA concentrations in the environment from 2010 to 2022. Monitoring data from both freshwater and saline surface waters and sediments across North America were gathered from peer-reviewed literature and publicly available monitoring databases. To ensure consistency and reliability, data were rigorously evaluated using the Criteria for Reporting and Evaluating Exposure Datasets (CREED) framework, developed by a team of experts, through the auspices of SETAC, aimed at standardizing the assessment of chemical exposure data. Relevant and reliable data were consolidated into a database covering 39 North American states and territories. Detection limits varied among studies, with a notable portion of data reported below the limits of detection (LOD).
The dataset was statistically processed to account for censored data and differences in detection limits. Summary statistics were calculated with adjustments for sample size and variations in sampling locations.

Mean concentrations, standard deviations, and other summary statistics were generated for each environmental compartment and compared to analyses from earlier periods.
BPA concentrations displayed significant spatial and temporal variability across states and territories, with reported levels spanning several orders of magnitude across environmental compartments. This study has provided an updated understanding of BPA presence in natural surface waters, built on previous analyses conducted from the 1990s to 2010, and aimed to establish a robust statistical foundation for assessing environmental exposures of BPA across North America.

3.10.P-Th177 Plastic Additives in Sediments of the Mero-Barcés River Basin (NW Spain): Monitoring and Environmental Trends

Estefania Concha-Graña[1], Jorge Lejo Santiago[1], Jose Luis Cereijo[2], Jorge Delgado[1], Purificacion Lopez-Mahia[3] and ***Soledad Muniategui-Lorenzo***[1]*, (1)University of A Coru a, Spain, (2)Univesity of A Coru a, Spain, (3)Universidade da Coru a, Spain*

Plastics may leach harmful chemicals, such as plastic additives and monomers, into the environment. Some of these additives are classified as toxic substances and are listed under REACH; therefore, they have harmful effects on the environment. Sediments are generally the sink for organic pollutants (especially apolar contaminants) and are used to monitor spatial and temporal trends of these substances in the environment. However, sediments can also be a source of contaminants due to their resuspension and remobilization.
In this work, levels of plastic additives, including plasticisers, flame retardants, antioxidants, UV filters, and antimicrobials in sediments of the Mero-Barcés River Basin (northwest Spain) were evaluated seasonally between winter 2023 and winter 2024 (6 sampling campaigns, 4 sites each). The Mero-Barcés River Basin encompasses the river basins of two rivers that supply water to the Abegondo-Cecebre reservoir, which provides drinking water to 500,000 inhabitants in the entire metropolitan area of A Coruña. The basin is of great ecological and environmental value. The extraction of 55 additives from the sediments was performed by sonication, with determination by PTV-GC-MS/MS.
The highest levels of plastic additives were detected in spring 2023 sampling, with plasticisers being the main family in almost all sampling campaigns. A hot spot was detected in MB6, located near the intake point of the drinking water treatment plant. Regarding the individual additives, TiBP, TBHQ and DEP were not detected in any sample above their quantification limits, whereas 2,6-DIPN, DINP, and Tinuvin 234 were detected in all samples. The average concentration of all additives in these sediments was low, with the highest average values remaining below 1 µg g-1. For most additives, there was a considerable variation in concentration depending on the sampling site and campaign.

3.11 Integrating Ion Mobility Separations with HRMS: Transforming Environmental Contaminant Identification and Quantification Workflows

3.11.T-01 Targeted and Non-Targeted Analyses of PFAS in Human Serum Samples Collected Yearly from 2003 to 2021

Gregory Kudzin[1]*, James Dodds[1], Kaylie Kirkwood-Donelson[2], Jessie Chappel[1], Dylan Johnson[3], Adam Schiffenbauer[4], Kakali Sarkar[4], Payam Noroozi Farhadi[4], Frederick Miller[4], Alan K. Jarmusch[2], Lisa G. Rider[4] and Erin Baker[1], (1)University of North Carolina, Department of Chemistry, United States, (2)Immunity, Inflammation, and Disease Laboratory, Division of Intramural Research, NIEHS, NIH, Research Triangle Park, NC 27709, USA, United States, (3)Integrative Bioinformatics Support Group, Division of Intramural Research, NIEHS, NIH, United States, (4)Environmental Autoimmunity Group, Clinical Research Branch, NIEHS, NIH, United States*

Per- and polyfluoroalkyl substances (PFAS) are a class of man-made chemicals commonly found in consumer and industrial applications as additives and surfactants. Recent evidence has linked several PFAS to concerning health outcomes, such as decreased vaccine response and increased cholesterol levels. Consequently, regulations have been introduced to limit the production and use of these substances, primarily targeting "legacy" PFAS, which have been extensively used and characterized over several decades. However, "emerging" PFAS remain largely unexplored due to their unknown chemistries and environmental presences. This is due to the analytical complexity of studying these chemicals, with data analysis workflow developments needed for their discovery and evaluation.

In this study, we present a novel non-targeted workflow that implements FluoromatchIM coupled to proprietary feature processing algorithms designed to utilize the unique orthogonality provided by ion mobility for PFAS analysis. Using this workflow, we simultaneously analyze quantitative targeted data, and non-targeted evaluations for a unique sample set comprising human serum samples collected from 2003 to 2021 (n = 156). The study specifically sampled serum from people with a systemic rheumatic disease (a recent diagnosis of one of Systemic lupus erythematosus (SLE), Rheumatoid arthritis (RA), Systemic sclerosis (SSC), Amyopathic dermatomyositis (ADM) or Juvenile dermatomyositis (JDM)), along with two control types: a sibling of similar age and an unrelated healthy control. This design enabled a comprehensive study of the potential role of PFAS exposure to the onset of an autoimmune disease, with controls designed to account for the influence of genetics.
The time span of sampling also enabled an in-depth temporal study of changes in PFAS exposure and bioaccumulation legacy and emerging during a critical period in global and domestic fluorinated chemical manufacturing. Moreover, the study includes individuals from major metropolitan areas such as Washington, D.C., New York City, and the Durham-Raleigh area, allowing for analysis of regional differences in PFAS exposure. Our results reveal regionalized patterns in PFAS bioaccumulation, contrasting known, legacy, PFAS with emerging PFAS. The findings suggest that emerging PFAS display distinct regionalized trends while legacy PFAS do not, suggesting the potential for unique exposure pathways for emerging PFAS which are mostly unstudied to date.

3.11.T-02 Unveiling the PFAS Fingerprint in Biota Leveraging the Technique LC-VIP HESI(-)-TIMS-HRMS and Untargeted Workflows

***Georgios Gkotsis**[1], Dimitrios E. Damalas[1], Reza Aalizadeh[1], Ilona Nordhorn[2], Carsten Baessmann[2] and Nikolaos S. Thomaidis[1], (1)National and Kapodistrian University of Athens, Greece, (2)Bruker Daltonics GmbH & Co KG, Germany*

The widespread environmental pollution caused by long-chain poly- and perfluoroalkyl substances (PFAS), known as forever chemicals, is a well-recognized issue in the last decades which has prompted significant chemical regulatory action and a global shift toward alternative PFAS. PFAS identification presents significant analytical challenges, such as the vast number of individual PFAS compounds, along with their transformation products and inefficiencies in MS/MS spectra acquisition, especially in data acquired using DIA modes. Given these complexities, it is essential to employ analytical techniques capable of identifying not only well-known PFAS but also identifying the PFAS "chemical fingerprint" in the environment.
The primary objective of this study was to evaluate the capabilities of ion mobility spectrometry (IMS) in the established LC-HRMS workflows for the in-depth monitoring of PFAS in complex environmental matrices, such as biota. This was achieved by leveraging the cutting-edge technique RPLC-VIP HESI(-)-TIMS-HRMS and an efficient untargeted workflow, combining novel chemometric tools and extensive suspect lists.
A PFAS dedicated sample preparation protocol was carried out, before IMS-HRMS analysis, which was conducted using the optimized broad mass and mobility transfer data dependent acquisition mode PASEF. An extensive suspect list containing more than 4,900 PFAS was used for the annotation of the features. Each annotated feature was thoroughly evaluated based on the precursor ion's mass error, isotope profile, retention time, MS/MS spectrum, and CCS value matching. Thus, the ion mobility-derived CCS values further enhanced the identification confidence by serving as an additional identification criterion. Some features were annotated with more than one fluorinated compound. To address this, a detailed investigation of the MS/MS spectra matching was conducted. Ion mobility filtering contributed to cleaner MS/MS spectra, while the data-dependent acquisition mode, PASEF, provided extensive MS/MS spectra coverage, which is often a challenge in untargeted workflows. These approaches enabled the confident identification of PFAS congeners. Additional chemometric tools were employed to support the untargeted identification and semi quantification of fluorinated compounds and their transformation products. This comprehensive IMS-HRMS-based untargeted workflow significantly enhanced the identification confidence of PFAS in biota samples.

3.11.T-03 Multidimensional-Constrained Suspect Screening of Hydrophobic Chemicals Using Gas Chromatography-Atmospheric Pressure Chemical Ionization-Ion Mobility-Mass Spectrometry

***Xiaodi Shi**[1], Anna Sobek[2] and Jonathan P. Benskin[3], (1)Stockholm University, Stockholm, Sweden, (2)Environmental Science, Stockholm University, Sweden, (3)Stockholm University, Sweden*

Suspect screening strives to rapidly monitor a large number of substances in a sample using mass spectral libraries. However, for hydrophobic organic chemicals (HOCs), these libraries are primarily based on low-resolution electron ionization mass spectra. To improve the efficacy of suspect screening, new libraries and workflows are required, leveraging the highly specific analytical data acquired by state-of-the-art mass spectrometers. In this study, we established a new library for 1,590 suspect contaminants, including identity, exact mass, and a combination of measured and model-predicted values for retention time (RT) and collision cross section (CCS). The assessment using standards for 102 environmental contaminants (1.44 < log Kow < 16.8; -9.31 < log Kaw < 11.3) demonstrated that the ALLCCS2 model overpredicted CCS values (a mean relative deviation ± standard deviation [SD] of -7.03% ± 5.42%) for HOCs, while uncertainties associated with RT predictions (mean of 0.086 min) are comparable to those of RTs converted from literature retention indices (mean of 0.15 min). Thereafter, using gas chromatography-atmospheric pressure chemical ionization-ion mobility-high resolution mass spectrometry, a suspect screening workflow constrained by full scan mass spectrum, RT, CCS, and fragmentation mass spectrum, together with a continuous scoring system, was established to reduce false positives and improve identification confidence. The true positive rates were estimated to be 79% and 64% for fortified and NIST standard reference marine sediment samples, respectively, with all false positives attributed to suspect isomers, indicating that the method is highly specific. The application of the novel method to surface sediment samples from the Baltic Sea, a Norwegian lake, and the East Siberian Sea screened 54 suspect contaminants, among which 11 tentative chemicals of emerging Arctic concern (CEACs) were detected in the East Siberian Sea sediment. An additional 34 compounds were found in the Arctic, but not listed as CEACs. This study offers a new workflow for improved suspect screening of HOCs using multidimensional information, and highlights the need to enrich CCS databases and extend the applicable chemical space of current in silico tools to non-polar contaminants.

3.11.T-04 Uncertainty Estimation of Qualitative and Quantitative Ion Mobility-Mass Spectrometry Workflows

Stephan Hann, *Tim Causon and Teresa Steininger-Mairinger, BOKU University, Austria*
Integration of ion mobility-mass spectrometry (IM-MS) in workflows combining identity confirmation and quantification demands for uncertainty estimation of both collision cross section (CCS) measurement as well as of quantification using integration of arrival time-filtered MS signals. The ISO/IEC Guide 98-3:2008 recommends a bottom-up approach which identifies all possible sources of uncertainty and estimates the total combined uncertainty by propagating the random error caused by the variation of different influence quantities mathematically, or with Monte Carlo simulations. The latter has been applied in this study to estimate the measurement uncertainty of DTCCSN2. The application of uncertainty propagation including the uncertainties obtained for calibration standards (DTCCSN2 reference standards) revealed uncertainty estimates of 4.7?9.1% (k = 2) for measured values using an established single-field calibration approach. Together with laboratory data obtained under repeatability conditions of measurement the confidence of DTCCSN2 in the context with identity confirmation was found to be comparable to retention indices used in GC.
During the last decade qualitative workflows have been developed and established, but the complexity of 4D LC-IM-TOFMS data has thus far hindered establishing an automated quantitative workflow. In this work, we are assessing the capabilities of LC-IM-TOFMS for quantification of contaminants of emerging concerns in surface water. Aqueous standards and spiked surface water samples were measured using both an LC-TOFMS and a LC-IM-TOFMS method. For the LC-IM-TOFMS data, a workflow using the open-source software packages MS-DIAL and Skyline was successfully developed. For identification of possible sources of uncertainty, an Ishikawa-diagram was created and employed to set-up a model equation for absolute concentration values obtained with the two methods. Uncertainty estimation revealed comparable measurement uncertainties for the results obtained with the two methods. DTCCSN2 obtained from transient signals are reliable identification points which are currently integrated into routine identity confirmation workflows. As EURACHEM s bottom-up approach allows estimation of uncertainty of DTCCSN2 and the uncertainty of quantitative workflows which integrate ion mobility, both strategies can be embedded into routine methods and considered for accreditation according to ISO 17025.

Disclaimer/Disclosure: The authors thank BOKU Core Facility Mass Spectrometry for providing mass spectrometry instrumentation.

3.11.P-Th184 One Step Closer to Accurate Quantification of Micro- and Nanoplastics Using Cyclic Ion Mobility Mass Spectrometry

Kas Houthuijs[1], *Justine Bissonnette*[2], *Nikita Harvey*[2], *Marja Lamoree*[1], *Karl Jobst*[2] *and Frederic Been*[1], *(1)Chemistry for Environment & Health, Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands, (2)Department of Chemistry, Memorial University of Newfoundland, St. John s, Canada*
Micro- and nanoplastics (MNPs) have been recognized as an environmental threat and there is global concern about their presence in humans. To investigate human exposure and the toxicological effects of

MNPs, robust methods to identify and quantify these plastic particles are essential. Pyrolysis coupled to gas chromatography mass spectrometry (Py-GC-MS) is currently the method of choice to analyse MNPs in complex biomatrices.
A novel direction in this field is the use of cyclic ion mobility spectrometry (cIMS) hyphenated to high-resolution MS (HRMS). The improved separation and resolution that can be achieved with Py-GC-cIMS-HRMS provide additional identification confidence and reduce spectral background noise, which improves method specificity and limit of detection. However, this novel instrumentation requires renewed method optimization, as for example optimal quantification markers ions are different compared to traditional Py-GC-MS.
In this contribution, we used a non-target approach to identify MS features that uniquely correlate to the polymers PE, PP, PS, PET, PVC and PMMA. Peak picking and integration of the experimental data resulted in 35,365 MS features to which linear calibration models could be fitted. Based on each model s coefficient of determination (R2), optimal markers for each polymer were identified. This non-target approach was then extended to visualize unique pyrolytic products for the different polymers as homologue series, which were found to be consistent with literature. Data-independent acquisition of tandem MS data was used to annotate highly-correlating features, providing increased identification confidence and insight into the pyrolysis and ionisation processes.
By employing an experimental design that varied the sample matrix and ion source humidity, the quantification performance of the method could be further improved. Of all polymers, pyrolysis products of PET and PMMA appear to be most influenced by these factors. We observed that markers show intensity fluctuation up to 3 orders in magnitude in blood compared to blank matrix. These effects may induce large quantification errors if not considered, as MNP quantitation typically relies on out-of-matrix calibration. Finally, it was found increasing ion source humidity can increase marker response factors up to 3 orders of magnitude, which provides a route towards increasing the limit of detection for MNP quantification with Py-GC-cIMS-HRMS.

3.11.P-Th186 Ion-Mobility Derived CCS-m/z Trendlines for Improved Annotation Confidence of Contaminants of Emerging Concern and their Biotransformation Products

Lidia Belova[1], *Mikel Musatadi*[2], *Maosen Zhai*[1], *Maarten Roggeman*[1], *Giulia Poma*[3], *Celine Gys*[1], *Paulien Cleys*[1], *Fatima den Ouden*[1], *Patrick Berghmans*[4], *Jan Peters*[4], *Maitane Olivares*[2], *Alexander van Nuijs*[3] *and Adrian Covaci*[1], *(1)University of Antwerp, Belgium, (2)University of the Basque Country, Spain, (3)University of Antwerp, ., Belgium, (4)Flemish Institute for Technological Research (VITO), Belgium*

Ion mobility high-resolution mass spectrometry (IM-HRMS) derived collision cross section (CCS) values can serve as an additional identification parameter in suspect and non-target screening analysis (SSA/NTS) of contaminants of emerging concern (CECs) and their biotransformation products. The utilization of CCS data usually relies on the comparison of experimental datapoints with library values or predicted CCS. However, for the latter high deviations to experimental data (> 10%) have been described for many compounds. The presented studies aimed to utilize CCS-m/z trendlines (i.e., describing the relationship between the CCS value and mass-to-charge ratio) for the annotation of suspect CECs and their biotransformation products.
In a first step, indoor dust samples (n = 46) were collected from 40 different locations in Flanders, Belgium. Phthalates and quaternary ammonium compounds (QACs) were identified as two relevant contaminant classes showing high abundances and detection frequencies. Three phthalates and 21 QACs were identified at confidence level (CL) 1. Additionally, 6 suspect phthalates and 17 suspect QACs, were tentatively identified. However, none could be assigned with a CL better than 3. Therefore, the CCS values for the assigned suspects were compared with the m/z-CCS trendlines established from available reference CCS data. This approach allowed the identification of extensive homologue series for both classes. For all suspect CECs, the experimental CCS values fell within the 95th percent confidence interval calculated for the reference CCS-m/z trendlines, contributing significantly to the confidence of the compound annotation. On the basis of these examples, a discussion on an appropriate communication of the added identification confidence was conducted.
In vitro biotransformation products of three QACs, identified as the most abundant homologues in indoor dust in the abovementioned study, were studied after incubation with human liver microsomes. A total of 31 phase I metabolites were annotated, derived from 19 biotransformation . For each metabolite average CCS values (n = 6) were calculated. After comparing these values with CCS data for parent QACs, changes in CCS values following metabolism were characterized. These findings describe characteristic gaseous confirmation of QAC metabolites and are expected to facilitate metabolite annotation in future in vitro and in vivo biotransformation studies.

3.11.P-Th190 Structural Insights into Dimeric Ions of Perfluorocarboxylic Acids (PFCAs) via Ion Mobility Mass Spectrometry (IMS-MS) and In-Silico CCS Prediction

Aurore Schneiders[1]*, Johann Far*[1]*, Edwin De Pauw*[1]*, Lidia Belova*[2]*, Adrian Covaci*[2]*, Allison Fry*[3]*, Erin Baker*[3] *and Gauthier Eppe*[1]*, (1)Mass Spectrometry Laboratory, MolSys Research Unit, Chemistry Department, University of Liège, Belgium, (2)Toxicological Centre, University of Antwerp, Belgium, (3)Department of Chemistry, North Carolina State University, United States*

Per- and polyfluoroalkyl substances (PFAS) are contaminants of emerging concern, with over 7 million compounds currently inventoried. This vast number of compounds necessitates the use of non-targeted screening methods capable of identifying them. In this regard, combining ion mobility spectrometry (IMS) with liquid chromatography (LC) and high-resolution mass spectrometry offers a powerful approach, adding a supplementary separation dimension and providing collision cross sections (CCSs) as an additional identifier based on gas-phase ion density. In LC-IMS-MS experiments, with negative electrospray ionization, perfluorocarboxylic acids (PFCAs), tend to form homodimeric ions ([2M-H]-) in addition to the expected deprotonated ion ([M-H]-). This phenomenon has been noted in our study using trapped IMS (TIMS) but has also been reported using drift-tube IMS (DTIMS) and traveling-wave IMS (TWIMS). We found that these dimeric ions can dissociate after mobility separation, generating the corresponding deprotonated ion ([M-H]-). As a result, the mobilogram of the deprotonated displays several peaks for a single m/z (mass-to-charge ratio) value: one for the monomeric [M H]- ion and another for the [M H]- ion resulting from the post-IMS dissociation of the dimeric ion ([2M-H]-). This phenomenon can negatively affect the sensitivity of the method and complicate the identification process. Moreover, limited information is available on the conformations these dimers might adopt. Beyond their analytical relevance, understanding the conformations of these dimers could provide insights into the environmental fate of PFAS or their potential biological interactions. The aim of our study was therefore to propose plausible conformations for PFCA dimers using a qualitative analysis of CCS-m/z trends, complemented by in-silico geometry optimizations and CCS calculations. The computational approach we developed predicted accurate CCS values for both monomeric and dimeric ions, revealing that, in dimers, the fluorinated chains are likely in close proximity. For further research, we wonder whether similar proximity occurs when dimers form with larger cations like Na? or K+. Furthermore, we observed that certain perfluoroether carboxylic acids predominantly form dimers. Future studies should explore the impact of oxygen atoms in their fluorinated chains on dimer structure.

3.11.P Integrating Ion Mobility Separations with HRMS: Transforming Environmental Contaminant Identification and Quantification Workflows

3.11.P-Th178 Target and Non-Target Screening of Environmental Contaminants During Water Reuse by Trapped Ion-Mobility

Jan Christof Specker[1]*, Alessia Ore*[2]*, Patricia Aguilar-Alarcon*[1]*, Rick Helmus*[1]*, Milo Leon de Baat*[1]*, Antonia Praetorius*[1]*, Nora B Sutton*[2] *and Annemarie van Wezel*[1]*, (1)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (2)Environmental Technology, Wageningen University & Research (WUR), Netherlands*

The myriad of potential environmental contaminants remains a significant obstacle when analysing complex environmental samples such as waste- or drinking water, as selecting appropriate target compounds is challenging. In particular, known or unknown transformation products (TPs) necessitate the use of advanced analytical techniques for their detection. Here, trapped ion mobility (TIMS) coupled to traditional liquid chromatography-mass-spectrometry (LC-MS) creates new opportunities for advancing targeted and non-target analyses of these complex mixtures. Using ion mobility introduces a novel characterisation parameter, enhancing selectivity and sensitivity for isobaric and isomeric compounds. In this work, we show two application examples utilizing LC-TIMS-MS for the identification and analysis of chemicals of emerging concern (CECs) in the aquatic environment. In the first example, advanced treated wastewater intended for potable and non-potable reuse was analysed by target and suspect screening. The second example employed non-target screening using patRoon for the analysis of ground- and drinking water samples. Aquatic samples were extracted by solid-phase extraction (Oasis HLB or Chromabond HR-X), evaporated, reconstituted in methanol, and extracts were diluted 1:5 before analysis by LC-TIMS-MS. A wide range of 100 CECs and TPs covering pharmaceuticals, pesticides, flame-retardants, and per- and polyfluoroalkyl substances, were analysed for their extraction efficiency, chromatographic separation, their mobility and detection limit. The mobility of each compound was assessed using three different concentrations to build an internal library of CCS values and compared to available literature.

Inclusion of CCS for compound identification improved method sensitivity but CCS values for comparison are currently limited in the literature. Moreover, using CCS to identify isomers remains difficult due to similar measured mobilities, as observed for the TPs of diclofenac, ibuprofen, or carbamazepine. However, the applied workflow allowed detection limits as low as 0.55 ng/L due to the clean-up of mass spectra. Preliminary non-target screening data show that filtering by CCS effectively prioritises features, highlighting the refinements of including mobility in non-target screening workflows. Overall, this work shows the advantages of LC-TIMS-MS for analysing CECs and TPs in aquatic samples while identifying critical quality factors for future improvement.

3.11.P-Th179 Application of Trapped Ion-Mobility Spectrometry for Environmental Contaminant Detection in Advanced Treated Wastewaters
Patricia Aguilar-Alarcon[1]*, Jan Christof Specker*[1]*, Rick Helmus*[2] *and Eva de Rijke*[1]*, (1)University of Amsterdam, Netherlands, (2)Institute for Biodiversity and Ecosystem Dynamics (IBED), University of Amsterdam, Netherlands*
Trapped ion mobility spectrometry (TIMS) is an innovative technique that effectively separates ionized compounds based on their charge, shape, and size, facilitating the removal of co-eluting isomeric/isobaric species. TIMS is often combined with ultra-high performance liquid chromatography (UHPLC) and high-resolution mass spectrometry (HRMS) to enhance the reliability of chemical identification. This is achieved by translating TIMS data into collision cross-section (CCS) values. The CCS provides an estimate of the size of the ion s colliding sphere as it traverses the gas phase, serving as an extra parameter for chemical identification and enabling comparability of measured CCS values across different instruments. However, TIMS for the identification of environmental contaminants has been scarcely explored, especially in treated wastewater matrices. In this study, a total of 100 reference standards including pharmaceuticals, pesticides, and per- and polyfluoroalkyl substances were analyzed through targeted analysis in both positive and negative ion modes using UHPLC coupled with TIMS and time-of-flight mass spectrometry (UHPLC-TIMS-TOF-MS). The TIMSCCSN2 values of the reference standards were obtained, and the accuracy of these measurements was evaluated by assessing various software parameters. The average values were employed to critically assess previously reported data from different instruments, calibration workflows, and predicted values. These findings were then used to increase the sensitivity of the detection of these environmental contaminants after advanced wastewater treatments with ozonation, ceramic membrane filtration, and activated carbon using the CCS values associated to each analyte as a filter, thus reducing the interferences and background noise and allowing their detection at trace levels. The findings not only improve the identification of environmental chemicals in wastewater through targeted analysis but also contribute valuable data to the scientific community. This supports efforts toward standardization across laboratories and aids in reducing false positive identifications in non-targeted analyses.

3.11.P-Th180 An Advanced Analytical Methodology for the Simultaneous Monitoring of more than 2,500 Emerging Pollutants in Soils and Biodiversity Leveraging the Technique LC-TIMS-HRMS
Georgios Gkotsis[1]*, Eleni Panagopoulou*[2]*, Antigoni Konomi*[1]*, Nikolaos Boinis*[3]*, Faidra-Angeliki Mourtzoukou*[1]*, Reza Aalizadeh*[1]*, Nikiforos Alygizakis*[4]*, Henrik Barmentlo*[5]*, Guy Duke*[4]*, Peter Fantke*[4]*, Romana Hornek-Gausterer*[6]*, Philipp Kropf*[5]*, Oliver Machate*[7]*, Paola Movalli*[8]*, Dominik Nerlich*[7]*, Tom M. Nolte*[8]*, Susan Oginah*[9]*, Peter Oswald*[4]*, Dorte Themann*[7]*, Gabriele Treu*[7]*, Martina G. Vijver*[10]*, Jaroslav Slobodnik*[4] *and Nikolaos S. Thomaidis*[1]*, (1)National and Kapodistrian University of Athens, Greece, (2)National and Kapodistrian University of Athens, Greece, (3)Chemistry, National and Kapodistrian University of Athens, Athens, Greece, (4)Environmental Institute s.r.o., Slovakia, (5)Leiden University, Netherlands, (6)Environment Agency Austria, Austria, (7)German Environment Agency (UBA), Germany, (8)Naturalis Biodiversity Center, Netherlands, (9)Technical University of Denmark, Denmark, (10)Leiden University, Leiden, Netherlands*
Environmental pollution remains a critical global challenge as terrestrial ecosystems are continuously exposed to a diverse and dynamically changing mixture of anthropogenic chemicals, commonly referred to as emerging pollutants. Systematic monitoring of these chemicals supports the European Commission s Chemicals Strategy for Sustainability, aiming to protect the environment, wildlife, and human health through a One Health approach. High Resolution Mass Spectrometry (HRMS)-based workflows are powerful tools for the simultaneous detection of emerging pollutants, covering a wide range of substances with diverse applications and physicochemical properties, including their metabolites and transformation products. Additionally, Ion Mobility Spectrometry (IMS) provides an additional dimension of separation, enhancing the identification of chemicals in complex matrices, such as biological organisms.
Within this context, the TerraChem project aims to develop, demonstrate, and apply a novel approach that integrates monitoring, environmental modeling, data management, analytical tools, and user guidance. The overall aim is to enhance the understanding of exposure of terrestrial biota across trophic levels to the universe of environmentally relevant anthropogenic chemicals and resulting damage on biodiversity and

ecosystem services.
In the framework, aiming to expand the chemical domain accessible to post-acquisition data treatment, generic sample preparation protocols were implemented to enrich final extracts with chemicals of varying physicochemical properties. The instrumental analysis was performed using LC-TIMS-HRMS. A comprehensive 4D target screening, utilizing a database of over 2,500 emerging pollutants, revealed that terrestrial wildlife is exposed to complex mixtures of anthropogenic chemicals. The results underpin the enhanced identification capabilities provided by the TIMS dimension within established LC-HRMS workflows, leading to increased confidence in the final identification of pollutants.

Disclaimer/Disclosure: Acknowledgments: This study has received funding from the HORIZON Europe project TerraChem From soils to apex species: chemical pathways, effects and impacts on terrestrial biodiversity and ecosystem services and applications for better chemicals management (project number: 101135483), which was co-funded by the European Union and the Swiss State Secretariat for Education, Research and Innovation (SERI).

3.11.P-Th181 Suspect and Non-Targeted Screening of Halogenated Contaminants in a Stranded Killer Whale (*Orcinus orca*) using GC-HRMS hyphenated with trapped ion mobility (TIMS)
Hugo Mueller[1]*, Krishna Das*[2]*, Georges Scholl*[1]*, Emma Schymanski*[3] *and Gauthier Eppe*[1]*, (1)Mass Spectrometry Laboratory, MolSys Research Unit, University of Liège, Belgium, (2)Laboratory of Oceanology, Freshwater and Oceanic ScienCes Unit of ReSearch (FOCUS), University of Liège, Belgium, (3)Environmental Cheminformatics group, Luxembourg Centre for Systems Biomedicine, University of Luxembourg, Luxembourg, Luxembourg*
The killer whale (*Orcinus orca*) is likely the most contaminated marine mammal globally, facing extremely high levels of contaminants.Beyond well-known pollutants like legacy persistent organic pollutants (POPs), killer whale tissues likely contain various emerging and unknown contaminants, potentially leading to additional toxic impacts. In this context, this study aims to assess the advantages of using high-resolution ion mobility for the suspect and non-targeted screening of halogenated contaminants in the blubber of a stranded killer whale.
Approximately 70 mg of blubber were collected from a killer whale that stranded on the beach of De Panne, Belgium. Following a simple sample preparation, the resulting solution was analyzed using a TIMS TOFpro II mass spectrometer (Bruker, Bremen) equipped with a GC-APCI source for sample separation and ionization before IM-MS analysis.
Suspect screening was conducted for various classes of legacy (e.g., PCBs, PBDEs, OCPs) as well as emerging (e.g., PXBs) persistent organic pollutants (POPs). Overall, approximately 150 suspected POPs were tentatively confirmed, with the vast majority being PCBs (104 congeners identified). Comparison of experimental CCS with those available in our in-house database greatly contributed to the confident confirmation of these features, since CCS deviations were typically below 1%. For those features whose CCS was not present in the database, confident confirmation of the contaminant class could still be obtained by checking whether these belonged to the CCS vs m/z trendline of a specific class of halogenated POP.
For the non-targeted analysis, several compounds were identified as probable halogenated compounds, based on their mass defect and isotopic pattern, which are characteristic for halogen-bearing molecules. Here, the additional dimension of separation provided by the ion mobility was of great help in obtaining clean mass spectra. Indeed, filtering the data according to the ion mobility unable to get rid of most matrix background signal as well as other coeluting isobaric interferences, greatly improving the quality of the spectra and the identification process, especially for low signal intensity features.
Taken together, these preliminary results demonstrate the potential of using IM to enhance both suspect and non-targeted screening of halogenated contaminants in complex matrices.

3.11.P-Th182 GC-Ion Mobility-HRMS as a Novel and Powerful Alternative to Magnetic Sector MS for a Comprehensive Quantitation and Identification of Dioxins and Multiple Classes of POP
Carsten Baessmann[1]*, Arnd Ingendoh*[1]*, Miguel Angel Perez*[2]*, Hugo Mueller*[3] *and Gauthier Eppe*[4]*, (1)Bruker Daltonics GmbH & Co KG, Germany, (2)Bruker Espanola S.A., Spain, (3)MolSys Research Unit, Liège Universite, Belgium, (4)CART-National Reference Laboratory for Halogenated POPs and Food Process Contaminants, MolSys Research Unit, Liège Universite, Belgium*
For the past decades, GC-HRMS on magnetic sector instruments has been the main technique approved by the regulatory bodies for dioxin quantification, because of its high selectivity and sensitivity in food and environmental samples. Magnetic sector instruments are costly in acquisition and maintenance and require highly skilled personnel. Consequently, the obligation for applying GC-HRMS for dioxin analysis is a limiting factor for monitoring these toxic pollutants in many countries. Proposed here is a novel workflow

which combines a GC-APCI source for high sensitivity, trapped ion mobility (TIMS) as an orthogonal criterion for the dioxin quantitation, and a high-resolution, ultra-sensitive QTOF. One of the main benefits of this approach is that various classes of POP can be analyzed and quantified jointly with dioxins in a single GC run.

1 uL of a sample containing the 29 known toxic congeners (dioxins, furans, PCB) was injected into the GC (35 min run, Restek 60 mx0.25 um column). A GC-APCI source was coupled to an ion mobility QTOF (timsTOF Pro 2, Bruker) enabling fast and sensitive quantitative analysis of these different classes of POP in a single GC/HRMS run. Criteria for validation and quantification of compounds included mass accuracy, retention time, isotope pattern matching, MS/MS qualifiers and collision cross sections (CCS) from ion mobility filtering. Kendrick mass defect plots filtered specific compounds containing Cl or Br from the complete GC/MS chromatogram.

The capabilities of the combination of GC-APCI-Trapped Ion Mobility-HRMS for the confident and sensitive quantitation of POP in accordance with the performance criteria of the worldwide standard methods (EPA 1613B, EN 1948) for environmental and food samples were evaluated and validated. It is shown that GC-APCI-TIMS-HRMS is a valid alternative to traditional magnetic sector MS with the benefit of a higher analytical flexibility for more POP classes and the separation of isomers and isobars. All PCBs have been detected at an LOD of ?10-20 ppt. The dioxins were detected down to levels of 25-125 ppt, depending on the individual compound. Examples of the analysis of real-life samples like rapeseed oil, milk fat, sludge extract and ash are presented.

3.11.P-Th183 Detection and Characterization of Environmental Contaminants by Direct Analysis in Real Time (DART) Mass Spectrometry Techniques

Arnd Ingendoh[1], *Kushal Modi*[2], *Calum Bochenek*[3], *Jack Edwards*[3] *and Chrys Wesdemiotis*[4], *(1)Bruker Daltonics GmbH & Co KG, Germany, (2)Bruker Applied Mass Spectrometry, Bruker Scientific LLC, United States, (3)Department of Chemistry, The University of Akron, United States, (4)School of Polymer Science and Polymer Engineering, University of Akron, United States*

PFASs or per- and polyfluoroalkyl substances is a widely used term for a broad family of chemicals that possess at least one fully fluorinated methyl or methylene group (CF3 or CF2 , respectively). In most cases, these molecules are extensively fluorinated, with long aliphatic chains saturated with C F bonds. PFASs have been commonly used in everyday life for almost a century, in products such as pharmaceuticals, pesticides, fabrics, nonstick cookware, adhesives, cosmetics, and even food packaging. Although these fluorinated substances may undergo chemical breakdown at their functional groups (typically carboxylic acid, sulfonic acid, or ether linkages), the high energy of the C F bond (488 kJ/mol) leads to their endured persistence and inertness in the environment. If ingested, PFASs can interfere with biological processes causing various health ailments and diseases. Another class of environmental contaminants that can cause adverse health effects are para-phenylenediamine (PPD) antioxidant additives in commercial materials, such as automobile tires. Once released into water or air, these diamines are easily oxidized to quinones which are toxic. Here, we demonstrate a sensitive, mass spectrometry (MS) based analytical procedure for the detection and quantitation of such environmental contaminants. It involves the use of the DART ambient ionization method coupled to inline ion mobility (IM) separation and tandem mass spectrometry (MS/MS) characterization. This DART-IM-MS/MS approach proceeds with practically no sample preparation, requires very small sample quantity, allows for fast sample fractionation by collision cross-section in the IM dimension, and provides conclusive structural identification of the separated sample components based on mass accuracy and fragmentation pattern in the MS and MS/MS dimensions, respectively; these advantages will be demonstrated with the analysis of several PFAS and PPD compounds.

3.11.P-Th184 One Step Closer to Accurate Quantification of Micro- and Nanoplastics Using Cyclic Ion Mobility Mass Spectrometry

Kas Houthuijs[1], *Justine Bissonnette*[2], *Nikita Harvey*[2], *Marja Lamoree*[1], *Karl Jobst*[2] *and Frederic Been*[1], *(1)Chemistry for Environment & Health, Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands, (2)Department of Chemistry, Memorial University of Newfoundland, St. John s, Canada*

Micro- and nanoplastics (MNPs) have been recognized as an environmental threat and there is global concern about their presence in humans. To investigate human exposure and the toxicological effects of MNPs, robust methods to identify and quantify these plastic particles are essential. Pyrolysis coupled to gas chromatography mass spectrometry (Py-GC-MS) is currently the method of choice to analyse MNPs in complex biomatrices.

A novel direction in this field is the use of cyclic ion mobility spectrometry (cIMS) hyphenated to high-resolution MS (HRMS). The improved separation and resolution that can be achieved with Py-GC-cIMS-

HRMS provide additional identification confidence and reduce spectral background noise, which improves method specificity and limit of detection. However, this novel instrumentation requires renewed method optimization, as for example optimal quantification markers ions are different compared to traditional Py-GC-MS.
In this contribution, we used a non-target approach to identify MS features that uniquely correlate to the polymers PE, PP, PS, PET, PVC and PMMA. Peak picking and integration of the experimental data resulted in 35,365 MS features to which linear calibration models could be fitted. Based on each model s coefficient of determination (R2), optimal markers for each polymer were identified. This non-target approach was then extended to visualize unique pyrolytic products for the different polymers as homologue series, which were found to be consistent with literature. Data-independent acquisition of tandem MS data was used to annotate highly-correlating features, providing increased identification confidence and insight into the pyrolysis and ionisation processes.
By employing an experimental design that varied the sample matrix and ion source humidity, the quantification performance of the method could be further improved. Of all polymers, pyrolysis products of PET and PMMA appear to be most influenced by these factors. We observed that markers show intensity fluctuation up to 3 orders in magnitude in blood compared to blank matrix. These effects may induce large quantification errors if not considered, as MNP quantitation typically relies on out-of-matrix calibration. Finally, it was found increasing ion source humidity can increase marker response factors up to 3 orders of magnitude, which provides a route towards increasing the limit of detection for MNP quantification with Py-GC-cIMS-HRMS.

3.11.P-Th185 Are Collision Cross Section Values Comparable Across Different Ion Mobility Separation Instrumental Designs? An Interlaboratory Evaluation
*Nikiforos Alygizakis[1], Konstantina Diamanti[2], Lubertus Bijlsma[3], Teresa Steininger-Mairinger[4], Jaroslav Slobodnik[1], Nikolaos S. Thomaidis[2] and **Alberto Celma**[5], (1)Environmental Institute, Slovakia, (2)Laboratory of Analytical Chemistry, Department of Chemistry, National and Kapodistrian University of Athens, Greece, (3)Environmental and Public Health Analytical Chemistry, Research Institute for Pesticides and Water (IUPA), University Jaume I, Spain, (4)Institute of Analytical Chemistry, BOKU University, Austria, (5)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden*
The hyphenation of ion mobility separation (IMS) to high resolution mass spectrometry (HRMS) has shown clear benefits for the identification of contaminants of emerging concern in complex environmental samples. IMS separates ions based on their shape, size and charge; and permits the measurement of collision cross section (CCS) values for the analyzed ions. This value gives an overall estimation of the size of the colliding sphere created by the ion when moving across a gas phase. However, the deviation error of CCS values for the different adducts, e.g., [M+H]+, [M-H]-, [M+Na]+, etc., between different IMS-HRMS technologies and/or instrumental designs is not fully clear. In this NORMAN interlaboratory exercise, we aim at evaluating the comparability of the measured CCS values across different instrumental platforms, establishing a maximum CCS value deviation from third-party measurements as well as identifying relevant analytical metadata that should be shared alongside CCS values for enhanced data quality.
To this end, a total of 76 reference standards comprising pesticides, pharmaceuticals, personal care products as well as other organic micropollutants have been measured in 19 laboratories, each of them with their own in-house methods. The study yielded 6,675 CCS data points (2,916 for [M+H]+, 620 for [M+K]+, 1,520 for [M+Na]+ and 1,619 for [M-H]-). This CCS measurement dataset was analyzed to address critical questions regarding CCS repeatability, quantitative evaluation of the average expected error, investigation of protomer generation factors, and evaluation of the impact of different calibration methods and IMS technologies on CCS accuracy. The dataset served as a valuable resource for confronting analytical challenges related to CCS measurement variability and provides a basis for future standardization efforts across laboratories. Overall, with the increasing availability of online databases as well as studies reporting CCS values, the IMS community needs clear and robust evidence on the possibility of comparing their own data with third-party data as demonstrated in this study.

Disclaimer/Disclosure: Authors acknowledge the NORMAN reference laboratories for their participation in the collaborative trial. The work presented in this publication is part of a project that has received funding from the NORMAN Association under the Annual Joint Proposals of Activities 2023.

3.11.P-Th186 Ion-Mobility Derived CCS-m/z Trendlines for Improved Annotation Confidence of Contaminants of Emerging Concern and their Biotransformation Products
***Lidia Belova**[1], Mikel Musatadi[2], Maosen Zhai[1], Maarten Roggeman[1], Giulia Poma[3], Celine Gys[1], Paulien*

Cleys[1], Fatima den Ouden[1], Patrick Berghmans[4], Jan Peters[4], Maitane Olivares[2], Alexander van Nuijs[3] and Adrian Covaci[1], (1)University of Antwerp, Belgium, (2)University of the Basque Country, Spain, (3)University of Antwerp, Belgium, (4)Flemish Institute for Technological Research (VITO), Belgium
Ion mobility high-resolution mass spectrometry (IM-HRMS) derived collision cross section (CCS) values can serve as an additional identification parameter in suspect and non-target screening analysis (SSA/NTS) of contaminants of emerging concern (CECs) and their biotransformation products. The utilization of CCS data usually relies on the comparison of experimental datapoints with library values or predicted CCS. However, for the latter high deviations to experimental data (> 10%) have been described for many compounds. The presented studies aimed to utilize CCS-m/z trendlines (i.e., describing the relationship between the CCS value and mass-to-charge ratio) for the annotation of suspect CECs and their biotransformation products.
In a first step, indoor dust samples (n = 46) were collected from 40 different locations in Flanders, Belgium. Phthalates and quaternary ammonium compounds (QACs) were identified as two relevant contaminant classes showing high abundances and detection frequencies. Three phthalates and 21 QACs were identified at confidence level (CL) 1. Additionally, 6 suspect phthalates and 17 suspect QACs, were tentatively identified. However, none could be assigned with a CL better than 3. Therefore, the CCS values for the assigned suspects were compared with the m/z-CCS trendlines established from available reference CCS data. This approach allowed the identification of extensive homologue series for both classes. For all suspect CECs, the experimental CCS values fell within the 95th percent confidence interval calculated for the reference CCS-m/z trendlines, contributing significantly to the confidence of the compound annotation. On the basis of these examples, a discussion on an appropriate communication of the added identification confidence was conducted.
In vitro biotransformation products of three QACs, identified as the most abundant homologues in indoor dust in the abovementioned study, were studied after incubation with human liver microsomes. A total of 31 phase I metabolites were annotated, derived from 19 biotransformation . For each metabolite average CCS values (n = 6) were calculated. After comparing these values with CCS data for parent QACs, changes in CCS values following metabolism were characterized. These findings describe characteristic gaseous confirmation of QAC metabolites and are expected to facilitate metabolite annotation in future in vitro and in vivo biotransformation studies.

3.11.P-Th187 Sample-Specific Machine Learning Modelling for CCS Prediction to Improve Compound Identification in Non-Target Analysis

***Lucas Ferrando** and Anneli Kruve, Department of Materials and Environmental Chemistry MMK, Sweden*
In current non-target mass-spectrometry (MS) experiments for environmental screening, more than 95% of measured spectra can not be correctly annotated. By leveraging machine learning (ML) modelling of additional analytical dimensions, the analyst can prioritize candidates through comparison of the prediction with the measured value. Most instruments in non-target analysis encompass a chromatograph as well as an MS, and some of them also feature a third separation dimension in the form of ion-mobility (IM). Although IM has been shown to be semi-orthogonal to MS and thus less informative than for example chromatography, IM instruments are capable of separating structural as well as geometric isomers and even diastereoisomers, making it a powerful complementary dimension. A typical ML workflow for collision cross-section (CCS) prediction relies on having the (putative) molecular structure of the compound in question to compute a molecular representation. To that end, experimental CCS databases covering different regions of the chemical space have been generated. Although CCSs are more reproducible than retention times, database merging still poses a problem difficult to tackle. On the other hand, training models on a sole database, that usually covers a smaller region of the chemical space, limits their application to certain samples. Our approach tries to tackle the applicability domain by building sample-specific models. ML will thus be trained on the most relevant data to the sample in question in terms of chemical space coverage. To do so, a molecular representation is inferred from each MS feature using ML. All representations are then used to train a CCS regression model. In a parallel way and independently to regression training, a candidate list is generated for each MS feature through available software. From each candidate structure, the same type of molecular representation as before is calculated and used to obtain a CCS value through the previously trained regression model. We will also implement probabilistic approaches to make statistical comparisons with the measured CCS value for candidate structure prioritization. The main challenge will be selecting a suitable molecular representation that (a) can be calculated from both the MS as well as from the structure and (b) can encode all the relevant information to predict CCS. We note that no stereochemistry will be involved. Its influence on CCS prediction is yet to be determined.

3.11.P-Th188 Overcoming Analytical Challenges in Xenometabolome Assessment - From Isomer Separation to Comprehensive MS/MS Coverage Combining LC-HRMS with TIMS-PASEF

Dimitrios E. Damalas[1], *Carsten Baessmann*[2] *and Nikolaos S. Thomaidis*[1], *(1)Laboratory of Analytical Chemistry, Department of Chemistry, National and Kapodistrian University of Athens (NKUA), Greece, (2)Bruker Daltonics GmbH & Co KG, Germany*

Xenometabolome characterization, encompassing the identification of biotransformation products (bio-TPs) modified by an organism in response to xenobiotic exposure, is essential for gaining insights into the mechanisms of toxicity and potential ecological impacts. Despite the technological advancements in LC-HRMS, the identification of bio-TPs remains challenging. A major challenge is the vast number of different biotransformation reactions, while some of them are still under investigation. On the other hand, even well-characterized reactions (e.g., hydroxylation) may lead to different isomeric bio-TPs. Sensitivity limitations can hinder low-abundance bio-TP detection, preventing a complete understanding of metabolic pathways. Finally, a crucial analytical challenge in the context of unknowns identification is the limited availability of experimental MS/MS spectra, highlighting the need for comprehensive data-dependent acquisition (DDA) modes.

To overcome the aforementioned challenges, this study presents a multidimensional analytical workflow integrating complementary chromatographic separations with trapped ion mobility spectrometry (TIMS), HRMS, and mobility-aligned DDA acquisition methods (Parallel Accumulation Serial Fragmentation - PASEF), to maximize analytical evidence generation. Zebrafish embryos exposed to benzotriazoles served as a case study, to demonstrate the workflow s effectiveness for bio-TPs identification.

The use of orthogonal separation techniques (RPLC, HILIC, TIMS) expanded the available analytical space, providing robust evidence for identifying both suspects and unknowns. TIMS dimension facilitated the separation of isomeric bio-TPs (OH-sulfate-MeBT) and reduced background interferences, leading to cleaner, more informative spectra. The improved S/N facilitated the detection of new low-abundance bio-TPs enabling a more complete xenometabolome assessment. Mobility-aligned DDA (PASEF) delivered extensive MS/MS coverage (>70% of precursors), capturing high-quality MS2 data even for low-intensity precursors, which is essential for confident identification of unknown bio-TPs. In conclusion, the integration of TIMS and PASEF with RPLC/HILIC-HRMS establishes a data-rich workflow that facilitates xenometabolome characterization, achieving high-confidence identifications and addressing key analytical challenges.

3.11.P-Th189 Investigating the Effect of Combining Trapped Ion Mobility Spectrometry with HRMS and its Resulting Data Acquisition Modes in Untargeted Workflows for Identifying Emerging Contaminants

Konstantina Diamanti[1], *Dimitrios E. Damalas*[1], *Carsten Baessmann*[2], *Birgit Schneider*[2] *and Nikolaos S. Thomaidis*[3], *(1)Laboratory of Analytical Chemistry, Department of Chemistry, National and Kapodistrian University of Athens, Greece, (2)Bruker Daltonics GmbH & Co KG, Germany, (3)Bruker Daltonics GmbH & Co KG, Greece*

Untargeted workflows using liquid chromatography coupled to high resolution mass spectrometry (LC-HRMS) play an important role in the identification of emerging contaminants (ECs). However, the effectiveness of untargeted workflows is influenced by the data acquisition schemes. This study investigates how incorporating trapped ion mobility spectrometry (TIMS) and Parallel Accumulation-Serial Fragmentation (PASEF) data-dependent acquisition (DDA) mode into LC-HRMS workflows impacts data quality and the identification of unknowns. TIMS separates ions in the gas phase based on their different size- and shape-to-charge ratio, while PASEF, enabled by TIMS, provides fast DDA MS/MS spectra without compromising sensitivity by synchronising the MS/MS precursor selection with TIMS separation.

To assess the impact of these technologies, standard solutions and spiked samples (blood serum, urine and wastewater) containing >200 emerging contaminants were prepared at different concentration levels and analyzed with and without TIMS dimension. The target compounds were treated as unknowns to evaluate the performance of the untargeted workflow. We specifically evaluated cases of missing MS/MS spectra, low-quality MS/MS spectra and co-fragmentation, across different acquisition modes. Moreover, we investigated the ability of TIMS to separate co-eluting isomeric/isobaric compounds, reduce background interferences, and enhance signal, facilitating the detection of low concentration analytes in complex matrices.

The addition of TIMS and PASEF in LC-HRMS significantly improved the identification of unknowns . TIMS dimension and mobility filtering increased sensitivity, leading to the detection of more features. PASEF acquisition provided a higher number of MS/MS spectra with improved quality, characterised by higher intensities and more fragments in some cases. This resulted in more confident compound identification, particularly in complex matrices (wastewater) and at lower concentration levels. Our findings demonstrate that TIMS and PASEF enhance the performance of untargeted LC-HRMS workflows, by generating multidimensional high quality data, leading to more comprehensive and reliable identification of unknown ECs.

Disclaimer/Disclosure: The authors thank the Hellenic Foundation for Research and Innovation under the 3rd call for H.F.R.I. scholarships for PhD candidates (Grant number: 6627), and SETAC Europe for the SETAC Europe 2025 Registration Grant - SETAC Europe Students.

3.11.P-Th190 Structural Insights into Dimeric Ions of Perfluorocarboxylic Acids (PFCAs) via Ion Mobility Mass Spectrometry (IMS-MS) and In-Silico CCS Prediction

***Aurore Schneiders**[1], Johann Far[1], Edwin De Pauw[1], Lidia Belova[2], Adrian Covaci[2], Allison Fry[3], Erin Baker[3] and Gauthier Eppe[1], (1)Mass Spectrometry Laboratory, MolSys Research Unit, Chemistry Department, University of Liège, Belgium, (2)Toxicological Centre, University of Antwerp, Belgium, (3)Department of Chemistry, North Carolina State University, United States*

Per- and polyfluoroalkyl substances (PFAS) are contaminants of emerging concern, with over 7 million compounds currently inventoried. This vast number of compounds necessitates the use of non-targeted screening methods capable of identifying them. In this regard, combining ion mobility spectrometry (IMS) with liquid chromatography (LC) and high-resolution mass spectrometry offers a powerful approach, adding a supplementary separation dimension and providing collision cross sections (CCSs) as an additional identifier based on gas-phase ion density. In LC-IMS-MS experiments, with negative electrospray ionization, perfluorocarboxylic acids (PFCAs), tend to form homodimeric ions ([2M-H]-) in addition to the expected deprotonated ion ([M-H]-). This phenomenon has been noted in our study using trapped IMS (TIMS) but has also been reported using drift-tube IMS (DTIMS) and traveling-wave IMS (TWIMS). We found that these dimeric ions can dissociate after mobility separation, generating the corresponding deprotonated ion ([M-H]-). As a result, the mobilogram of the deprotonated displays several peaks for a single m/z (mass-to-charge ratio) value: one for the monomeric [M H]- ion and another for the [M H]- ion resulting from the post-IMS dissociation of the dimeric ion ([2M-H]-). This phenomenon can negatively affect the sensitivity of the method and complicate the identification process. Moreover, limited information is available on the conformations these dimers might adopt. Beyond their analytical relevance, understanding the conformations of these dimers could provide insights into the environmental fate of PFAS or their potential biological interactions. The aim of our study was therefore to propose plausible conformations for PFCA dimers using a qualitative analysis of CCS-m/z trends, complemented by in-silico geometry optimizations and CCS calculations. The computational approach we developed predicted accurate CCS values for both monomeric and dimeric ions, revealing that, in dimers, the fluorinated chains are likely in close proximity. For further research, we wonder whether similar proximity occurs when dimers form with larger cations like Na+ or K+. Furthermore, we observed that certain perfluoroether carboxylic acids predominantly form dimers. Future studies should explore the impact of oxygen atoms in their fluorinated chains on dimer structure.

3.11.P-Th191 Comparison of Electrospray Ionisation with Unispray in Ion Mobility-High-Resolution Mass Spectrometer for Suspect and Non-Target Screening

***Victoria Eriksson**[1], Kalpana Munnnuru Singamshetty[2], Johan Dahlen[1], Foon Yin Lai[3] and Thanh Wang[1], (1)Department of Physics, Chemistry and Biology (IFM), Linkoping University, Sweden, (2)Department of Thematic Studies (TEMA), Linkoping University, Sweden, (3)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden*

Ion mobility (IM) coupled with high-resolution mass spectrometry (HRMS) has become more and more popular for suspect and non-target screening (SNTS) of environmental samples, where ion mobility can increase the confidence in identification of unknown compounds. High mass accuracy measurements with HRMS facilitates the discovery of unknown and unexpected compounds in environmental samples. However, the downside is the lower sensitivity compared to targeted approach using low-resolution mass spectrometers. This can inhibit the detection of low-abundance compounds in SNTS. Unispray is a newer type of ion source which has been shown previously to yield a higher sensitivity for target analysis in comparison to the commonly used electrospray ionization (ESI). Our aim is to investigate the suitability of using Unispray for chemical screening in environmental matrices. For this purpose, the ion source parameters are optimized for both Unispray and ESI for a broad range of environmentally relevant compounds with different physio-chemical properties. Comparison will thereafter be made regarding their intensities, signal-to-noise, reproducibility, robustness, and precision, among others. Furthermore, the extent of in-source fragmentation and MS2 spectra similarity are compared for the compounds. Lastly, samples with different matrices (drinking water, wastewater, and dust) will be used for matrix effect comparison as well as their suitability in SNTS based on performance on detecting unknown compounds.

To facilitate the SNTS, an in-house spectral library has been constructed with MS2 fragments from ESI for a wide range of different compounds suitable for its use in open-source data processing software. Additionally, the spectral library contains the CCS values, which can increase the confidence in the identification of compounds. Furthermore, a workflow has been developed to process high-resolution ion mobility data with open-source software. From our preliminary results, Unispray seems well-suited to be applied for SNTS since it in general shows 3-15 times higher signal intensities, 2-17 times higher signal-to-noise, and 2-17 times lower limits of detection compared to ESI, for the measured compounds. Hence, Unispray shows good promise to better detect lower abundance compounds in real samples than ESI.

3.11.P-Th192 Exploring the Integration Benefits of Ion Mobility Mass Spectrometry (IMS) and MS2 Analytical Workflows with MALDI-HRMS for Small Molecule Analysis; Zebrafish Exposed to Xenobiotics as a Case Study

Eleni Aleiferi*, Dimitrios E. Damalas, Eleni Panagopoulou and Nikolaos S. Thomaidis, Laboratory of Analytical Chemistry, Department of Chemistry, National and Kapodistrian University of Athens (NKUA), Greece*

Matrix assisted laser desorption/ionization mass spectrometry (MALDI-MS) is a powerful analytical tool, traditionally utilized for the analysis of large molecules like proteins and glycans. However, its application in small molecules analysis can been challenging due to interfering matrix-related ion in the lower m/z mass range. Despite that, the growing interest in omics approaches for unveiling toxicity and disease pathways, especially with the integration of imaging techniques, has increased the relevance of MALDI in small molecules analysis. Coupling ion mobility spectrometry (IMS) with high-resolution mass spectrometry (HRMS) techniques, adds a size-based separation dimension, enabling the separation of isomeric and isobaric species. This is particularly relevant for omics approaches, such as lipidomics, where identifying structurally similar molecules is crucial. IMS also provides collision cross section (CCS) values, further enhancing the confidence and specificity of analyte identification. Therefore, the integration of IMS with MALDI, promises significant advancements in small molecules analysis. This study explores the benefits of integrating trapped ion mobility (TIMS) with MALDI-HRMS and ion mobility-aligned MS/MS workflows for lipidomic analysis of zebrafish (*Danio rerio*) exposed to various xenobiotics. Zebrafish are a powerful model organism for toxicology studies due to their physiological similarities to humans. Various MALDI-MS matrices, including 2,5-DHB, ?-CHCA, were initially screened at different matrix concentrations to optimize lipid profiling. Analysis was performed on a MALDI-QTOF-MS timsTOF flex instrument (Bruker, Germany) with both TIMS on and TIMS off modes, and in both positive and negative ionization modes. MALDI-TIMS-HRMS analysis unveiled the lipidomic profile of zebrafish after xenobiotic exposure. The TIMS dimension enhanced the MALDI identification workflow. The additional CCS value information of the detected lipids, combined with the TIMS-aligned MS/MS data, greatly facilitated lipid annotation and enhanced the identification confidence. This approach highlights the potential of MALDI-TIMS-HRMS for advancing small molecule analysis in toxicological studies.

3.12 Passive Sampling: Monitoring of Environmental Contaminants Fluxes Across Spatial and Temporal Scales

3.12.T-01 Furthering the Capabilities of Diffusive Gradient Passive Sampling for Per- and Polyfluoroalkyl Substances

***Jarod Snook**[1], Jitka Becanova[2], Simon Vojta[1] and Rainer Lohmann[1], (1)University of Rhode Island, United States, (2)University of Rhode Island, Kingston, United States*

Per- and polyfluoroalkyl substances (PFAS) are chemical pollutants of growing concern for stakeholders including regulators, water managers, and consumers of contaminated seafood or drinking water. Due to their ubiquity, persistence in the environment, and potential for toxicity at low environmental concentrations, it is necessary to have convenient and reliable methods to measure PFAS in natural waters a challenge still being addressed by the scientific community. Passive sampling methods (in situ pre-concentration of PFAS) may be suitable for many monitoring situations. One passive sampling design successfully employed for historic contaminants (e.g., methylmercury) is the diffusive gradient in thin film sampler (DGT), but the design must also be validated for PFAS. Here, we iterate on previous PFAS-DGT studies by introducing a re-designed diffusive gradient sampler for PFAS in water and show that it reliably measures 25 PFAS in water consistent with diffusion theory. Diffusion through the agarose hydrogel construction material was measured in the laboratory, and the sampler was evaluated in a combination of laboratory and field deployments. Diffusion and whole-sampler uptake rates consistently agreed with model predictions within ?50% relative percent difference, including when tested at cold temperature (5?C). Because of its accuaracy and easy applicability to any PFAS compound, we suggest a model-based framework for predicting DGT sampling rate. In field and laboratory deployments, DGT samplers measured PFAS concentrations within ?28% of grab sample results on average in each case; better performance than co-deployed polyethylene tube passive samplers. In sum, we expand the experimentally-validated PFAS analyte list from 16 compounds (combined previous studies) to 25 PFAS, introduce a modeling framework to predict DGT uptake of even untested PFAS, and demonstrate the DGT sampler s precise and accurate performance in two field deployment campaigns (one requiring significant temperature adjustment). Based on the evidence in this study, the DGT passive sampler is a promising tool for consistently and accurately passive sampling PFAS in natural waters.

3.12.T-02 Application of Chemical Activity in Environmental Risk Assessment Using a Rapid Equilibrating Sampler: A Case Study on Perfluorooctane Sulfonate (PFOS)

Sophia S.H. Hsu[1]*, Frank Gobas*[2] *and Barry C. Kelly*[2]*, (1)Simon Fraser University, Azimuth Consulting Group, Canada, (2)Simon Fraser University, Canada*

Current approaches for evaluating risks of contaminant exposure to human health and ecological receptors rely on the comparison of exposure and toxicological effect or no-effect concentrations. A key limitation of this approach is the inherent difficulty of comparing substances across different environmental media. Additionally, these methods are often restricted to one-to-one comparisons between exposure and effects concentrations in a single medium such as water or sediment. Consequently, much available information for risk assessments is not used. In this study, we explore the application of a chemical activity-based approach to facilitate the comparison of concentrations of PFAS among different environmental media and enhance the risk assessment process. Chemical activity is a thermodynamic quantity that describes the effective concentration for a substance in a sample, accounting for factors such as chemical s interaction with the media, temperature, and pressure. As such, chemical activity provides a way to better describe chemical partitioning, bioaccumulation, and toxic modes of action. It also enables the direct comparison of concentrations of a substance in different media. This study focuses on the application of activity on the behaviour and toxicity of perfluorooctane sulfonate (PFOS). A rapid-equilibrating thin-film passive sampler was developed and calibrated with a wide range of concentrations of PFOS in water and buffered saline. The thin-film sampler was subsequently used as a proxy to estimate the chemical activity of PFOS in samples. Results show a distinct relationship between the concentration measured in the thin-film and the activity of PFOS in the incubation solution at environmentally relevant concentrations. The thin-film sampler also effectively estimates the concentration, sorptive capacity, as well as partition coefficients for PFOS in serum albumin. Overall, we illustrate the measurement of chemical activity through rapid equilibration and demonstrate its potential as an integrative tool for supporting more comprehensive and effective environmental risk assessments.

3.12.T-03 Fluxes of Bisphenols and Phthalates on Trap Sediments from a Tropical Reef System of the Southern Gulf of Mexico

Laura Salazar Remigio[1]*, Guadalupe Ponce-Velez*[2]*, Hugo F. Olivares Rubio*[2]*, Omar Amador Munoz*[3]*, Antonio Zoilo Marquez Garcia*[4] *and Jorge Feliciano Ontiveros-Cuadras*[2]*, (1)Posgrado en Ciencias del Mar y Limnología, Universidad Nacional Autonoma de Mexico, Mexico, (2)Unidad Academica de Procesos Oceanicos y Costeros, Instituto de Ciencias del Mar y Limnología, Universidad Nacional Autonoma de Mexico. Ciudad Universitaria, Mexico, (3)Laboratorio de Especiacion Qu mica de Aerosoles Organicos Atmosfericos, Instituto de Ciencias de la Atmosfera y Cambio Climatico, Universidad Nacional Autonoma de Mexico. Cto. Exterior s/n Cd. Universitaria, Mexico, (4)Laboratorio de Geología, Departamento de Hidrobiología, Universidad Autonoma Metropolitana Unidad Iztapalapa, Mexico*

The Veracruz Reef System is a natural protected area located off the coast of Veracruz in the southern Gulf of Mexico. It has been declared a Ramsar site and biosphere reserve with great biological, tourist, and economic importance. Various pollutants are present due to anthropic activity, river discharges, and marine and coastal currents. Bisphenols and phthalate acid esters or phthalates are emerging contaminants associated with plastic pollution since they are used in their manufacture. They are easily separated from these synthetic materials, making their presence in sediments feasible. In this work, sediment parameters such as organic matter and carbonates were quantified such as bisphenols and phthalates by gas chromatography coupled to a triple quadrupole mass spectrum after organic extraction and derivatization in trap sediments to determine the flux of these pollutants to the Veracruz Reef System. The high values of organic matter and carbonates were 1.8 % and 34%, respectively, mainly sand and silt. The fluxes were calculated by the product of the sediment flux by the concentration of each pollutant and were 54.95 ?g m-2 days -1 for the sum of bisphenols and 1588.75 ?g m-2 days -1 for the sum of phthalates. The statistical analyses showed a positive correlation between organic matter and phthalates but not with bisphenols. In the sites with more significant anthropic influence, bisphenols' values were relatively higher, while the most protected sites registered higher values for phthalates. However, their presence in a natural environment indicates the alteration caused by anthropic activities. This work represents the first record of emerging contaminants in a Mexican reef ecosystem subject to enormous anthropogenic pressures. This study's contribution is the generation of the baseline on these two important groups of plasticizers in a Mexican region of great marine importance. This supports the need to establish monitoring focused mainly on the phthalates that are not commonly studied in coastal and marine ecosystems.

3.12.T-04 Chasing Equilibrium Partitioning with Water Using Silicone Chemometers

Elisa Rojo-Nieto[1]*, Sylvain Zonkpoedjre*[1] *and Annika Jahnke*[2]*, (1)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ) & Institute for Environmental Research (IFER), RWTH Aachen University, Germany*

Although partitioning between passive samplers and sediment or tissue in aquatic organisms may occur relatively quickly over several hours to days or weeks, approaching equilibrium partitioning with water presents a major challenge for highly hydrophobic organic compounds (HOCs), bringing equilibrium out of reach even after a few months. Our gold standard is to achieve equilibrium partitioning with water in a reasonable time frame to enable direct comparison of the concentrations in chemometers (passive equilibrium samplers for multimedia environments) equilibrated with other compartments. In this work, we focus on a small and shallow lake ecosystem with stable conditions for exploring a new approach aimed to reach equilibrium partitioning between silicone chemometers and water in a reasonable time frame. We used silicone-coated jars in situ (coated with Dowsil DC-2577 Low VOC, Dow Chemical Company, USA) for equilibration with water, with coating thicknesses of 0.6, 1.0, 2.0 and 3.5 µm (n = 2 each). In order to challenge the establishment of equilibrium, a novel device with three pumps was used to pump water out of the jars on site, while they were submerged in the water (94 h). Targeted analytes were hexachlorobencene (HCB), pyrene, phenanthrene, dichlorodiphenyldichloroethylene (DDE), PCB44, PCB52, PCB101, PCB153 PCB138 and PCB118.
We used two approaches for calculating the equilibrium concentration in the chemometers exposed to water, and we modeled the uptake of the studied chemicals into the µm-thin coatings of the chemometers under the scenario of different water boundary layer thicknesses (?). Using coated jars with different thicknesses for each sample to assess the equilibration status, we could confirm the attainment of equilibrium for pyrene (log KOW 4.93), phenanthrene (log KOW 4.35) and HCB (log KOW 5.86). Furthermore, in the case of DDE and the PCBs, equilibrium was attained in the two thinner thicknesses. The results of the modeling indicated that if we consider a turbulent system (? = 10 µm) and an equilibration time of ~4 d, the thinner chemometers will be close to 95% of equilibrium for the PCBs, except for PCB138, agreeing with the results obtained. This exploratory work opens up for passive equilibrium sampling in water using silicone-coated jars. Equilibrium for compounds with log KOW up to 6 has been achieved with water in a few days using silicone chemometers, extending their applicability to a new environmental compartment.

3.12.P-Th196 Passive Sampling and Non-Targeted Screening for Emerging Contaminants in Multi-Basin: Prioritization, Identification and Quantification

lei tong[1]*, Drew Szabo*[2]*, Angelica Islas*[2]*, Jun Li*[2]*, Alexandra Kate Richardson*[3]*, Leon Barron*[3] *and Alistair Boxall*[2]*, (1)China University of Geosciences, China (Mainland), (2)University of York, United Kingdom, (3)Imperial College London, United Kingdom*

Emerging contaminants (ECs), encompassing a diverse range of pharmaceuticals, pesticides and industrial chemicals, pose a growing challenge to water quality and ecosystem health. Their chemical diversity and patterns of use often render traditional grab sampling methods inadequate for capturing the dynamic and fluctuating nature of pollutants in river systems, along with the restricted number of detectable target substances, resulting in an incomplete assessment of water pollution. To overcome these limitations, based on the energy-saving, environmentally friendly and reusable properties of passive sampling methods, combining them with non-targeted screening techniques would be an effective solution. 3D-printed portable passive sampling devices (PSDs) equipped with HLB disks were deployed at 19 river sites (different environment and pollution sources) from Yorkshire, UK, over seven days across different seasons. Meanwhile, composite river samples were collected in the same period using automatic samplers for comparison. A total of 38,829 features were extracted from passive samplers deployed in 19 river sites across Yorkshire, UK. Robust validation has successfully extracted 98% of spiked substances and a true positive rate (TPR) of 0.71 and accuracy of 0.99 for matches with MassBank. A total of 220 features were matched with the MassBank online spectral library and 2,503 were annotated by SIRIUS CSI:FingerID. 69 features had high-confidence library match (cosine similarity > 0.9; explained peaks > 2), resulting in assigned confidence of Level 2a. A further 91 features had fair library match (cosine similarity > 0.7) and were assigned Level 3c. Of the features matched confidently with MassBank, 12% have reported pharmaceutical applications, and a further 7% have drug and other medication information. 4% are food-related substances, and 3% have agrochemical uses. 24% of identified substances do not have any associated information accessible via PubChem. Identification and classification results from SIRIUS are in preparation, and analysis of feature abundance with respect to geographical location is under review. Our preliminary results indicate the viability of an integrated assessment approach for watershed health utilizing a combination of passive sampling and non-targeted screening techniques.

3.12.P-Th204 New Mathematical Tools to Model Accumulation in Diffusion Gradients in Thin-films (DGT) Passive Samplers Deployed in Soils and Sed

Josep Galceran[1]*, Guanlei Li*[2]*, Jordi Sans-Duno*[3]*, Carlos Rey-Castro*[1]*, Lauren Yabuki*[1]*, Carol de Faria*[1]*, Jaume Puy*[1]*, Joan Cecilia*[4] *and Yue Gao*[2]*, (1)Departament de Qu mica, F sica i Ci ncies Ambientals i del S l. Universitat de Lleida, and AGROTECNIO-CERCA, Spain, (2)Chemistry Department (AMGC), Vrije Universiteit Brussel, Belgium, (3)Departament de Quimica, Fisica i Ciencies Ambientals i del S l. Universitat de Lleida, and AGROTECNIO-CERCA, Spain, (4)Departament de Matematica. Universitat de Lleida, and AGROTECNIO-CERCA, Spain*

The passive sampler Diffusion Gradients in Thin-films (DGT) is a very popular technique for dynamic speciation. DGT can be applied to natural waters, soil or sediments for a wide range of analytes, including cationic/anionic inorganic species, organic contaminants, etc. DGT devices comprise a holder, a binding/resin gel disc, a diffusive gel layer and a filter. The mass of analyte accumulated in the binding disc during the deployment time is quantified, from which an operational concentration cDGT is computed. In soils, the resupply parameter R is obtained by dividing cDGT by the total analyte concentration in the porewater. Previous modelling tools such as the one-dimensional DGT-induced Fluxes in Soils and Sediments code (1D-DIFS), fail to consider partially labile dissolved complexes or adsorption saturation at the soil sites. Our new open-source code SSOCO (Sediments and SOils with COmplexation) solves the diffusion-reaction equations including effects such as complexation of the target analyte (M) with a generic dissolved ligand, specific diffusion coefficients and porosities in gel and soil phases, and reaction rate constants for complexation and soil adsorption. Notably, SSOCO is not constrained by the assumption of excess soil adsorption sites. Also, we have analytically solved (using Laplace transforms) the particular case of a single species M diffusing through the gel and soil phases. With a suitable definition of an effective porosity and average diffusion coefficients, this analytical solution can be used in the limit of fast complexation and adsorption kinetics. The presentation will discuss the impact of several parameters (kinetic rate constants of complexation and adsorption, soil porosity, diffusive gel thickness, etc.). We also suggest a practical strategy, supported by numerical simulation, that involves using variable gel thicknesses to obtain the R peak within the typical measurement window. These mathematical tools could, in principle, be adapted to other passive samplers that rely on the reaction-diffusion of the analyte.

3.12.P-Th205 Mobility, Bioavailability and Toxicity of Sediment Contaminants

Betty Chaumet[1]*, Anna Sobek*[2]*, Elena Gorokhova*[3]*, Stefano Bonaglia*[4]*, Hoi Shing Lo*[5]*, Alyssa Azaroff*[3] *and*

Sofi Jonsson[2], (1)Environmental Science, Stockholm University, Stockholm, Sweden, (2)Environmental Science, Stockholm University, Sweden, (3)Stockholm University, Sweden, (4)Gothenburg University, Sweden, (5)Department of Environmental Science, Stockholm University, Sweden
The MOBILITY project investigates the risks posed by contaminated sediments, focusing on the release, bioavailability, and toxicity of hydrophobic organic contaminants (HOCs) like polycyclic aromatic hydrocarbons (PAHs). These sediments act as sinks for persistent pollutants, which can be released into the water column through sediment resuspension, increasing their bioavailability and ecological risks. The project aimed to: (i) identify sediment properties affecting contaminant release, (ii) link dissolved and bioaccumulated HOC concentrations to biological effects, and (iii) demonstrate the utility of passive samplers for monitoring and risk assessment.

Experimental studies used artificial sediments spiked with four PAHs, assessing the impact of turbidity, hydrophobicity, and sediment grain size (PSD) on contaminant release and uptake by algae (Ceramium tenuicorne). Passive samplers quantified freely dissolved PAHs, enabling comparisons of bioavailability across experimental compartments using chemical activity as a common metric. Biological effects were assessed via photosynthesis inhibition.

Results revealed that turbidity significantly influenced PAH release, with high turbidity enhancing desorption of hydrophobic PAHs (e.g., fluoranthene), while low turbidity favored diffusion of less hydrophobic PAHs (e.g., acenaphthene). Sediment grain size also played a role, as finer sediments produced higher turbidity but lower dissolved organic carbon release, while coarser sediments facilitated PAH diffusion through organic matter. PAH uptake by algae correlated with passive sampler measurements, confirming their utility for bioavailability assessment. Algae exposure resulted in photosynthesis inhibition, highlighting PAH toxicity.

The project demonstrated the value of passive samplers for quantifying freely dissolved contaminant concentrations, which better reflect bioavailability and toxicity than traditional sediment analyses. Recommendations include incorporating passive samplers into regulatory frameworks, accounting for site-specific sediment properties, and standardizing passive sampler protocols to improve risk assessments and monitoring practices.

Disclaimer/Disclosure: This project was funded by the Swedish Environmental Protection Agency (Naturvårdsverket)

3.12.P Passive Sampling: Monitoring of Environmental Contaminants Fluxes Across Spatial and Temporal Scales

3.12.P-Th193 AQUA-GAPS/MONET-Derived Concentrations and Trends of PFAS Across Global Waters

*Sarit Kaserzon[1], Kristie Thompson[1], Rainer Lohmann[2], Derek C.G. Muir[3], Katerina Sebkova[4], Petra Pribylova[4] and **Branislav Vrana**[4], (1)Queensland Alliance for Environmental Health Sciences (QAEHS), The University of Queensland, Australia, (2)Graduate School of Oceanography, University of Rhode Island, United States, (3)Environment and Climate Change Canada, Aquatic Contaminants Research Division, Canada, (4)RECETOX, Masaryk University, Czech Republic*
Per- and polyfluoroalkyl substances (PFAS) are a large group of compounds that have been used in countless industrial, commercial and manufacturing processes and products for decades. The use and waste disposal of PFASs have resulted in widespread environmental contamination. Due to the high stability and mobility PFASs have been detected in all environmental compartments.
Despite restrictions on the use of certain PFAS, the legacy use of consumer products containing PFAS, their environmental persistence, and diffuse sources are likely to contribute to ongoing PFAS contamination of surface waters for years to come, highlighting the need for ongoing environmental monitoring for human and environmental risk assessment. Under the Stockholm Convention Global Monitoring Programme, water has been identified as a core matrix for monitoring PFAS, based on the evidence that water is the main transport medium for these chemicals in the environment. Moreover, the open ocean water column has been suggested to be the final sink of PFAS.
Passive sampling is emerging as an important tool for the monitoring and identification of PFAS in waters as they provide in situ concentration of samples, in some cases can increase sensitivity and provide a more representative image of PFAS contamination in comparison to grab sampling due to time-integrative

character of sampling.
In the present study, we present results on PFAS in surface waters from across the world, monitored within the AQUA-GAPS/MONET network between 2020-2024. A microporous polyethene tube (MPT) passive sampler was applied in the campaign and a centralized sample analysis that allows for direct comparison of data while minimizing measurement uncertainty. The MPT sampler has been successfully calibrated and validated in surface water for a broad range of PFAS with long-term deployment capability and sensitivity.
The main objectives of the current study were to (i) deploy passive samplers for PFAS at a wide range of lake, estuarine, coastal, and oceanic sites across the world; (ii) determine background concentrations of PFAS across the waters of the world; (iii) assess the relation of dissolved PFAS concentrations with latitude, temperature, and population density; (iv) investigate the PFAS patterns at the sampling sites using suspect screening and non-targeted analysis methods and (v) use the information gained from the first set of deployments to optimize site distribution for long-term monitoring efforts.

3.12.P-Th194 Long-Term Monitoring of Hazardous Substances in Czech River Ecosystems
Hedvika Roztocilova*, Czech Hydrometeorological Institute, Czech Republic*
Environmental monitoring of hazardous substances in aquatic ecosystems is essential for understanding pollution patterns and protecting environmental and human health. Persistent organic pollutants and heavy metals pose significant risks due to their ability to bioaccumulate in organisms, biomagnify through food chains and often act as carcinogens or endocrine disruptors. This study aims to evaluate temporal trends of selected contaminants across various environmental matrices in major Czech rivers over the period 2012 to 2023. The monitoring program includes annual sampling of biota (biofilm, fish, benthic organisms), abiotic matrices (sediments, suspended particulate matter) and passive samplers from 43 river sites. Passive samplers provide complementary data on dissolved contaminant concentrations, offering valuable information about pollutant bioavailability that cannot be obtained from solid matrix sampling. Results reveal distinct distribution patterns among different matrices. For example benthic invertebrates show highest benzo[a]pyrene accumulation compared to fish, while mercury concentrations are highest in adult fish, regularly exceeding environmental quality standards. Systematic monitoring of more matrices is required for a comprehensive assessment of aquatic ecosystem contamination due to uneven pollutant distribution. However, despite the extensive number of monitored parameters, environmental quality standards are established for only a limited number of substances, which remains a significant challenge for result interpretation.

3.12.P-Th195 Assessing the Spatial Distribution and Ecological Risks of Freely Dissolved PAHs in Sediments Using the Ex-Situ Method in Highly Industrialized Bay of South Korea
Hyeonju Jung*, Jin-Su Oh and Gi Beum Kim, Gyeongsang National University, "Korea, Republic of"*
Organic carbon, including black carbon or soot, can strongly bind hydrophobic organic contaminants (HOCs), thereby reducing their bioavailability. As a result, predicting contaminant concentrations or ecotoxicity in organisms based on total concentrations (Ctotal) in sediments may lead to overestimations. The bioavailable concentration of contaminants in sediments is represented by the freely dissolved concentration (Cfree) in sediment porewater, which is considered suitable for assessing ecological toxicity. Previous studies have employed the in-situ method using passive samplers deployed directly in the field to measure Cfree in porewater. However, the in-situ method often requires extended exposure times and, in some cases, the involvement of specialized personnel, such as scuba divers. In contrast, the ex-situ method offers the advantage of shorter exposure durations and lower costs for Cfree measurement. In this study, the ex-situ method was used to measure the Cfree of 16 priority PAHs in sediments from 33 sites in Busan Bay, South Korea, an area of concern for PAHs contamination from industrial activities. The concentrations of ?15PAH (excluding naphthalene) ranged from 6 to 67 ng/L. Higher concentrations (36 67 ng/L) were observed at sites with high shipping activities, including ship repairs. Across all sampling sites, acenaphthylene exhibited the highest relative contribution, exhibiting 3 4 benzene rings were the most predominant PAHs. To assess the ecological risk to benthic organisms, interstitial water toxicity units (IWTUs) were calculated. The ?IWTU values ranged from 0.01 to 0.12, remaining below the threshold value of 1, suggesting no anticipated ecotoxicological risk to benthic organisms. Despite the low ?IWTU values, continuous environmental monitoring of freely dissolved PAHs in sediment porewater using the ex-situ method is necessary in pollution-prone areas with intensive industrial activities, such as Busan Bay.

Disclaimer/Disclosure: This work was supported by Development of Source Identification and Apportionment Methods for Toxic Substances in Marine Environments program of the Korea Institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220534) and Basic Science Research Program through the National Research Foundation of Korea(NRF) funded by the Ministry of Education(RS-2024-00413748).

3.12.P-Th196 Passive Sampling and Non-Targeted Screening for Emerging Contaminants in Multi-Basin: Prioritization, Identification and Quantification

***Lei Tong**[1], Drew Szabo[2], Angelica Islas[2], Jun Li[3], Alexandra Kate Richardson [4], Leon Barron[5] and Alistair Boxall[2], (1)China University of Geosciences, China (Mainland), (2)University of York, United Kingdom, (3)Department of Environment and Geography, University of York, United Kingdom, (4)Imperial College London, South Kensington, United Kingdom, (5)Environmental Research Group, Imperial College London, United Kingdom*

Emerging contaminants (ECs), encompassing a diverse range of pharmaceuticals, pesticides and industrial chemicals, pose a growing challenge to water quality and ecosystem health. Their chemical diversity and patterns of use often render traditional grab sampling methods inadequate for capturing the dynamic and fluctuating nature of pollutants in river systems, along with the restricted number of detectable target substances, resulting in an incomplete assessment of water pollution. 3.12.P-Th197 Application of Passive Sampling to Identify Groundwater Pollutants from Different Sources in Irrigated Areas

***Vit Kodes**[1], Roman Grabic[2], Marketa Ackermanova[1], Hedvika Roztocilova[1], Alina Sadchenko[2], Helena Svecova[2], Petr Valek[1] and Libor Mikl[1], (1)Czech Hydrometeorological Institute, Czech Republic, (2)University of South Bohemia in České Budějovice, Czech Republic*

Various micropollutants may contaminate groundwater. One of the sources of these contaminants is agricultural practice, where a variety of pesticides is used for plant protection. Another source of contamination can be river water that is often used for irrigation. River contamination depends on the sources of the compounds, that can be, for example, discharged wastewater, surface water runoff from agricultural or urban land, etc. In addition to conventional groundwater sampling, passive samplers for hydrophilic compounds were used in order to characterize a pollution pattern that may be influenced also by irrigation.

In total 11 boreholes in or close by irrigated areas in different parts of the Czech Republic were selected for sampling. AttractSPE® POCIS HLB for Groundwater (Affinisep, France) passive samplers were used in the study. One set of samples was collected prior and the second one at the end of irrigation season in 2024. Samples were analyzed using LC-MS/MS (targeted analysis) a LC-HRMS (suspect screening). Several pollution patterns were found even within the same irrigation area, where either agriculture pollutants (pesticides) or municipal pollutants (pharmaceuticals) or industrial pollutants (benzotriazoles etc.) prevail. The most frequently found contaminants were metabolites of chloroacetanilide and triazine herbicides as agriculture pollutants, caffeine, carbamazepine and sulfamethazine as municipal pollutants and 5-4-methyl 1H-benzotriazole as an industrial pollutant. Additionally we found several new groundwater pollutants such as 2-naphthalenesulfonic acid, triethyl citrate, 4-acetamidoantipyrine and 1,3-diphenylguanidine (municipal and industrial pollutants) that may be also relevant for the other parts of the Czechia territory.

Disclaimer/Disclosure: The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QK23020018.

3.12.P-Th198 Passive Sampling as Seawater Monitoring Procedure for Environmental Control at Various Marine Locations Throughout Italy

***Laura Caiazzo**[1], Barbara Benedetti[2], Marco Capello[3], Tamara Cibic[4], Laura Cutroneo[3], Marina Di Carro[2], Valentina Esposito[4], Michela D'Alessandro[4], Irene Geneselli[3], Emanuele Magi[2], Marco Munari[5], Maria Rita Montereali[1], Luisa Parrella[6], Simona Schiavo[6] and Sonia Manzo[6], (1)CR ENEA Casaccia, Italy, (2)Department of Chemistry and Industrial Chemistry, University of Genoa, Italy, (3)DISTAV University of Genoa, Italy, (4)Oceanography Section, National Institute of Oceanography and Applied Geophysics-OGS, Italy, (5)Department of Biology, University of Padova, Italy, (6)CR ENEA Portici, Italy*

Concerning the ecological effects of chemical pollutants in aquatic systems, it is crucial assessing the condition of the marine ecosystem today, as it affects the economic and social lives of millions of people around the world. The significant deficiencies in monitoring the presence of contaminants of various chemical groups lead to international challenges in findings of increasingly innovative monitoring techniques, associated with their ecological and ecotoxicological impact measurements.

In the framework of the RETURN project, our group is focused on optimizing sampling campaigns for monitoring traditional and emerging contaminants and the assessing of their ecotoxicological effects and ecological risk.

Passive sampling (PS) methods are distinguished by their ease of maintenance and straightforward design. It is possible to identify pollution at levels below ng/L, as they measure the time-weighted average concentrations of both organic and inorganic substances in a range of matrices, including water.

Monitoring seawaters at several locations around Italy, including Genoa **H**arbour, Panarea, Vulcano, Ischia, Trieste, and Grado-Marano lagoon, is the aim of our research, together detecting any ecological risks associated with chemical pollutants under climate change scenarios.

For each location, from two to six sites were chosen for the positioning of PS, as well as for sediments and water samplings. Using a multiparametric probe, physical measurements specifically, temperature, conductivity, pH, and oxygen will be integrated.

For 21 days, the Semi-Permeable Membrane Device (SPMD) and the Polar Organic Chemical Integrative Sampler (POCIS) will be used to sample organic chemicals with lipophilic and hydrophilic substances, respectively. Mercury and metals will be sampled using Diffusive Gradients in Thin Films (DGT) for seven days.

Aliivibrio fischeri, *Artemia salina*, and *Dunaliella tertiolecta* are the organisms that will be utilised in a battery of three bioassays on polar and non-polar passive sampler extracts to find ecotoxicological implications at the investigated sites.

According to preliminary findings from the initial experiment, which was conducted in Genoa Harbour from December 2023 to January 2024, passive sampling is the simplest method to quantify both organic and inorganic pollutants. Therefore, from an analytical, practical, and economical perspective, these initial data serve as a first validation of the effectiveness of passive samplers.

3.12.P-Th199 Development of Alabaster-Cement Composite Disks for DGT

***Yutaka Kameda** and Emiko Fujita, Chiba Institute of Technology, Japan*

Passive sampling techniques are valuable for estimating time-weighted average concentrations (TWAc) of various chemicals in water over both short and extended periods. However, estimating TWAc requires in-situ sampling rates that depend on variables such as water temperature, flow velocity over the absorbent, and other environmental conditions. Recently, alabaster disks developed by Glanzmann et al. have been proposed as an alternative to performance reference compounds (PRCs), which can be challenging to select for specific target compounds. Alabaster disks offer a simple and reliable means of estimating in-situ sampling rates, as their weight loss can be measured precisely with a balance. However, their use in long-term field experiments is limited by their rapid dissolution within a few days.

In this study, we developed alabaster-cement composite (ACC) plates to extend the use of Diffusive Gradients in Thin-films (DGT®) passive samplers for monitoring over several weeks. In preliminary

experiments, we prepared small plates from mixtures of alabaster and cement in varying concentrations, suitable for DGT® passive samplers. We then deployed DGT® samplers with ACC plates in coastal waters near Okinawa to determine in-situ weight-loss rates. Results indicated that an alabaster concentration of 15– 17% was optimal for durability and sampling performance.
Further laboratory calibration tests were conducted to assess the relationship between the weight-loss rates of ACC plates and water velocity. Ongoing calibration tests are now examining sampling rates of UV-absorbing chemicals in different water flow conditions using DGT® samplers with these composite plates. This study demonstrates the potential of ACC plates for DGT® samplers to reliably estimate TWAc of UV-absorbing compounds in coastal waters and beach environments over extended periods.

3.12.P-Th200 EXPOSO-METER: Characterizing of Lifelong Exposure to Environmental Mixtures of Pollutants (Exposome) of High-Trophic Arctic Marine Mammals

Elisa Rojo-Nieto[1]*, Eva B. Reiter*[1]*, Iker Alvarez-Mora*[2]*, Angelina Miller*[3]*, Christian Sonne*[4]*, Rune Dietz*[4] *and Annika Jahnke*[5]*, (1)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ) & Research Centre for Experimental Marine Biology and Biotechnology (PIE), University of the Basque Country (UPV/EHU), Germany, (3)Institute for Environmental Research (IFER), RWTH Aachen University, Germany, (4)Department of Ecoscience, Arctic Research Centre (ARC), Aarhus University, Denmark, (5)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ) & Institute for Environmental Research (IFER), RWTH Aachen University, Germany*

EXPOSO-METER aims to assess environmental exposure to chemicals through practical, economical, and easy-to-use silicone-based passive equilibrium sampling. These allow identification, characterization, and direct comparison of mixtures of environmental pollutants across multiple organisms, species, and matrices. The chemometers provide advanced chemical profiling that integrates the lifelong exposome of environmental organisms to mixtures of pollutants. By defining them as a common reference phase, the chemical concentrations in the chemometers at equilibrium can be directly compared between organisms, circumventing normalizations. In this work, silicone chemometers have been used to analyze regulated and emerging hydrophobic organic pollutants present in 84 lipid-rich tissues from Arctic marine mammals collected in the surroundings of Tasiilaq and Kulusuk, at the southeast coast of Greenland. Samples of pilot whales, white-sided dolphins, white-beaked dolphins, narwhals, orcas and polar bears were analyzed. Around 100 compounds were quantified by gas chromatography coupled to high-resolution mass spectrometry (HRMS), including polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), pyrethroids (PYRs), chlorinated hydrocarbons (CHCs), organochlorine pesticides (OCPs), musks, UV filters and antioxidants. The results indicate that PCBs and OCPs were the predominant compound groups across all species when considering the fraction of each group of compounds in the total mixture. There was substantial variation between species, with, e.g., PCBs ranging from 35% in white-beaked dolphins to 68% in polar bears. Other groups of chemicals, such as musks, PAHs, and PYRs, showed largely differing percentages across species, ranging over two orders of magnitude. The results also indicate interspecies differences in contaminant exposure, showing a clustering by species when a principal components analysis is applied, but no clear intraspecies differences, evaluated as sex- or age-related patterns. To further extend the list of explored pollutants, especially among the legacy compounds, further additional processing based on high-resolution filtering (HRF) score and NIST library search is currently being applied in Compound Discoverer 3.3. Within this project, chemometers will help to capture and understand the exposome in Arctic top predators regarding mixtures of environmental pollutants.

Disclaimer/Disclosure: The authors acknowledge funding of first-time appointments of excellent women scientists (EXPOSO-METER, W2/W3-126). Some of the analytical instruments used in this study are part of the major infrastructure initiative CITEPro (Chemicals in the Environment Profiler) funded by the Helmholtz Association.

3.12.P-Th201 Pioneering Pollutant Detection: A Novel Passive Sampling Method for Analysing Persistent Organic Pollutants in Antarctic Sea Ice

Moritz Kielmann[1]*, Matthias Brenner*[2]*, Hendrik Wortmann*[1] *and Gesine Witt*[1]*, (1)HAW Hamburg, Germany, (2)Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany*

The project recording the baseline before the change: First steps towards an integrated chemical and

biological pollution and effects assessment off Dronning Maud Land aims to investigate the concentrations of bioavailable anthropogenic pollutants and their effects on Antarctic ecosystems. By examining pollutants like polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and organochlorine pesticides, this study underscores the significance of noninvasive sampling methodologies that maintain the pristine balance of these ecosystems.
Materials and Methods: The Antarctic approach involves transporting non-living biota samples, snow, ice, and water from the Atka Bay ice shelf to Neumayer Station III, where sample preparation is performed without altering the environment. This noninvasive capability is crucial for operating within the constraints of the Antarctic's pristine ecosystems. Methodological development for the project focuses on comparing the efficacy of Stir Bar Sorptive Extraction (SBSE) with solid-phase extraction (SPE). The evaluation of analytical parameters emphasizes sustainability, reproducibility, stability, and sensitivity, aligning scientific goals with environmental stewardship in the Antarctic context. In this project stir bars coated with polydimethylsiloxane (PDMS) are used for the determination of POPs in snow, ice and water samples. The SBSE method is coupled to thermal desorption (TD)-GC-MS to determine ultratrace level (sub-ng/L to ng/L) of POPs in Antarctic aqueous samples. A stir bar (Twister; GERSTEL GmbH) coated with 24 µl of PDMS is used for SBSE.
Results and Discussion: Preliminary experiments focused on optimizing SBSE parameters, revealing high sensitivity and reproducibility. Main experiments further validated the SBSE-GC/MS method's robustness under challenging conditions. Calibration with concentration standards ensured precise quantification, demonstrating the method's effectiveness in detecting and quantifying targeted pollutants at low concentrations.
Conclusions: This research established a robust SBSE-GC/MS protocol with high sensitivity and precision. The method proved repeatable and accurate, withstanding challenging Antarctic conditions, thus offering a reliable tool for understanding the distribution and impacts of anthropogenic pollutants in the region. These advancements support ongoing global conservation efforts while maintaining the region's environmental integrity.

Disclaimer/Disclosure: The authors thank the German Research Foundation (DFG) for the financial support of the project (Project number WI1410/13-1) and the team of Neymayer III station Antarctica for their support.

3.12.P-Th202 Laboratory Performance Study on Chemical Analysis of Hydrophobic and Hydrophilic Compounds in Two Aquatic Passive Samplers

Branislav Vrana[1]*, Kees Booij*[2]*, Celia Martins Bento*[3]*, Steven Crum*[3] *and Roman Grabic*[4]*, (1)RECETOX, Masaryk University, Czech Republic, (2)PaSOC, Netherlands, (3)Wageningen Environmental Research, Netherlands, (4)Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, University of South Bohemia in České Budějovice, Czech Republic*

Quality assurance and quality control of chemical analyses are fundamental for analyses in laboratories, but also for passive sampling-based environmental assessments. The present study reports on a proficiency testing (PT) program, organised by WEPAL-QUASIMEME, for the chemical analysis of hydrophobic organic compounds (HOC) in silicone passive samplers and polar organic compounds (POC) in polar organic chemical integrative samplers (POCIS). A PT development exercise for passive sampling of HOC was initiated in 2014. Since then, six and two rounds of the exercise have been organised for the analysis of HOC and POC, respectively. The design of the study was common passive samplers were deployed for several weeks in surface water or treated wastewater, and homogenised sampler aliquots were distributed to participants for chemical analysis by methods routinely established in their laboratories. The number of participants in all rounds varied from 15 and 25 for HOCs and from 17 to 18 for POCs. Analysed HOC groups included polycyclic aromatic hydrocarbons, polychlorinated biphenyls, organochlorinated pesticides and polybrominated diphenyl ethers, whereas POC included pharmaceuticals, currently used pesticides and PFAS. The primary focus of the study was on the variability of the chemical analysis of passive samplers rather than on variability associated with sample preparation, deployment, and modelling, but the consequences for the uncertainty in estimates of aqueous concentrations are discussed. The median between-laboratory coefficients of variation (CV) of HOC analysis in silicone sampler over the previous five rounds of the PT was 32%, but the previous two rounds of POC analysis in POCIS resulted in a much higher CV of 50%. The variability for POC is high compared with the requirements of environmental monitoring programs. Repeated exercise allows laboratories to improve their performance from lessons learned in the previous rounds. The figures from previous rounds indicated especially that the elevated uncertainty of POC data reported from polar passive samplers is not only associated with the inherent variability of sampling, but also the insufficient quality of the laboratory analysis. The implications are that proficiency testing programs may give more realistic estimates of uncertainties in chemical analysis than within-laboratory quality control programs and that these high uncertainties should be taken into account in environmental assessments.

3.12.P-Th203 Determining Polyoxymethylene-Water Partition Coefficients for 67 Polycyclic Aromatic Compounds (PACs) and Applying Them to Determine the Contaminant Availability in Thermally Treated Contaminated Soil

Ayan Au Musse[1], *Anja Enell*[2] *and Maria Larsson*[1], *(1)MTM Research Center, Orebro University, Sweden, (2)Swedish Geotechnical Institute, Sweden*

Due to the different physiochemical properties of polycyclic aromatic compounds (PACs), the environmental behavior and fate of these compounds are different. This is the result of some compounds being more polar, e.g., oxygenated PACs and NSO-heterocyclic PACs, which results in them being more mobile in the environment. As soil has the ability to act as both a sink and secondary source of organic contaminants like polycyclic aromatic compounds, when remedial efforts are conducted, a question that needs to be investigated is whether the remedial efforts have any impact on the contaminant availability and consequently its environmental mobility and toxicity.

Passive sampling methods such as the polyoxymethylene (POM) method facilitates the determination of the freely dissolved concentration of the organic contaminants of interest, i.e., PACs in this study. By utilizing the POM method to determine the availability of PACs prior to and after remedial efforts have been conducted, both the effectiveness of the remediation technique implemented and any changes in contaminant availability can be assessed.

Currently, POM-water partitioning coefficients have been established for 33 PACs. Therefore, in this study, the number of PACs with determined POM-water partition coefficients have been expanded from 33 to 67 compounds, encompassing native, alkylated, oxygenated, and NSO-heterocyclic PACs. These partition coefficients will be used to determine the soil porewater concentrations in soil samples taken prior to and after thermal remediation of a former gasworks site to determine whether there are any changes in the soil porewater concentrations after remedial efforts have been conducted.

3.12.P-Th204 New Mathematical Tools to Model Accumulation in Diffusion Gradients in Thin-Films (DGT) Passive Samplers Deployed in Soils and Sed

Josep Galceran[1], *Guanlei Li*[2], *Jordi Sans-Duno*[3], *Carlos Rey-Castro*[1], *Lauren Yabuki*[1], *Carol de Faria*[1], *Jaume Puy*[1], *Joan Cecilia*[4] *and Yue Gao*[2], *(1)Departament de Química, Física i Ciències Ambientals i del Sòl, Universitat de Lleida, and AGROTECNIO-CERCA, Spain, (2)Chemistry Department (AMGC), Vrije Universiteit Brussels, Belgium, (3)Departament de Química, Física i Ciències Ambientals i del Sòl, Universitat de Lleida, and AGROTECNIO-CERCA, Spain, (4)Departament de Matematica. Universitat de Lleida, and AGROTECNIO-CERCA, Spain*

The passive sampler Diffusion Gradients in Thin-films (DGT) is a very popular technique for dynamic speciation. DGT can be applied to natural waters, soil or sediments for a wide range of analytes, including cationic/anionic inorganic species, organic contaminants, etc. DGT devices comprise a holder, a binding/resin gel disc, a diffusive gel layer and a filter. The mass of analyte accumulated in the binding disc during the deployment time is quantified, from which an operational concentration cDGT is computed. In soils, the resupply parameter R is obtained by dividing cDGT by the total analyte concentration in the porewater. Previous modelling tools such as the one-dimensional DGT-induced Fluxes in Soils and Sediments code (1D-DIFS), fail to consider partially labile dissolved complexes or adsorption saturation at the soil sites. Our new open-source code SSOCO (Sediments and SOils with COmplexation) solves the diffusion-reaction equations including effects such as complexation of the target analyte (M) with a generic dissolved ligand, specific diffusion coefficients and porosities in gel and soil phases, and reaction rate constants for complexation and soil adsorption. Notably, SSOCO is not constrained by the assumption of excess soil adsorption sites. Also, we have analytically solved (using Laplace transforms) the particular case of a single species M diffusing through the gel and soil phases. With a suitable definition of an effective porosity and average diffusion coefficients, this analytical solution can be used in the limit of fast complexation and adsorption kinetics. The presentation will discuss the impact of several parameters (kinetic rate constants of complexation and adsorption, soil porosity, diffusive gel thickness, etc.). We also suggest a practical strategy, supported by numerical simulation, that involves using variable gel thicknesses to obtain the R peak within the typical measurement window. These mathematical tools could, in principle, be adapted to other passive samplers that rely on the reaction-diffusion of the analyte.

Disclaimer/Disclosure: the Spanish Ministry of Science and Innovation (Projects PID2019-107033GB and PID2020-117910GB-C21 funded by MCIN/AEI/10.13039/ 501100011033); MCIN/AEI for CdF predoctoral fellowship; European Union´s Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 101034288 for LY.

3.12.P-Th205 Mobility, Bioavailability and Toxicity of Sediment Contaminants

Betty Chaumet[1]*, Anna Sobek*[2]*, Elena Gorokhova*[3]*, Stefano Bonaglia*[4]*, Hoi Shing Lo*[5]*, Alyssa Azaroff*[3] *and Sofi Jonsson*[2]*, (1)Environmental Science, Stockholm University, Stockholm, Sweden, (2)Environmental Science, Stockholm University, Sweden, (3)Stockholm University, Sweden, (4)Gothenburg University, Sweden, (5)Department of Environmental Science, Stockholm University, Sweden*

The MOBILITY project investigates the risks posed by contaminated sediments, focusing on the release, bioavailability, and toxicity of hydrophobic organic contaminants (HOCs) like polycyclic aromatic hydrocarbons (PAHs). These sediments act as sinks for persistent pollutants, which can be released into the water column through sediment resuspension, increasing their bioavailability and ecological risks. The project aimed to: (i) identify sediment properties affecting contaminant release, (ii) link dissolved and bioaccumulated HOC concentrations to biological effects, and (iii) demonstrate the utility of passive samplers for monitoring and risk assessment.

Experimental studies used artificial sediments spiked with four PAHs, assessing the impact of turbidity, hydrophobicity, and sediment grain size (PSD) on contaminant release and uptake by algae (*Ceramium tenuicorne*). Passive samplers quantified freely dissolved PAHs, enabling comparisons of bioavailability across experimental compartments using chemical activity as a common metric. Biological effects were assessed via photosynthesis inhibition.

Results revealed that turbidity significantly influenced PAH release, with high turbidity enhancing desorption of hydrophobic PAHs (e.g., fluoranthene), while low turbidity favored diffusion of less hydrophobic PAHs (e.g., acenaphthene). Sediment grain size also played a role, as finer sediments produced higher turbidity but lower dissolved organic carbon release, while coarser sediments facilitated PAH diffusion through organic matter. PAH uptake by algae correlated with passive sampler measurements, confirming their utility for bioavailability assessment. Algae exposure resulted in photosynthesis inhibition, highlighting PAH toxicity.

The project demonstrated the value of passive samplers for quantifying freely dissolved contaminant concentrations, which better reflect bioavailability and toxicity than traditional sediment analyses. Recommendations include incorporating passive samplers into regulatory frameworks, accounting for site-specific sediment properties, and standardizing passive sampler protocols to improve risk assessments and monitoring practices.

Disclaimer/Disclosure: This project was funded by the Swedish Environmental Protection Agency (Naturvårdsverket)

3.12.P-Th206 Atmospheric Deposition of Airborne Microplastics in Urban Background Site in Helsinki

Markus Sillanpaa[1]*, Tatu Martinmaki*[1]*, Hilkka Timonen*[2] *and Sanna Saarikoski*[2]*, (1)Finnish Environment Institute (Syke), Finland, (2)Finnish Meteorological Institute, Finland*

Urban environments are increasingly affected by microplastic and tire wear rubber pollution, which pose ecological and human health risks. Since the production of plastics is annually increasing and their applications are broadening, there are potentially myriad types of microplastics sources. Microplastics have been shown to spread in the environment via rivers, wastewater treatment plants, stormwaters, soils and atmosphere. Even though these pathways have been recognized and explored, the results are often not comparable partly due to the unharmonized methodology. In this study, the influence of sampling height and the repeatability of sampling are investigated.

Wet and dry deposition samples were collected as three parallel samplings at a height of 4 m (60.20288, 24.96125) and 15 m (60.20342, 24.96088) from ground level in Kumpula campus of University of Helsinki (N60.20, 24.96) that represents an urban background site. The 14-day samples were collected with in-house, plastic-free samplers (sampling area 20 cm in diameter) between April 8 and May 20, 2024.

Air quality data and meteorological data including temperature, wind speed and direction, relative humidity and precipitation were continuously collected at the SMEAR III sampling station (60.20288, 24.96125). Samples were analyzed with a gas chromatography-mass spectrometer (GC-MS; Shimadzu QP2020NX) coupled with a microfurnace pyrolizer (Py; Frontier Laboratories EGA-PY-3030D). The vertical distribution of the mass concentrations of four plastics (polyethene, polypropene and polystyrene) and tire rubbers (styrene butadiene and natural rubber) will be presented. In addition, the deviations between the three parallel samplings during different events (snowing, raining and dry period as well as varying pollen conditions) will be discussed.

Disclaimer/Disclosure: The authors thank Research Council of Finland for funding the project Abundance, characteristics and significance of nano- and microplastics in urban air (ACINMUA) (funding decisions 354844 and 354845).

3.12.P-Th207 Ambient Air Contamination: European Assessment of Pesticide Residues in Ambient Air Using Passive Sampling

***Adelcia Veiga**, Wageningen University and Research (WUR), Netherlands*

The intensive and widespread use of pesticides, sometimes including misuse, has led to their detection in various environmental matrices, including ambient air. Pesticides are particularly important in agriculture for plant protection and subsequently increased yields. At the same time, agricultural practices, particularly spraying, are a significant source of pesticide residues in rural and surrounding areas. Some of these residues, e.g. organic pollutants and some current-use pesticides, persist in the air and can travel long distances. However, knowledge of the distribution and the atmospheric transport of pesticides is still incomplete. This study aims to assess the occurrence and possible levels of multiple pesticide residues in European ambient air using passive air sampling as a harmonized and emerging cost-effective method. This study was part of the monitoring campaign of the SPRINT project covering 10 European countries and primary crop types in Europe, under conventional (CONV), and organic (ORG) system. Ambient air sampling occurred during the growing season using passive samplers (TIEM, Germany), which combined polyurethane foam (PUF) and polyester (PEF) filters. For PEF filters, Glyphosate and aminomethylphosphonic acid (AMPA) were analyzed using liquid chromatography-tandem mass spectrometry (LC-MS/MS), with a modified QuEChERS extraction method. PUF filter extractions were analyzed through LC MS/MS and GC MS/MS. Out the 161 compounds analyzed, 75 were quantified, and 8 were not approved in the EU at the sampling date (2021). Glyphosate (100%), AMPA (75%), and pendimethalin (70%) are the most frequently quantified residues. DDE p,p', a banned pesticide, was detected in 25% of the samples. Our results revealed the occurrence of multiple pesticide residues in the ambient around both conventional and organic fields. The number of pesticides quantified per site ranged from 3 to 26 residues. Across all the Case Study Sites (CSS), the highest number of residues next to conventional fields occurred in the Netherlands (n = 26), while the highest number adjacent to organic fields occurred in Portugal (n = 26).
Results show several remarkable patterns on pesticide residue mixture profiles. Complex mixtures of pesticides are ubiquitously spread in ambient air suggesting the need for a systematic monitoring of pesticide in ambient air within agricultural and surrounding areas.

3.12.P-Th208 Passive Sampling of Persistent Organic Chemicals Under Free Tropospheric Conditions

***Baris Yaman**[1], Matthew MacLeod[1] and Bo Yuan[2], (1)Unit of Contaminant Chemistry, Department of Environmental Science, Stockholm University, Sweden, (2)Department of Chemistry, Norwegian University of Technology and Science, Norway*

The free troposphere (FT) is defined as the middle and upper part of the troposphere that dynamically extends from the top of the planetary boundary layer (PBL) up to the tropopause. Compared to the PBL, the FT is characterized by lower atmospheric pressure, increased wind speed, and high solar radiation causing differences in the physicochemical behaviors of organic chemicals. High-altitude regions are in near-constant contact with the FT, and thus provide the opportunity to investigate the levels and behaviors of organic pollutants in such unique conditions. Many studies have reported persistent organic chemicals (POCs) in remote environments like the Antarctic and Tibetan Plateaus, and Himalayas that clearly emphasize long-range atmospheric transport (LRAT) and cold-condensation effect. However, the role of FT in these processes still needs to be clarified. Moreover, previous studies often focus on specific altitudes and lack data across altitudinal gradients. Therefore, it is crucial to reach sites where FT conditions occur at different frequencies and where episodes in which air parcels from the PBL are transported to the site vary. Chacaltaya Mountain, in the range of Bolivian Andes, was selected as the study site within this work. Sixteen polyurethane foam (PUF) passive air samplers (PASs) were deployed in 8 sampling points spanning altitudes from 3600 (City Center of La Paz) to 5240 masl. Additionally, 4 PAS-PUFs equipped with automatic activation/deactivation setups were mounted at the summit (approx. 5380 masl) to continuously monitor day-long fluctuations of atmospheric POCs. The setup was designed to track the influence of FT conditions on these fluctuations by employing each unit for selected 6 hour periods in a day. Before they were deployed, all the PUF samplers were spiked with isotopically labeled compounds having a range of volatilities to determine compound-specific sampling volumes at the relevant conditions. Although the effects of the wide range of ambient temperatures and wind speeds on passive air sampling have already been reported in previous studies, atmospheric pressure has not been fully explored as a parameter that determines PAS sampling rate in this context. Thus the other aim of the present work is to investigate the possible effects of low atmospheric pressures (i.e., approx. 0,51 atm at 5240 masl) on uptake rates of gas-phase POCs by PAS-PUF samplers.

Disclaimer/Disclosure: This project is funded by the Swedish Research Council FORMAS (grant number 2020-01067). We would like to thank our colleague Isabel Moreno and her team from Universidad Mayor de San Andrés in La Paz, Bolivia, for their technical, logistical, and communication support. We also thank Draupnir Einarsson from Stockholm University, Department of Geological Sciences for his efforts in manufacturing the automated sampling setup. Finally, we acknowledge the co-applicants of the project, Marcos Andrade, Cynthia de Wit, Claudia Mohr, and Cheng Wu for their invaluable contributions.

3.12.P-Th209 Determination of NO2, SO2 and O3 Levels in Ankara, Türkiye: Assessment of the Exposure of Primary School Children

Gönenç Ozarlı[1]*, Eftade Emine Gaga*[1]*, Ozlem Ozden Uzmez*[1] *and Yucel Can Severcan*[2]*, (1) Eskişehir Technical University, Türkiye, (2)Middle East Technical University, Türkiye*

The quality of urban air, particularly in regard to the concentrations of nitrogen dioxide (NO2), sulfur dioxide (SO2) and ozone (O3), presents a significant health risk, particularly for those populations considered vulnerable, including children. This study includes the passive sampling of NO2, SO2, and O3 along routes frequently traversed by primary school children in a large urban area in Ankara, Türkiye. Novel passive samplers developed by Eskişehir Technical University Air Quality Research Group were deployed at 160 points on the walking paths from schools to students' homes to obtain pollutant concentrations. The primary aim was to assess the exposure of children to air pollutants during their daily commutes, given that these routes often intersect with high-traffic zones. The data collected in two sampling campaigns (winter and summer) over a two-week period were subjected to analysis in order to identify any spatial or temporal variations in pollutant concentrations. The highest concentrations of NO2, SO2 and O3 obtained during the initial sampling period (winter) were 78.58, 34.59 and 99.53 µg/m³, respectively, while the corresponding sampling results for the subsequent sampling period (summer) were 73.63, 88.71 and 182.58 µg/m³. The findings provide valuable insights into the micro-environments that children are exposed to and highlight the importance of targeting pollution reduction strategies in specific urban pathways. This study contributes to the growing body of research on air quality monitoring and offers a unique perspective on children's exposure to urban air pollutants.

Disclaimer/Disclosure: This project is supported by TÜBİTAK. (Project code: 219K243).

3.13.A Advances in Bioaccumulation Science and Assessment

3.13.A.T-01 Irreversible Receptor Binding Causes Long-Lasting Bioaccumulation of Insecticides in Two Invertebrate Species

Clarissa von Au*, Johannes Raths, Juliane Hollender and Natsumi Maeda, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Monitoring data revealed that polar compounds such as neonicotinoids substantially influence the total toxic pressure on non-target invertebrates, posing environmental concerns. Irreversible receptor binding to

the nicotinic acetylcholine receptors (nAChRs) may explain accumulation, potentially causing long-lasting toxic effects. Accordingly, an elimination-resistant fraction independent of concentration level and exposure dynamics has been observed for thiacloprid.
This study examines the toxicokinetic mechanisms of lasting bioaccumulation caused by receptor binding for four insecticides of different substance classes in the two freshwater invertebrate species *Gammarus pulex* and *Hyalella azteca*.
Amphipods were exposed to four polar insecticides (i.e., thiacloprid, acetamiprid, imidacloprid, and flupyradifurone), and uptake and elimination kinetics were investigated over 6 to 18 days for different exposure concentrations (5, 10, 25, 50 ?g L-1). Further, in vivo nAChR-binding assays were performed at the uptake and elimination phases to determine the contribution of the membrane protein extraction fraction to the total body burden. Concentrations in the medium and extracts were determined using an online-solid phase extraction system coupled with liquid chromatography, and high-resolution tandem mass spectrometry (online-SPE LC-HRMS/MS).
Results confirm an elimination resistant fraction for the three N-cyanoamidines and N-nitroguanidine insecticides (i.e., thiacloprid, acetamiprid and imidacloprid) independent of concentration levels, species, and compounds. The fraction associated with membrane proteins accounted for the largest amount of the total body burden at the elimination phase. In contrast, the newer butenolide insecticide flupyradifurone is fully eliminated and no membrane protein associated fraction could be detected.
Irreversible binding to the nAChRs and accordingly elimination resistance in both amphipod species may explain previously reported delayed toxicity caused by neonicotinoids. Our findings support that receptor binding as a cause for bioaccumulation should be considered in chemical risk assessment.

3.13.A.T-02 Toxicokinetics of Per- and Polyfluoroalkyl Substances (PFAS) in Amphipods Using Online-SPE-LC-HRMS/MS

***Kaue de Oliveira Chinaglia**[1], Johannes Raths[2], Amanda dos Santos[3], Jose Luiz da Costa[4], Gisela de Aragão Umbuzeiro[4] and Juliane Hollender[2], (1)Universidade Estadual de Campinas (UNICAMP); Swiss Federal Institute of Aquatic Science and Technology (Eawag), Brazil, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag); ETH Zurich, Switzerland, (3)Universidade Estadual Paulista "Julio de Mesquita Filho" (UNESP), Brazil, (4)Universidade Estadual de Campinas (UNICAMP), Brazil*
Per- and polyfluoroalkyl substances (PFAS) represent a group of more than 9000 synthetic organic compounds detected globally as contaminants. They are used as surfactants and non-stick agents since the early 1950s. Toxicokinetic is essential for understanding the relationship between contaminants concentrations and toxic effects on organisms such as *Hyalella azteca*, which is easy to culture and considered a good alternative for animal testing with fish (i.e., OECD 305). The general objective of this work is to determine PFAS toxicokinetics in *H. azteca* and applying a state-of-the-art analytical methodology. We want to compare PFAS with different functional groups and chain lengths as well as correlate concentration in different matrices (whole-body and hemolymph). 22 PFAS were selected and preliminary exposure and toxicity experiments were performed at concentrations observed at contaminated sites (i.e., 50 ?g/L) with different PFAS mixtures in triplicate over 7 days. Then, a full toxicokinetic experiment was performed over 28 days (10 days for uptake, 18 days for elimination phase). Organisms, hemolymph, medium and food samples were sampled at different time points, extracted and analysed by online-SPE-LC-HRMS/MS. The methodology was successfully applied for different biota samples with calibration curve from 0.005 to 250 µg/L (r^2 ? 0.99; CV% ? 20%). Organisms presented satisfactory survival rate (? 80%) when preliminarily exposed with PFAS classes X:2 FTS or DiPAPs at 50 ?g/L. 8:2 DiPAP presented the average concentrations: 3,720 ± 724 µg/kg for whole-body, 5,767 ± 2,581 µg/kg for hemolymph, with an average concentration ratio of 0.6, and a whole-body and hemolymph BCF values equal to 74 and 115 L/kg, respectively. 10:2 FTS, with the longest chain length, had the highest average concentrations: 121,766 ± 72,976 µg/kg for whole-body, 28,000 ± 11,067 µg/kg for hemolymph, with an average concentration ratio of 4.3, and a whole-body and hemolymph BCF values equal to 2,435 (potential for bioaccumulation) and 560 L/kg, respectively. With these results and concentrations ratios, it is possible to see that PFAS concentration can change in different matrices, which may be related to their different chemical properties. In the next steps, the full toxicokinetic experiment data (28 days) will be analysed, toxicokinetic modelling will be performed and the final results will be presented.

3.13.A.T-03 Bioaccumulation and Biomagnification of Per- and Polyfluoroalkyl Substances at Different Trophic Levels in the Food Web of a Polluted Ecosystem

Ioanna Spyridoula Gkika[1], *J. Arie Vonk*[1], *Cornelis A.M. van Gestel*[2], *Thomas L. ter Laak*[3], *Jildou Dijkstra*[1], *Thimo Groffen*[4], *Lieven Bervoets*[4] *and Michiel Kraak*[1], *(1)Department of Freshwater and Marine Ecology (FAME), Institute for Biodiversity and Ecosystem Dynamics (IBED), University of Amsterdam, Netherlands, (2)Vrije Universiteit Amsterdam, Netherlands, (3)KWR Water Research Institute, Netherlands, (4)Department of Biology, University of Antwerp, Belgium*

Per- and polyfluorinated substances (PFAS) are widely used anthropogenic compounds, with a multitude of industrial and consumer applications. The widespread use of PFAS together with their persistence and mobility has led to global contamination of the abiotic and biotic environment. Nevertheless, important knowledge gaps remain concerning their occurrence, bioaccumulation and biomagnification across aquatic ecosystems, while even less is known about terrestrial ecosystems. The aim of the present study was therefore to unravel the aquatic and terrestrial pathways of PFAS in a polluted ecosystem, ending up in predatory spiders as top predators. To this end, abiotic and biotic samples from the aquatic and terrestrial compartments of a PFAS polluted ecosystem were collected and screened for 44 PFAS. The food web structure and trophic relationships between the organisms were investigated using stable isotopes and a mixing model analysis. Sampled organisms were grouped according to their trophic level into primary producers (PP), primary consumers (PC) and predators (PR). The quantified concentrations revealed that a wide range of PFAS is present in the abiotic and biotic environment with total average concentrations reaching up to 11 ?g/g dw in the case of aquatic PC, corresponding to 34 detected PFAS with PFOS constantly appearing among the compounds with the highest concentrations. Biota-to-soil and biota-to-sediment accumulation factors (BSAFs) confirmed the high bioaccumulation potential of PFAS, with BSAF values reaching 91,971 kg sediment/kg biota. Similarly, a high bioconcentration potential from water was observed, with bioconcentration factors (BCFs) reaching 33,087 L water/kg biota. Considerable variation was observed in the bioaccumulation between the different trophic levels, but also between the different species. Furthermore, biomagnification of PFAS through the food web appeared to depend both on the intrinsic PFAS properties, and on the trophic interactions within the examined ecosystem. Our results highlight that a wide spectrum of PFAS detected in terrestrial and aquatic environments can be taken up by organisms from different trophic levels. PFAS biomagnification is substantial and hence, food web transfer of PFAS is of concern, contributing to the environmental risks of these forever compounds.

3.13.A.T-04 Benchmarking Approach in Bioaccumulation Assessment

Shoko Furuno[1], *Jane Caley*[1], *Doris Hirmann*[2], *Romanas Cesnaitis*[3] *and Anu Maarit Kapanen*[1], *(1)European Chemicals Agency (ECHA), Finland, (2)European Chemicals Agency (ECHA), Helsinki, Finland, (3)Telakkakatu 6, European Chemicals Agency (ECHA), Finland*

Recently updated ECHA Guidance on information requirements and chemical safety assessment (IR&CSA), Chapter R.11 provides general recommendations on how to apply a benchmarking approach as part of an overall weight of evidence in PBT/vPvB assessment. The benchmarking approach is defined as the approach where the fate or behaviour of a substance is measured relative to the fate or the behaviour of a well-described substance(s), the so-called benchmark chemical(s). Benchmarking relies on the similarity between the fate or the behaviour of the benchmark chemical and the substance of interest in the environmental system being studied. It is a comparative method, and, unlike the read-across approach, it does not require structural similarity.
In this presentation, a benchmarking approach in addressing bioaccumulation potential based on information on fish dietary exposure bioaccumulation studies will be presented with neutral organic substances as illustrative case examples. The studies have been collected for substances identified as bioaccumulative (B) or very bioaccumulative (vB) and as Substances of Very High Concern (SVHC) according to REACH Article 57 (d) or (e), with relevant parameters (e.g. physico-chemical properties of a substance, experimental design and test conditions) that may influence the outcomes of the tests. The factors which may significantly influence the outcome of dietary studies and hence should be considered in the benchmarking approach will be discussed in detail. Potential for benchmarking approaches based on

other bioaccumulation assessment scenarios than dietary fish data will also be presented.
The benchmark approach demonstrates:
• What to take into account when selecting benchmark chemicals;
• Most relevant parameters which appear to influence the outcomes of the study;
• Need for consensus building on the parameters to check for benchmarking;
• Frequent data/reporting gaps, which needs to be improved, to allow for meaningful comparison of studies.
In the future, benchmark examples for so called 'safe case' substances that have been concluded as not bioaccumulative will be included. This is expected to further facilitate the use of available dietary studies to conclude on the bioaccumulation potential of other substances. We will provide an overview of possible bottlenecks with the benchmarking approach, as well as suggestions for further development for other types of substances (e.g. ionisable and surface-active substances).

3.13.A.T-05 Assessment of the Bioaccumulation of Organic Pollutants Using Zebrafish Liver Cells and Evaluation of the Important In Vitro Parameters

Paloma de Oro-Carretero *and Jon Sanz-Landaluze, Department of Analytical Chemistry, Complutense University of Madrid, Spain*

The development of alternative methods that link cellular and predictive toxicity to high-level toxicity is a key focus of current research within the framework of the 3Rs (Reduce, Replace, Refine) in animal experimentation. In the field of bioaccumulation, significant progress has been made through the development of empirical predictive regression models and in vitro-in vivo extrapolation (IVIVE) techniques using rainbow trout hepatocytes. However, substances with slow metabolism rates face limitations with 4-hour assays. Additionally, these models often rely on the octanol-water partition coefficient of compounds to evaluate absorption, the depletion of the parent compound to assess metabolism, or mass balance models (MBMs) to determine internal concentrations without accounting for the kinetics of absorption and metabolism. This approach overlooks crucial information, as biological processes occur simultaneously and interact dynamically.
This study assessed a methodology employing the zebrafish liver cell line (ZFL) to predict the bioconcentration factor (BCF). A miniaturized analytical method was utilized to measure the concentrations of the parent compounds (BDE-47 and phenanthrene) and their primary metabolites in the exposure medium and within the cells (Ccell,exp). The cells were cultured on glass plates and exposed for varying durations of up to 72 hours. Conversely, the bioavailable concentration (Cfree) and the predicted internal concentration (Ccell,MBM) were determined using mass balance modeling. Bioconcentration factors (BCFs) were calculated by integrating these values, applying toxicokinetic modeling, and accounting for metabolism through the IVIVE model.
The results revealed discrepancies between Ccell,exp and Ccell,MBM, indicating that the most accurate BCFs, closely aligned with in vivo values, were achieved by incorporating Ccell,exp, Cfree, and the uptake and biotransformation kinetics of the compounds. This study confirmed the capability of ZFL cells for BCF prediction, demonstrating a rapid and animal-free methodology. The findings provide valuable data for refining predictive models.

3.13.B Advances in Bioaccumulation Science and Assessment

3.13.B.T-01 Consensus for a Better "B"-Assessment

Caren Rauert[1]*, Daniel Frein*[2]*, Verena Kosfeld*[3]*, Monika Nendza*[4] *and Christian Schlechtriem*[5]*, (1)German Environment Agency (UBA), Germany, (2)Biocides, German Environment Agency (UBA), Germany, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)AL Luhnstedt, Germany, (5)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Bioaccumulation assessment is an essential part in all regulatory frameworks on chemicals. In the past years, there have been significant developments to incorporate the demands of the 3Rs (reduce, replace, refine animal testing) and to extend the bioaccumulation assessment to substances other than neutral, lipophilic substances, and to air-breathing organisms, where necessary. These advancements should be considered in revised European testing and assessment guidances.
The German Environment Agency has initiated a project with the aim of integrating current scientific advancements into a comprehensive bioaccumulation assessment concept. Multiple lines of evidence are

combined, based on in silico methods, in vitro assays and tests with invertebrates in addition to existing in vivo data and results from environmental monitoring. Their consolidation by consensus approaches includes an evaluation of the applicability and uncertainties with due regard to regulatory thresholds. Several building blocks were addressed in the project, such as a consensus modelling approach for consolidated log Kow and log Koa values and recommendations for obtaining reliable and robust pKa estimates. Also, fish BCF QSAR data was generated from several available QSAR models. For 30 substances, fish BCF data was compared to results of *Hyalella azteca* bioconcentration tests (HYBIT) according to OECD TG 321, in vitro assays (OECD TG 319 A/B) for the assessment of the bioaccumulation potential of substances in aquatic species and in vitro depletion assays with rat hepatocytes/ S9 fractions to assess the bioaccumulation potential in air-breathing organisms. Where literature data was not complete, HYBIT tests and both fish and rat in vitro tests were conducted to complete the data set.
The consensus modelling improves the reliability of B-assessments based on consolidated predictions and test results, leading to reduced uncertainties.
On the basis of a dedicated workshop with the European regulatory community from the different substance regulations in March 2025, a revised proposal will be presented together with the conclusions of the workshop.

3.13.B.T-02 Determining the Uptake and Depuration Rates of Polycyclic Aromatic Compounds in a Popular Biomonitoring Species

Danielle Philibert[1] *and Benjamin Patrick de Jourdan*[2]*, (1)Huntsman Marine Science Center, Canada, (2)Huntsman Marine Science Centre, Canada*

Polycyclic aromatic compounds (PACs) are ubiquitous contaminants that are commonly measured in biomonitoring programs, and the bioavailability of each PAC can be determined by physical-chemical properties like the octanol-water partitioning coefficient (Kow). Though uptake and depuration rates of PACs in mussels have been previously studied, some data gaps remain in our understanding the toxicokinetics of these compounds in tissue. The goal of this study was to address these gaps by measuring the accumulation and depuration rates of a suite of PACs in mussels exposed to different oils and pre-made PAC blends. These measurements allowed us to test whether water PAC composition is predictive of tissue PAC profiles, if Kow is predictive of the update and depuration rates of PACs within complex mixtures, if artificially made PAC blends are reflective of the toxicokinetics of crude oil mixtures, and to determine how rapidly uptake can occur in an acute exposure scenario. Two experiments were conducted. For the first experiment, 7-day exposures to two different types of crude oil (a light and a heavy crude oil) followed by a 14-day depuration period were conducted. Mussel samples were pooled for PAC tissue analysis on days 0, 3, 7, 10, 14, and 21. In the second experiment 72h exposures were conducted with light crude oil, a PAC blend. Mussels were sampled at 0, 3, 6, 24, 48, and 72h during the exposure phase, and 10 and 17 days during the depuration phase of the study. Water samples were taken during the exposure period for PAC and biomimetic extraction-solid phase microextraction (BE-SPME) analysis for both studies. In the oil comparison study, the light crude oil had higher concentrations of the lower molecular weight PACs accumulated in the mussel tissue compared to the heavy oil. In our second experiment, we found that the PACs accumulated in the mussel tissue rapidly, with ~1000ng/g concentrations of naphthalene and 1-methylnaphthalene measured within 3 hours of exposure. In both experiments most of the lower molecular weight (and lower Kow) compounds were completely depurated by our first sampling period post exposure. The tissue concentrations remained above baseline on the last day of the trial for the higher molecular weight compounds. The data generated in this study can be used to improve our understanding of the toxicokinetics of PACs in a species that is used as both a food source for human consumption and a key part of biomonitoring programs.

3.13.B.T-03 Does Dietary Microplastic Enhance the Bioaccumulation of Environmental Contaminants and Polymer Additives?

Frank Wania[1]*, Desmond Ng*[1]*, Yuhao Chen*[1]*, Ying Duan Lei*[1]*, Wanzhen Chen*[2]*, Hui Peng*[2] *and Sarra Gourlie*[3]*, (1)University of Toronto Scarborough, Canada, (2)University of Toronto, Canada, (3)Toronto Zoo, Canada*

While there is consensus on the presence of microplastic contamination in food, this consensus does not extend to the question of how this presence influences the uptake of organic contaminants from the gastrointestinal tract. Hypotheses range from the idea that microplastic acts as carrier of sorbing contaminants facilitating biological uptake to the opposite view that the sorptive capacity of microplastic, which is not diminished during digestion, lowers the thermodynamic driving force responsible for diffusion from gut lumen to the organism's tissues. Using silicone-based equilibrium sampling we quantified the effect of polyvinylchloride (PVC) microplastic on this thermodynamic driving force, expressed in terms of fugacity, for polychlorinated biphenyls (PCBs) and polymer additives in dietary and fecal samples of a zoo-housed polar bear. Whereas PVC microplastic at concentrations well above current observations reduced the fugacities of spiked isotopically labelled PCBs in polar bear diet and feces slightly, but significantly, leaching from those microplastic greatly elevated fugacities of the additives U-328 and octabenzone in those samples. The impact of microplastic in the diet on the biological uptake of environmental hydrophobic organic contaminant is likely to be negligible. Microplastic has the potential to be an effective vector for the dietary uptake of polymer additives.

3.13.B.T-04 Comparing the Predictive Capacity of the OECD 319B In Vitro Fish Biotransformation Assay to the In Vivo OECD 305 Study for a Hydrophobic Organic Chemical

*Gordon Sanders[1], Heike Laue[2], **Aurelia Lapczynski**[3] and Suzanne Zvalaren Schneider[4], (1)Product Safety Sciences, Givaudan, Switzerland, (2)Givaudan International SA, Switzerland, (3)Research Institute for Fragrance Materials, United States, (4)Eurofins EAG Agroscience, United States*

This presentation describes the remarkable potential and capacity of the OECD 319B Rainbow Trout liver S9 fraction in vitro assay to accurately predict not only the bioconcentration potential of organic chemicals, but also the metabolic pathway of transformation products formed in the traditional OECD 305 In vivo fish bioconcentration study, which is still the gold standard test for establishing the bioconcentration factor (BCF) of chemicals. Two high quality studies were performed on the hydrophobic organic cyclic acetal fragrance molecule Okoumal (EC No. 412-950-7), which has an experimentally determined LogKOW of 5.15. The first study, an OECD 305 in vivo fish bioconcentration study, followed the uptake and depuration of the 14C-radiolabelled test item in the tissue of Fathead Minnow (*P. promelas*), and identified the major metabolite formed in the fish tissue. The second study, an in vitro fish metabolism study using Rainbow Trout (*O. mykiss*) liver S9 fractions according to the OECD 319B test guideline was conducted with non-radiolabelled Okoumal. In the in vivo study, a steady-state BCF of 412 L/kg (wet wt.), normalised to 5% lipid content, was determined for the parent molecule, attaining a plateau within the first 7days of exposure. The in vitro study demonstrated high metabolic turnover (90% of starting material) with a relatively rapid intrinsic clearance rate. The predicted BCF from the in vivo to in vitro extrapolation (IVIVE) model of Nichols et al. (2013) of 309 L/kg (wet wt.), in close agreement with the In vivo result. The principal metabolite, representing 60% of total C14 in fish tissue in the in vivo OECD 305 study, was identified as the Hydroxy-Glucuronide of the parent molecule, and was rapidly eliminated from the fish with a tissue half-life of between 1.0 and 1.8 days. The same structure was also identified putatively as a major Phase II biotransformation metabolite in the In vitro study, confirming the utility of the OECD 319B assay as not only an efficient and fit-for-purpose screening approach which can be employed to de-/prioritise the requirement for full in vivo testing, but is also capable of predicting similar mechanistic metabolism pathways as the in vivo study supporting the rational that the OECD 319B should be integrated in to a systematic tiered assessment approach for evaluating bioaccumulation potential.

3.13.B.T-05 Adapting In Vitro Substrate Depletion Assays (TG 319) to Study Biotransformation of Organic Chemicals in Mallard Duck

***Matthew Schultz**[1], Michelle Rau Embry[2], Robert J. Letcher[3], Christy A. Morrissey[4] and Markus Brinkmann[4], (1)Toxicology Centre, University of Saskatchewan, Canada, (2)Health and Environmental Sciences Institute (HESI), United States, (3)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Canada, (4)University of Saskatchewan, Canada*

Avian species play a critical role in aquatic and terrestrial ecosystems by providing many ecosystem services, and historically have been significantly impacted by the bioaccumulation of organic pollutants due to their trophic positioning, diverse life traits, and complex migration patterns. Bioaccumulation is typically assessed in fish using B-metrics such as bioconcentration/bioaccumulation factors (BCF/BAF) depending on exposure route; however such methods are challenging to apply to air breathing organisms, but are often considered protective. These metrics are determined using costly in vivo testing in fish and rats, with little focus on birds outside of field studies which have inherent modelling limitations. Recently, it has been suggested that a kinetic approach that views these B-metrics as the product of competing rates of whole-body uptake and elimination may be refined by incorporating tissue-specific biotransformation rates derived from substrate depletion assays using isolated hepatocytes or liver S9 sub-cellular fractions. The present study seeks to optimize, evaluate, and apply these assays to multiple relevant bird species using a diverse suite of benchmark compounds, by adapting the Organisation for Economic Co-operation and Development (OECD) Test Guideline 319A/B. In initial studies using mallard duck (*Anas platyrhynchos*) metabolic material, in vitro intrinsic clearance rates of pyrene and 4-n-nonylphenol were consistently determined across multiple assay conditions, with various thawing and handling protocols to test for robustness. Further research will apply an optimized assay protocol to additional relevant chemicals including anticoagulant rodenticides, polychlorinated biphenyls (PCBs), organochlorines, and emerging contaminants of wildlife concern. Such clearance data can be used flexibly within integrative frameworks to refine predictions of bioaccumulation. The goal of this study is to generate consistent data for tiered bioaccumulation assessment strategies, as well as lay the foundation for future ring trial or similar applications to inform wildlife risk assessment.

Disclaimer/Disclosure: The authors acknowledge funding of this research by the Health and Environmental Sciences Institute through the Next Generation Environmental Risk Assessment Committee.

3.13.P Advances in Bioaccumulation Science and Assessment

3.13.P-Th210 Why the Bioconcentration Factor (BCF) Fails for Superhydrophobic Chemicals

***Andrea Ebert**[1], Juliane Ackermann[2], Gabriele Treu[2], Wiebke Drost[2], Christian Schlechtriem[3] and Kai-Uwe Goss[1], (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Chemicals Division, German Environment Agency (Umweltbundesamt), Germany, (3)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Assessing the bioaccumulation potential of superhydrophobic chemicals is extremely challenging. Next to problems generally encountered when testing superhydrophobic chemicals in experimental systems, there are specific influencing factors in bioconcentration (BCF) tests that have apparently not been sufficiently considered in current guidelines (e.g. OECD 305). Effects such as binding of chemicals to organic carbon (TOC) in the test medium, significant growth dilution and elimination via feces, and (extreme) times till steady-state make performance, interpretation and validity of bioconcentration tests for superhydrophobic chemicals extremely challenging. These effects can lead to the counter-intuitive observation of decreasing BCF in the superhydrophobic range with increasing octanol/water partition coefficients Kow, even in the absence of biotransformation.
To address this problem, the German Environment Agency (UBA) launched a project with the objectives to i) provide a precise definition of superhydrophobicity, ii) to quantify whether and to what extent the bioaccumulation potential of superhydrophobic substances has been underestimated so far, iii) to examine existing tests and models for their suitability in assessing the bioaccumulation potential of superhydrophobic compounds, iv) to provide a concept and proposals for revision of guidance documents for the future bioaccumulation assessment of superhydrophobic compounds and to v) communicate and find an agreement regarding the approaches with the expert community.
This abstract and the respective poster presentation at the start of the project strive to create awareness for the problems regulators are facing when assessing superhydrophobic compounds for bioaccumulation, elucidate first project outcomes and encourage discussions that will ultimately help achieving an improved bioaccumulation assessment in Europe.

Disclaimer/Disclosure: This project (project No. 3723 64 405 0) is supported and funded by the German Environment Agency, who also originated the project idea. This text does not necessarily represent the official opinion of the German Environmental Agency.

3.13.P-Th211 How Does Active Transport affect Toxicokinetics of Cationic Psychoactive Drugs in Aquatic Invertebrates?

***Johannes Raths**, Salome Loepfe, Oliver Klaus and Juliane Hollender, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Toxicokinetics of ionic compounds are still not well understood. Recent studies on the toxicokinetics of cationic pharmaceuticals in aquatic invertebrates reported a strong influence of exposure concentration and temperature on both uptake and elimination rates of these chemicals. Both observations may be indicative for active transport mechanisms facilitated by certain membrane proteins. Such proteins include

ATP-binding cassette transporters (ABC-transporters) or solute carriers (SLCs).
The potential active transport of cationic pharmaceuticals was studied by performing uptake and elimination experiments with the freshwater amphipod *Gammarus pulex*. Different mixtures and exposure sequences of the target analyte, i.e. the antidepressant citalopram, and inhibitors of membrane transport proteins (ABC and SLC transporters), i.e. verapamil and cyclosporine A, were performed to understand the interactions of these two compound classes. Furthermore, a neutral benchmark compound (fluopyram) known to be unaffected by transporter inhibition was added to the exposure mixtures. Contaminant concentrations were determined using an online-SPE LC-HRMS/MS system. Toxicokinetic parameters were estimated using the build your own model (BYOM) platform.
The co-exposure with verapamil reduced the uptake rate of citalopram by 40% and the elimination rate by 75%, whereas cyclosporine A and other inhibitors showed no effect. Consequently, the bioconcentration factor (BCF) of citalopram was two times higher if verapamil was co-exposed during both uptake and elimination phase, and six times higher if verapamil was only co-exposed during the elimination phase. The present study provides insights into transport pathways that may be specific to cations. Furthermore, it was demonstrated that the effect of transporter inhibition could be detectable on in vivo scale for verapamil. However, it remains unclear why other inhibitors known to be efficient in in vitro experiments showed no effect. The results may help to understand why some contaminants show higher bioaccumulation potential under environmental conditions (i.e. low exposure concentrations, mixtures, matrix components such as DOM) than estimated based on highly standardised laboratory experiments.

3.13.P-Th212 Phenolic Compounds in the Freshwater Environment in South Korea: Occurrence and Tissue-specific Distribution

***Jeong-Eun Oh**[1], Da-Hye Kim[2] and Jaeyeon Park[3], (1)Pusan National University, "Korea, Republic of", (2)Institute for Environment and Energy, Pusan National University, "Korea, Republic of", (3)Pusan National Univerisity, "Korea, Republic of"*

In this study, we investigated the occurrence and distribution of phenolic compounds, including phenol, cresols, chlorophenols, nitrophenol, and bromophenols, in freshwater environments. We also focused on phenolic compounds in crucian carp (*Carassius auratus*) tissues, specifically the muscle, gills, brain, blood, liver, and gonads, to assess their potential bioaccumulation in fish and human health risks. Phenolic compounds were found to be widespread in various freshwater environments throughout South Korea. Phenol was predominant in all matrices, with median concentrations of 57.0 ng/L in freshwater, 54.3 ng/g dry weight (dw) in sediment, and ranging from 71 ng/g wet weight (ww) to 621 ng/g ww in crucian carp tissues. Cresols were the second most dominant compound, with m-cresol exhibiting the highest prevalence. Most of the compounds detected in crucian carp samples were also detected in freshwater and sediment, whereas pentachlorophenol and 2,4,6-tribromophenol were exclusively detected in crucian carp tissues. A high bioaccumulation potential in the liver was observed for most phenolic compounds [median log bioconcentration factor (BCF): 3.2 3.7]. Interestingly, only m-cresol showed high bioaccumulation potential in the gills (median log BCF: 3.1). The estimated daily intake of phenolic compounds suggested that it does not pose an immediate concern for human exposure owing to crucian carp consumption. These findings enhance our understanding of the exposure status, distribution, and bioaccumulation potency of phenolic compounds in aquatic ecosystems and emphasize the importance of ongoing monitoring and risk assessment efforts.

3.13.P-Th213 Integrated Approaches to Testing and Assessment (IATA) for Bioaccumulation: A Surfactant Case Study

*Devrah Arndt and **Kristin Connors**, The Procter and Gamble Company, United States*

Bioaccumulation assessment is a critical component of a chemical hazard and risk assessments. Under the Registration, Evaluation, Authorisation, and Restriction of Chemicals (REACH) framework, a Weight of Evidence (WOE) approach is recommended when performing bioaccumulation assessments to allow for the integration of multiple lines of evidence (LoE). An OECD Bioaccumulation Integrated Approach to Testing and Assessment (B IATA) was recently adopted, providing guiding principles for the collection, generation, evaluation, and integration of multiple LoE to inform bioaccumulation assessments. Assessing the bioconcentration of surfactants is inherently challenging due to their amphiphilic nature. For example, partitioning coefficients (e.g., logP) can be technically challenging to measure; however several experimental and predictive models are available. In this presentation, we use leverage the B IATA framework to assess the bioaccumulation potential of the anionic surfactant linear alkylbenzene sulfonate (LAS). Multiple LoE are integrated including various logP methodologies, in silico predictions, in vitro clearance data, and standard in vivo fish bioaccumulation (OECD 305) results. We demonstrate how this framework can provide useful insight and transparent interpretation of bioaccumulation potential for surfactants across variations in alkyl chain length.

3.13.P-Th214 Metabolic Activities in Rainbow Trout (*Oncorhynchus mykiss*) S9 Fractions from Liver and Extrahepatic Organs as an Alternative In Vitro Ecotoxicity Assessment Approach

*Marcel Reu[1], Tanja Krimmling[1], Melissa Thiede[1], Amani Alkufairi[1], Alexander Sattler[1], Kim Damrau[1], Jennifer Schuldt[1], Dieter Runge[2] and **Anett Ullrich**[1], (1)Primacyt GmbH, Germany, (2)Primacyt GmbH, Schwerin, Germany*

Whole body biotransformation rate constants can be calculated by using appropriate in vitro to in vivo extrapolation (IVIVE) models. These models use in vitro intrinsic clearance CL in vitro, int rates derived with OECD Test Guideline (TG) 319A/B to estimate liver clearance rates in Rainbow trout, which are then extrapolated to a whole-body (in vivo) biotransformation rate constant. Primacyt GmbH supports this approach of alternative method to animal experiments.

Rainbow trout were maintained under controlled housing conditions according to OECD TG 319A/B. Specimens of eight sexually immature animals were obtained and pooled, including liver, gill, intestine, brain, heart and spleen to generate S9 fractions. These fractions were prepared to determine the Cytochrome P450 Phase I and Phase II enzyme activities by liquid chromatography-mass spectrometry analysis. Phase I activities were determined by using 7 compounds and glucuronidation and sulfation of 7-OH-Coumarin as Phase II reactions were analyzed as well.

Liver and intestine displayed the highest Cytochrome P450 activities of all organs tested. The Phase I formation of four metabolites (Acetaminophen, 1-OH-Midazolam, 4-OH-Diclofenac, and 6-OH-Chlorzoxazone) were linear up to 60 min in intestine and 120 min in liver. One metabolite (OH-Bupropion) was only detectable in liver with a moderate increase and two (4-OH-Mephenytoin and 7-OH-Coumarin) did not indicate a time-dependent increase or were not detectable. Extrahepatic Phase I activities of four enzymes were found in all organs with different specification to the tested compounds, three were not detectable. Phase II activities were detected in liver, intestine, gill and heart, but not in brain and spleen.

In summary, liver is the major organ for detoxification of compounds in Rainbow trout. Extrahepatic organs, mainly intestine, but also brain, heart, gill and spleen exhibit certain Phase I Cytochrome P450 activities with different specification to the reference compounds. Phase II enzyme activities were besides liver also detectable in intestine and gill. Our results suggest that extrahepatic organs, mainly intestine, should also be taken into account when bioaccumulation and in vitro clearance rates are determined for IVIVE modeling in Rainbow trout.

3.13.P-Th215 Can a Modified CaCo2 Assay Support the Assessment of Secondary Poisoning in Birds and Mammals?

*Barbara Birk[1], Manuela Mayer[2], Julia Przibilla[2], **Maike Habekost**[1], Kai Ristau[1] and Christian Imholt[1], (1)BASF SE, Agricultural Solutions - Ecotoxicology, Germany, (2)Pharmacelsus GmbH, Germany*

A new Birds and Mammals Guidance document was published by EFSA to revise the way of risk assessment for the registration of plant protection products (PPP). Trophic interactions through secondary poisoning assume the transfer of a PPP from the soil into the target organism, e.g. earthworms (1. Step) and then from earthworm into the mammal/bird after ingestion (2. Step). EFSA proposes a simplified but conservative approach by calculating the bioconcentration factor (BCF) value in the earthworm considering the logPow and predicted environmental concentration in soil and pore water. This equation leads to often unrealistically high BCF values. An alternative approach is a radioactive BCF study in earthworm, which can deliver data for the 1. Step of secondary poisoning process. The transfer from the earthworm to the bird and mammal remains unclear. An innovative alternative could potentially be the human CaCo2 assay, a well-established intestinal cell barrier model in human toxicology. We present here method development activities by adding the soil into the CaCo2 system to explore the transfer of substances in the context of secondary poisoning.

The gastrointestinal tract in the earthworm but also in the bird/mammal is an important barrier for absorption of PPP. CaCo2-cells are seeded on a transwell device, substance is applied to the apical compartment and the transfer over time to the basal compartment is measured by HPLC-MS to derive a Papp-value (cm/s). Substances were applied to two different soil types in different concentrations to allow an interaction between the soil and the substance. The prepared soil was applied afterwards to the CaCo2 assay. The addition of unsterile soil to the sterile CaCo2 assay was applicable under defined circumstances

(e.g. soil/buffer concentration, duration of the assay).
Different substances were tested in the assay. Orlistat, with high logPow, showed high adsorption to soil, while testosterone, erythromycin and acetaminophen with lower logPow showed low adsorption. Testosterone, acetaminophen and erythromycin showed the expected transfer rate also in this set-up, while Orlistat showed no transfer due to high adsorption rate. With this case study we showed promising first results to use the model also in an ecotoxicological context, like secondary poisoning. Future effort will expand the data set to better understand the applicability of the test system.

3.13.P-Th216 Legacy and Emerging Per- and Polyfluoroalkyl Substances (PFASs) in Tropical Marine Food Webs

Luhua You[1], *Wai Yee Jason Ku*[1] *and Karina Yew-Hoong Gin*[2], *(1)NUS Environmental Research Institute, National University of Singapore, Singapore, (2)Dept. of Civil & Environmental Engineering & NUS Environmental Research Institute, National University of Singapore, Singapore*

The bioaccumulation and trophic transfer of legacy and emerging per- and polyfluoroalkyl substances (PFASs) were determined within tropical food webs of the offshore zones in Singapore. Multiple aquatic organisms, surface water, sediments, soils and sea grasses were analysed for 44 PFASs (including long and short chain lengths). Stable isotope analyses of carbon and nitrogen were performed to elucidate the food web structure and trophic dynamics. Results revealed that PFASs were prevalent in all food web compartments. Perfluorobutanoic acid (PFBA) and perfluorobutane sulfonate (PFBS) were the predominant PFASs in water phase, while perfluorooctane sufonate (PFOS) and perfluoroundecanoic acid (PFUnA) contributed most to the sum of target PFASs in sediments and marine organisms. Perfluoroalkyl carboxylates (PFCAs), GenX and perfluoroalykyl ether sulfones were potentially bioaccumulative with bioconcentration factors (BCFs) exceeding 2000. In addition, there was a significant positive correlation between BCFs and the carbon chain length of perfluoroalkyl carboxylic acids (PFCAs). This study emphasizes the importance to monitor PFASs in food webs to gain greater insight into the PFAS contaminations and thus provide complete evaluations of PFAS risk for humans through consumption of marine organisms.

Disclaimer/Disclosure: This research is supported by the National Research Foundation, Prime Minister s Office, Singapore under its Campus for Research Excellence and Technological Enterprise (CREATE) programme (E2S2- CREATE: Detection, assessment & modelling of emerging contaminants in the urban environment) and the Intra-CREATE Seed Collaboration Grant (Grant number: NRF2022-ITS011-0009).

3.13.P-Th217 Trophic Transfer of Halogenated Polycyclic Aromatic Hydrocarbons in Benthos from Gyeonggi Bay, South Korea

Seojoon Yoon[1], *Taewoo Kim*[1] *and Junghyun Lee*[2], *(1)Seoul National University, "Korea, Republic of", (2)Kongju National University, "Korea, Republic of"*

Trophic magnification factor (TMF) of traditional and halogenated polycyclic aromatic hydrocarbons (T-PAHs and Hl-PAHs in a benthic web (8 invertebrates) was determined in Gyeonggi Bay, South Korea. Hl-PAHs included chlorinated-PAHs (Cl-PAHs) and brominated-PAHs (Br-PAHs). The nitrogen-stable isotope ratios (?15N) were used to estimate the trophic position (TP) of invertebrates. The TP of invertebrates ranged from 0.90 to 3.43, with a mean of 2.29. 1-**B**romopyrene, **b**enzo[k]fluorine, and other high molecular T-PAHs (5 and 6 rings) were biomagnified through the whole food web (TMF > 1.2)**,** while low molecular T-PAHs and other Hl-PAHs showed similar levels (TMF = 1.0) or were not biomagnified (TMF < 1.0). In particular, the trophic transfer of T-PAHs and Hl-PAHs was pronounced in the polychaetes and bivalves (e.g., *Perinereis nuntia*, manila clam, and oyster). The relatively lower accumulation rate in crabs with the highest TP appears to be due to the contribution of different food sources. The highest abundance of polychaetes and mollusks, which feed primarily on sediments and particles, suggests that food sources are a major factor in determining TMF in benthic ecosystems. However, the detection frequencies of Cl-PAHs and Br-PAHs in invertebrates are low (20.5% and 21.2%), making accurate data interpretation difficult, so more precise measurements and analysis of many samples are needed in the future. Overall, this study provided TPs of T-PAHs and Hl-PAHs in invertebrates and could be applied to determine the trophic transfer of contaminants in coastal food webs.

3.13.P-Th218 R-BIONIC – An R Package to Build Confidence in, and Drive Understanding of In Silico Predictions for Bioconcentration in Ionisable Compounds Using Toxicokinetics

*Patrik Engi[1], Jacob-Joe Collins[2], Tymoteusz Pietrenko[2], Dawei Tang[2], Ans Punt[2] and **Bruno Campos**[3], (1)Unilever, United Kingdom, (2)Unilever, United Kingdom, (3)Unilever, Bedford, United Kingdom*
There is regulatory and societal drive to move away from traditional toxicity testing to animal-free new approach methodologies (NAMs). An essential part of NAMs is in silico tools able to deliver robust predictions used to support safety decisions. The BIONIC model by Armitage et al. (2013) is a toxicokinetic model designed to predict bioconcentration for a wide range of chemical groups, including ionisable compounds (IOCs) and quaternary ammonium compounds (QACs).
We present an R-package based on the BIONIC model. The package reviews and implements the mathematical model, building a complete view of the parameter space for the model and each sub-model, and structuring them as modules within the R package. We determined sensitive parameters for specific applicability domains/chemical groups and explored the robustness of the model through its R implementation (programmatically).
The main output is an open source, readily available R-package with accompanying technical documentation. The package mirrors the functionality of the previously published Excel/VBA tool for this model, with some enhancements such as a modern user interface written in Rshiny. The package implements modern software architectures and paradigms that enable robust and streamlined downstream analyses e.g. uncertainty and sensitivity calculations on predictions. The motivation for building the package is the hope that more users can further develop and contribute to the model for their own use cases facilitated by links to programmatic workflows and better integration with other R packages. Finally, we expect that the learnings and results from this work may help the modelling community build confidence and experience in the use of this model.

3.13.P-Th219 Validation and Application of the Multibox AQUWAWEB Model for Trophic Magnification Factors of Volatile Methylsiloxanes
***Jaeshin Kim**, Debra Ann McNett and Kathleen Plotzke, The Dow Chemical Company, United States*
Bioaccumulation assessment employs various metrics derived from quantifying chemical uptake and depuration rates. These metrics indicate the likelihood of a chemical accumulating within an organism and potentially biomagnifying up the food chain. For highly lipophilic compounds such as volatile methylsiloxanes (VMS), Trophic Magnification Factors (TMF) are especially important as it indicates a chemical s bioaccumulation behavior within a food web, considering all exposure routes and potential magnification effects. The objective of the current study is (i) to validate the Multibox-AQUAWEB (MBAW) model using measured concentrations of three cyclic VMS (D4, D5, and D6) and two polychlorinated biphenyls (PCB-153 and -180 as references) in biota from food webs in Yugawara coast, Japan and (ii) to predict TMFs of cyclic and linear VMS in real-world food webs. For model validation, Chi-square goodness-of-fit tests revealed good agreements between the modeled and measured concentrations, indicating the model's accuracy. Accordingly, the modeled TMFs of the cyclic VMS and PCBs were also in good agreement with the measured TMFs. For the food webs of Yugawara coast, the mean TMF of each cyclic VMS was less than 1 with strong or moderate statistical significance (p-value <0.10), suggesting trophic dilution, while the mean TMFs of PCB-153 and -180 exceeded 1 with strong statistical significance (p-value <0.05), indicating trophic magnification. The MBAW model was applied to the selected six food webs (Lake Erie, USA; False Creek, Canada; Lake Pepin, USA, Lake Ontario, USA/Canada; Oslofjord, Norway; and Tokyo Bay, Japan) to predict TMFs of cyclic and linear VMS. The mean TMF of each VMS in each food web selected was shown to be less than 1, indicating trophic dilution of VMS through dietary exposure pathways. An exception to this trend was observed for L5 in one food web, with a mean TMF of 1.1 (without statistical significance). In laboratory studies, measurement of the uptake and biotransformation rates of L5 was more challenging, resulting in greater uncertainty associated with the rates determined. Further research to generate more accurate uptake and biotransformation rates for L5 would enhance the model predictions. Overall, the MBAW model predicted that cyclic and linear VMS are likely to undergo trophic dilution in the selected food webs.

3.13.P-Th220 Evaluating Bioaccumulation Potential of Cyclic and Linear Volatile Methylsiloxanes: A Comprehensive Analysis Using the Bioaccumulation Assessment Tool
***Jaeshin Kim**[1], Debra Ann McNett[1], Sami Belkhiria[2] and Kathleen Plotzke[1], (1)The Dow Chemical Company, United States, (2)The Dow Chemical Company, Belgium*
The Bioaccumulation Assessment Tool (BAT, v2.02) collects and incorporates various lines of evidence (LoEs) related to the bioaccumulation of chemicals in both aquatic and terrestrial species. By using LoEs of bioconcentration factor (BCF), bioaccumulation factor (BAF), biomagnification factor (BMF), and trophic magnification factor (TMF), the process generates quantitative strengths of evidence, enhancing the comprehensive understanding of the bioaccumulation of compounds. This study reviewed 49 published articles and laboratory reports on fish (82%) and terrestrial species (18%). The objective was to

perform a comprehensive analysis of the bioaccumulation of three cyclic (D4, D5, and D6) and five linear (L2, L3, L4, L5, and L6) volatile methylsiloxanes (VMS) in biota. A total of 167 bioaccumulation values were extracted, underscoring the significance of multiple outcomes of bioaccumulation metrics. Considerable variability of BCF and BAF values was observed for VMS in aquatic organisms, which ranged from below to above their respective threshold values. The strength of evidence for non-bioaccumulation was ?50% for D6, L2, L5, and L6 based on BCF and BAF while the other VMS compounds showed week strength. Conversely, laboratory BMF values were generally less than 1 (i.e., the strength of evidence for non-bioaccumulation >67%), indicating low bioaccumulation through dietary uptake. Field BMFs displayed more variability but still suggested a low bioaccumulation potential. For the bioaccumulation assessment in terrestrial species, the study examined several physiologically based toxicokinetic and in vitro-in vivo extrapolation studies and derived BMFs of VMS in rats. The derived and predicted BMFs for terrestrial species are relatively small (less than 0.153), suggesting a low bioaccumulation potential. All field BMFs in terrestrial species were less than 1. This is primarily because all VMS are predominantly depurated via respiratory elimination. According to a single field TMF study for air-breathing species, D4 demonstrated trophic dilution in the terrestrial food-web, while no definitive conclusion was reached for D5 and D6 regarding either trophic magnification or dilution. For a better bioaccumulation assessment of VMS, comprehensive surveys of spatial chemical exposures, biota home range, and sampling locations are needed to address the inherent variability in environmental conditions contributing to uncertainties in the bioaccumulation assessment.

3.13.P-Th221 The Freshwater Amphipod *Gammarus Fossarum* as European Model Species for HYBIT Application: Review from Literature and Case Study

Anthony Gérard Edouard Mathiron[1], *Vanessa Brosselin*[2], *Melaine Claitte*[2], *Pierre-Louis HOMBERT*[2], *Vivien Lecomte*[3], *Nicolas Delorme*[3], *Mathilde Duny*[4], *Anthony Catroux*[4], *Mickael Nicolas*[4], *Pascal Pandard*[5], *Guillaume Cottin*[6], *Alaa Bensetra*[6], *Celine Le Cocq*[6], *Cyril Sweetlove*[6], *Olivier Geffard Pr*[3] *and Guillaume Jubeaux*[7], *(1)BIOMAE, France, (2)BIOMAE, France, (3)INRAE Riverly, France, (4)CARSO LSEHL, France, (5)INERIS, France, (6)L'Oreal Research & Innovation, France, (7)BIOMAE, Château Gaillard, France*

The *Hyalella azteca* Bioconcentration Test (HYBIT) provides a non-vertebrate alternative to fish bioconcentration studies for determination of bioconcentration factor (BCF) as part of the regulatory chemical safety assessment of pollutants in aquatic ecosystem (REACH regulation). HYBIT test guideline focused on the North American amphipod *H. azteca*, but it also includes the possibility to work with other amphipod species. Here, we aim at highlighting the interest for including the European freshwater amphipod *Gammarus fossarum* as model species in HYBIT test guideline. First, we reviewed the literature to compare BCF values that are already available for *Gammarus* sp. and *H. azteca*. We found that BCF in both models are strongly correlated. Then, as a proof study of feasibility, an aqueous bioconcentration experiment in semi-static conditions was conducted with *G. fossarum* to assess the kinetics of bioaccumulation and depuration of prochloraz (fungicide of the imidazole family) and phenanthrene (polycyclic aromatic hydrocarbon) by following HYBIT protocol. HYBIT criteria validity were respected and BCF values were determined for both molecules. We thus demonstrate the applicability of HYBIT protocol to *G. fossarum*. Altogether, both review from literature and case study will support an interlaboratory assay project planned in 2025 with several European countries that aim to include gammarids as a second amphipod model in HYBIT test guideline.

3.13.P-Th222 From Plastic Debris to Sea Turtles: A Comparative Analysis of Plastic Additive Profiles

Ye lim Moon[1], *Wonjoon Shim*[2], *Gi Myung Han*[2], *Sung Yong Ha*[2], *Mi Jang*[2] *and Sang Hee Hong*[2], *(1)Department of Ocean Science, University of Science and Technology, "Korea, Republic of", (2)Ecological Risk Research Department, Korea Institute of Ocean Science and Technology, "Korea, Republic of"*

Sea turtles are key bioindicators of chemical pollution due to their long lifespans, slow digestion, high trophic level, and frequent plastic ingestion. Plastic additives, which enhance plastic properties, can leach easily into the environment and cause health impact. However, research on these additives in marine top predators, including sea turtles, and their links to diet and plastic ingestion remains limited. We investigated plastic additives and polychlorinated biphenyls (PCBs) in the livers of 20 sea turtle carcasses, including 9 loggerheads (*Caretta caretta*) and 11 green turtles (*Chelonia mydas*), along with nine types of plastic commonly ingested by sea turtles. The target chemicals included PCBs, hexabromocyclododecanes (HBCDs), antioxidants, phthalate esters, UV stabilizers, and tire related additives.
The accumulation pattern in sea turtles was phthalate esters > UV stabilizers > antioxidants > tire related additives > PCBs > HBCDs. Plastic additives were widely detected in the liver tissues of both species.

Interestingly, green turtles showed significantly higher levels (143 ± 93 ?g/g lw) than loggerheads (92 ± 35 ?g/g lw, $p < 0.05$). Green turtles also had higher levels of antioxidants and UV stabilizers, though not significantly. This finding is notable given green turtles in this study (72 ± 22 n/ind.) ingested more plastic than loggerheads (40 ± 24 n/ind., $p > 0.05$). In contrast, loggerheads accumulated more PCBs (54 ± 199 ng/g lw) than greens (8.5 ± 8.1 ng/g lw), reflecting their omnivorous diet and greater PCB exposure through the food web. Plastics showed high concentrations of phthalate ester (DEHP: 11,061 ± 6,504 ng/g dry weight (dw)), followed by antioxidant (Irganox 1076: 816 ± 550 ng/g dw). Phthalates were predominant in several plastics (e.g., black plastic bag), implying that plastic additives in sea turtles are linked to plastics they commonly ingest. In contrast, antioxidants were dominant in other plastics (e.g., food packaging), but their lower accumulation in sea turtles may reflect their relatively low bioconcentration potential. This study underscores the significant accumulation of plastic additives in marine wildlife, particularly sea turtles, surpassing traditional POPs like PCBs. While further analysis of prey is needed for confirmation, we suggest that plastic ingestion may play a key role in the transfer of plastic additives.

Disclaimer/Disclosure: This research was supported by the grant Development of Technology for Impact Assessment of Marine Plastic Debris on Marine Ecosystem from the Korea Institute of Ocean Science and Technology.

3.13.P-Th223 Evaluation of Bioaccumulation Thresholds for Aquatic Invertebrates and Fish Relative to Different Environmental Protection Goals

Leslie J. Saunders[1] *and Delina Lyon*[2]*, (1)Concawe, Belgium, (2)CONCAWE, Belgium*

The assessment of chemical bioaccumulation (B) in aquatic organisms is a critical component of global chemical assessment and regulatory programs. A metric typically used to describe a chemical s B potential is the bioconcentration factor (BCF), which is commonly measured in the laboratory following aqueous exposures with fish. However, because fish BCF tests require large numbers of experimental (vertebrate) animals, there has been increased efforts to develop new approach methodologies (NAMs) for B assessment. An example of one of these efforts is the non-vertebrate *Hyalella azteca* BCF test (i.e., "HYBIT"; OECD TG 321). Although the HYBIT has been adopted for regulatory assessments in Europe, it is unclear if B thresholds derived from fish data are appropriate for aquatic invertebrates. Between these two taxa there are notable differences in their physiology (e.g., biotransformation capacity, lipid content) and ecology (e.g., trophic position, lifespans, feeding habits) which influences chemical uptake and elimination. Historically, B criteria developed under the Stockholm Convention and other regulatory jurisdictions were established to prevent biomagnification in higher trophic level species and across food webs. The adoption of an invertebrate BCF test suggests that regulatory B protection goals have shifted from preventing B in higher trophic level species to avoiding accumulation in species living at the base of food webs. It is therefore important to assess and compare accumulation patterns in aquatic invertebrates relative to those expected in higher trophic level fish species. Here we employ empirical and model-based assessments to compare BCFs in *H. azteca* with B metrics derived in fish, examine biological, chemical, and ecological conditions that influence derived B metrics (i.e., BCFs, biomagnification factors [BMF], and trophic magnification factors [TMF]), and evaluate where there may be differences in accumulation between these two taxa. Proposals will be developed to support the robust use of bioaccumulation metrics derived for aquatic organisms in scientific and regulatory contexts.

3.13.P-Th224 Advancing Ecotoxicological In Vitro Testing: Comparative Evaluation of Trout Liver Metabolic Assay (OECD TG 319 A & B) and the *Hyalella azteca* Bioconcentration Test (HYBIT, OECD TG 321) Bioassays

Karla M. Johanning[1]*, Markus Brinkmann*[2]*, Pippa Kate Curtis-Jackson*[3]*, Michelle Rau Embry*[4]*, Heike Laue*[5] *and Gordon Sanders*[6]*, (1)KJ Scientific, United States, (2)Toxicology Centre, University of Saskatchewan, Canada, (3)Chemicals Assessment Unit, Environment Agency (England), United Kingdom, (4)Health and Environmental Sciences Institute (HESI), (5)Givaudan Suisse SA, Switzerland, (6)Givaudan International SA, Switzerland*

The development of reliable and relevant in vitro assays for ecotoxicology is crucial for reducing dependency on whole-organism bioassays while improving the accuracy of chemical hazard assessments. We discuss the advantages of the trout in vitro metabolic assays over the *Hyalella azteca* (HYBIT) bioassays in evaluating xenobiotic metabolism and Bioaccumulation prediction.

Liver S9 fractions and hepatocytes offer a mammalian-based metabolic model incorporating phase I and phase II enzymatic pathways, enabling detailed insight into xenobiotic biotransformation. In contrast,

Hyalella azteca bioassays, while ecologically relevant, are limited by their inability to provide mechanistic understanding of metabolic pathways and are resource-intensive in terms of time, organismal use and costly.
Our comparative analysis revealed that liver S9 and hepatocytes metabolism assays not only reduction of organisms used but also allowed for high-throughput screening and quantitative assessment of metabolic kinetics. The *Hyalella azteca* assays, while valuable for whole-organism exposure studies, were less sensitive to detecting sub-lethal metabolic perturbations and lacked the resolution provided by biochemical assays.
By integrating trout liver S9 and hepatocytes assays into the workflow, researchers can achieve a more efficient and mechanistically informative approach to chemical hazard assessment. This aligns with global initiatives to refine and reduce whole-organism testing while enhancing predictive accuracy for bioaccumulation in ecological risk assessments.

3.13.P-Th225 Integrated Approaches to Testing and Assessment (IATA) for Bioaccumulation: Fragrance Ingredients as Case Studies

Heike Laue[1]*, Gordon Sanders*[1]*, Michelle Rau Embry*[2]*, Georg Kreutzer*[1] *and Andreas Natsch*[3]*, (1)Givaudan International SA, Switzerland, (2)Health and Environmental Sciences Institute (HESI), United States, (3)Givaudan Suisse SA, Switzerland*

As part of national and international regulatory programs, the assessment of the potential for a chemical to bioaccumulate is an essential endpoint e.g. as part of PBT (persistent, bioaccumulative and toxic) assessment of chemicals. A weight of evidence (WoE) approach is recommended by most regulatory jurisdictions, such as REACH. However, there is often no clear strategic guidance for implementing this. For the purposes of B assessment, multiple lines of evidence (LoE) can be used to quantify, measure, and qualify the common metrics of the e.g. bioconcentration factor (BCF). LoE can comprise laboratory or field data; in silico predictions; and combinations of in vitro and in silico data. An Integrated Approach for Testing and Assessment (IATA) for Bioaccumulation has recently been published (OECD) encompassing these LoE, in order to facilitate the process for evaluators to collate, generate, integrate, evaluate, and compare LoE for clear and transparent decision making in B assessment.
Here we demonstrate the applicability of the IATA to combine different LoEs for the bioaccumulation assessment of fragrance ingredients: Musk Xylene, Opalal, 8-Cyclohexadecen-1-one and Cyclohexyl Salicylate. LoEs include in silico predictions of log Kow values, measured log Kow values, predicted biotransformation half-lives, in vitro intrinsic clearance measured in the trout liver S9 fractions substrate depletion assay (OECD Test Guideline (TG) 319B), predicted bioconcentration factors (BCF) using QSARs and measured BCFs in fish (OECD TG 305).
These case studies demonstrate how multiple LoEs can be integrated for bioaccumulation assessment of data poor and data rich fragrance ingredients, illustrating how this tiered assessment approach can be effectively and transparently applied to prioritise / de-prioritise the need for higher tier B testing.

3.13.P-Th226 Intelligent Sampling in Standard In Vivo Toxicity Studies to Complement Bioaccumulation Assessments in Mammals – Fragrance Ingredients as Case Studies

Heike Laue[1]*, Leonida Maliqi*[2]*, Tina Haupt*[2]*, Gordon Sanders*[1] *and Andreas Natsch*[2]*, (1)Givaudan International SA, Switzerland, (2)Givaudan Suisse SA, Switzerland*

Traditionally, a fish bioconcentration factor has been employed to determine the propensity of chemicals to bioaccumulate in organisms in the environment. The requirement to perform a separate assessment of bioaccumulation in terrestrial air-breathing species was introduced in the 2017 revision of the Guidance on Information Requirements and Chemical Safety Assessment, however without technical guidance on how to develop/achieve such an assessment, beyond partitioning-based screening criteria. A tiered assessment approach was proposed in an ECHA guidance document; i.e. in silico screening, in vitro biotransformation assays, in vivo mammalian studies as a last option.
In the two case studies presented here, a smart sampling approach within standard in vivo repeated dose toxicity studies required from Annex VIII and above in REACH was applied for two fragrance ingredients, Ambermax and Glycolierral. The OECD TG 421 Reproduction/Developmental Toxicity Screening Tests were carried out as a REACH requirement. Rats were exposed daily for 28 days by oral gavage. Plasma, urine, faeces and organs (liver, kidney), which are routinely collected at the end of chemical exposure were used for analytical screening. In addition, adipose and muscle tissues were collected from the same animals. Plasma samples were collected at 0 h, 0.5 h, 2 h, 4h and 24 h post dose at day 1 and at day 28. Plasma and tissue samples were analysed by GC-MS and LC-MC for parent chemicals and potential metabolites from the vehicle control group, low and mid dose.

Rapid metabolic transformations of Ambermax and Glycolierral were observed with peak plasma concentrations at 2-4 h post dose. Hydroxylated and glucuronidated metabolites were detected for both chemicals. Concentrations in adipose tissue were dose dependent and in the low ng/mg tissue range, indicating that these rapidly metabolized molecules did not bioaccumulate in the fat tissue.
By integrating additional samplings without requiring additional animals in line with the 3Rs, data from standard repeated dose studies can be leveraged to develop further weight-of-evidence with respect to body distribution (in particular adipose tissue) and elimination half-lives of chemicals. Combining data from in vitro intrinsic clearance in S9 fractions with IVIVE modeling will allow to use these case studies of highly hydrophobic chemicals to model bioaccumulation based on in vitro data.

3.13.P-Th227 Exploring the Potential of Bioconcentration, Bioaccumulation and Trophic Transfer of Pesticide Mixtures in Freshwater Ecosystems
Isabel Campos[1]*, Ana Re*[1]*, Mariana Rodrigues*[1]*, Joana Luisa Pereira*[2]*, Hans Mol*[3]*, Rima Osman*[4]*, María Ángeles Martinez*[5]*, Adrian De La Torre*[5]*, Irene Navarro*[5]*, Francisco Alcon*[6]*, Josefina Contreras*[7]*, Jakub Hofman*[8]*, Paula Harkes*[4]*, Vera Silva*[4]* and Violette Geissen*[4]*, (1)Centre for Environmental and Marine Studies (CESAM) & Department of Environment and Planning, University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (3)Wageningen Food Safety Research (WFSR), part of Wageningen University & Research, Netherlands, (4)Soil Physics and Land Management Group, Wageningen University & Research, Netherlands, (5)Unit of POPs and Emerging Pollutants in the Environment, Department of Environment, CIEMAT, Madrid, Spain, (6)Department of Business Economics, Universidad Politecnica de Cartagena, Spain, (7)Department of Agricultural Engineering, Universidad Politecnica de Cartagena, Cartagena, Spain, (8)RECETOX, Masaryk University, Czech Republic*
Freshwater ecosystems, especially those near agricultural fields, are highly susceptible to complex pesticide mixtures that can harm aquatic organisms. One of the key challenges in ecotoxicological risk assessment is predicting how organisms will respond to exposure to multiple pesticides simultaneously. As part of the H2020 SPRINT project, this study aimed to tackle this challenge by assessing the ecotoxicity of pesticide mixtures on aquatic organisms using a high-tier evaluation approach, employing a three trophic level aquatic microcosm. The experimental design included a trophic chain model with a producer (*Nasturtium officinale*), a primary consumer (*Atyaephyra desmarestii*), and a secondary consumer (*Procambarus clarkii*). This setup enabled the evaluation of pesticide bioconcentration, bio-amplification, and transfer across trophic levels. We tested two pesticide mixtures (five pesticides each) based on the pesticides found in aquatic systems of two case studies (Spain and Czechia) under two conditions: control and predicted environmental concentrations (PEC). Bioconcentration tests showed significant pesticide accumulation in the three aquatic organisms from both Spain and Czechia, with *N. officinale* accumulating the most. Overall, organisms in Czechia had higher pesticide levels. *N. officinale* consistently had the highest bioconcentration factors (BCFs), acting as a pesticide reservoir, while BCFs decreased from *A. desmarestii* to the *P. clarkii*, suggesting reduced accumulation at higher trophic levels. The pesticides transfer across trophic levels showed that the pesticides levels in the producer directly influenced the levels ingested by the primary consumer and that the highest bioconcentration occurred when the primary consumer ingested a contaminated producer while exposed to the PEC, highlighting the importance of both contaminated food sources and pesticide mixtures in the environment. The biomagnification factors were consistently low across both countries, indicating minimal trophic transfer of pesticides from primary to secondary consumers. These findings suggest that while primary producers are at greater risk for pesticide toxicity, the overall risk of bioaccumulation and biomagnification within this food chain is low. Further research is crucial to gain a deeper understanding of the ecological impacts of pesticide mixture bioaccumulation and to assess its wider effects on biodiversity and ecosystem health in aquatic environments.

3.13.P-Th228 Crayfish Behavior in the Shadow of Bioaccumulation of Ionizable and Neutral Pharmaceuticals

Anna Koubova[1], Jan Kubec[1], Worrayanee Thammatorn[2], Petra Novakova[1], Ganna Fedorova[1], Anton N. Kouba[1] and ***Vladimír Žlábek****[1], (1)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Czech Republic, (2)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Czech Republic; 2) Department of Veterinary Public Health, Faculty of Veteri, Thailand*

Ionizable environmental pollutants, including pharmaceutical residues, can be readily bioavailable, bioaccumulative, and potentially toxic for aquatic biota. Risks for exposed organisms arise from continuous exposure, accessible ion entrance through cell membranes and various modes of action on cell receptors. In the present study, we determined behavioral changes in marbled crayfish *Procambarus virginalis* exposed to environmentally relevant (EC) and lowest observed effect concentrations (LOEC) of three selected pharmaceuticals. Anticonvulsant carbamazepine (neutral compound; EC =11.6; LOEC = 116 µg/L), anti-inflammatory diclofenac (ionizable weakly acidic compound; EC =31; LOEC = 310 µg/L), and antihistamine diphenhydramine (ionizable weakly basic compound; EC =1.4; LOEC = 95 µg/L) were selected to investigate pharmaceutical-induced behavioral alterations in crayfish after the 96-hour exposure under laboratory conditions (water pH 7.6 and temperature 22°C). The results revealed that neutral carbamazepine caused alterations in crayfish behavior, while ionizable diclofenac and diphenhydramine showed insignificant changes. We observed almost twice the distance moved and walking rates in crayfish exposed to EC carbamazepine compared to solvent control. However, carbamazepine exposure LOEC did not show any difference in the crayfish distance moved or walking rate. All test pharmaceuticals on both EC and LOEC levels evoked increments in movement activity, but only carbamazepine exposure elicited a significant effect. This study clarifies that physico-chemical properties and modes of action of the test pharmaceutical compounds could play important roles in how aquatic crustaceans distinctly cope with chemical stressors. Changes in ecologically important behavioral traits can potentially arise from exposure to environmental pharmaceuticals.

3.13.P-Th230 *Hyalella azteca* Bioconcentration Test (OECD 321) - Optimisation and Automatisation

Guillaume Cottin*[1], Cyril Sweetlove[1], Celine Le Cocq[1], Mahily Cereyon[1], Alaa Bensetra[2] and Rita Castor[2], (1)L'Oréal Research & Innovation, France, (2)L' Oréal Research & Innovation Analytical Sciences Department, France*

In the context of the Animal Testing Ban (ATB) regulation for cosmetics sector, in vivo tests involving laboratory animals (OECD 305) cannot be carried out. The publication of OECD 3212 using a freshwater amphipod supports a robust bioaccumulation assessment of cosmetic ingredients1. Performing this test brings technical difficulties and requires expertise in both biology and analytical chemistry.
The aim of this study is to present optimized and automated methods for performing the bioaccumulation test according to OECD guideline 321 and aims to present the best practice guidance for assessing the bioaccumulation of cosmetic ingredients.

Performing an OECD 321 test (HYBIT) in the laboratory requires rearing *Hyalella azteca*. Although *Hyalella azteca* is an easy organism to breed under laboratory conditions, it requires suitable infrastructures and a considerable amount of human time. Depending on the size of the farm, preparation of culture media, maintenance and feeding can monopolize up to 50% of a technician's time.
As the HYBIT test is only carried out on male hyalella, it is necessary to carry out a sexing sort prior to the bioaccumulation test. Added to this is the optimization of the analytical monitoring method (in water and in *Hyalella azteca*) as well as ecotoxicity pre-testing to define the target exposure concentration. These constraints limit testing capacities and make it difficult to carry out environmental assessments of a global product portfolio in a short space of time.
Optimizations and automations have been developed by L'Oréal to scale up OECD 321 testing capabilities and reduce operator-dependent biological variability.
These developments mainly concern the semi-automation of hyalella breeding and the development of a sorting robot. The limiting step remains the development of an analytical method.
Advances in the development of alternative methods provide a toolbox to correctly assess the

bioaccumulation of chemical substances placed on the market. B criteria assessment should follow a multi-source data approach, integrating models, in vitro biotransformation data and monitoring studies, for a more accurate assessment of the bioaccumulation potential of hydrophobic substances.
These developments on the optimization and automation of the OECD HYBIT 321 test support and promote a NAMs methodology for bioaccumulation assessment, particularly in a regulatory context that prohibits testing on laboratory animals.

3.14 From Persistence to Mobility: Integrating Science with Policy and Bridging Gaps in Understanding Impact and Mobility

3.14.T-01 Scoping the Limitations of Koc to Assess Mobility of Acidic Pesticides

Reiner Yah[1]*, Gabriel Sigmund*[2]*, Steven Droge*[3]*, Ivo Roessink*[4]*, Wim Beltman*[1]*, Marc-Sven Roell*[5]*, Sebastian Schmidt*[5]*, Thomas Augustin*[5] *and Nora B. Sutton*[6]*, (1)Wageningen University and Research (WUR), Netherlands, (2)EDGE, Wageningen University and Research (WUR), Wageningen, Netherlands, (3)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands, (4)Wageningen University and Research (WUR), Wageningen, Netherlands, (5)Bayer AG, Germany, (6)Environmental Technology, Wageningen University and Research (WUR), Wageningen, Netherlands*

The mobility of pesticides is evaluated by studying the sorption affinity these chemicals have towards soil or sediment particles. A low sorption constant for organic carbon (Koc) of less than Log 2 indicates high mobility and potential for surface and groundwater contamination. However, in contrast to neutral chemicals, the sorption of ionizable pesticides is additionally influenced by environmental conditions such as pH. In the case of neutral pesticides at soil-relevant pH values (i.e., pH 4-9) approaches to determine Koc have been developed. Nonetheless, the behavior of compounds that are permanently charged or ionizable is not consistently taken into account in assessing their environmental mobility. Based on this, the aim is to understand how logKoc varies between ionizable and non-ionizable pesticides, depending on ionization.
Pesticide characteristics (Koc or Kfoc, pKa, acid or base indication, and dissociation) were obtained from the Pesticide Properties DataBase. The charge state for the ionizable chemicals was determined and the experimental values of Koc or Kfoc were obtained from the peer-review risk assessment reports of the European Food Safety Authority. From this data recompilation, the minimum logKoc and maximum logKoc were calculated to derive a ?logKoc to evaluate the variation in sorption behavior of acidic, basic, and neutral pesticides.
The charged anionic compounds exhibit great ?logKoc variability ranging from 0-1.7 indicating substantial variation in their sorption affinity. Their mobility is highly influenced by the charge state of the pesticide and also by environmental factors like pH and the charged state of different soil constituents. This also applies to chemicals that may be partly anionic and neutral (5 < pKa <7), since a high variability of ?logKoc is observed but with a slightly narrower range. For the cationic and non-ionizable chemicals, more consistent ?logKoc are observed with relatively narrow ranges indicating relatively stable sorption affinity.
In conclusion, the high variability of ?logKoc for anionic and ionizable acids indicates the need for pH-sensitive methods to evaluate their mobility in the environment. Due to the charge of the acidic compounds, these show weak interactions with organic matter and charged particles. Their sorption affinity may vary in different soil types which makes average Koc more uncertain for risk assessment.

3.14.T-02 Weight of Evidence in the Persistence and Mobility Assessment of Data-Rich Substances

Dieter Schaefer[1]*, Philip Branford*[2]*, Stuart Leslie*[3]*, Hazel Walshaw*[4]*, Jose Luis Gomez-Eyles*[5]*, Dragan Jevtic*[1]*, Derek Wallace*[6] *and* ***Bernhard Jene***[7]*, (1)Bayer AG, Germany, (2)ADAMA Agricultural Solutions Ltd, United Kingdom, (3)FMC Agricultural Solutions, United Kingdom, (4)Corteva Agriscience, United Kingdom, (5)Syngenta Ltd, Bracknell, United Kingdom, (6)ISK Biosciences Europe, United Kingdom, (7)BASF SE, Germany*

PMT and vPvM will be included as new hazard classifications in the EU for the labelling of chemicals within CLP. The criteria for persistence (P) and mobility (M) have been defined and technical guidance

has been developed. In the regulation and the guidance it is foreseen that (i) all available data should be considered and (ii) a weight of evidence (WoE) approach should be applied.
Compared to many other classes of chemicals, plant protection products (PPP) are data rich concerning information about their behaviour and fate in the environment. This is due to extensive data requirements in the PPP EU and national regulations in which the potential transport of PPP to drinking water sources such as groundwater or river-bank filtrate has been addressed for several decades.
Principles for WoE published by ECHA state that a combination of information from several independent sources is used to give sufficient evidence to fulfil an information requirement. This depends on (i) quality, (ii) reliability, (iii) consistency and (iv) relevance regarding the respective issue. Consequently, it should be possible to overrule a first-tier assessment based on conservative simple standardized key studies by sufficient evidence from more reliable and realistic higher tier studies if these provide alternative or complementary information.
In the context of PPP registration many additional information sources and higher tier studies are available which should be used for a WoE approach. Since used in authorization of a PPP these studies have all or most of the following characteristics which justify their consideration and adequate weighting in the WoE approach: (i) Performed according to current guidelines, guidances or well described frameworks, (ii) extensive documentation, (iii) high quality standards (e.g. GLP for experimental or Good Modelling Practice for modelling studies) and (iv) peer reviewed (EFSA, RMS, stakeholders and public).
Additional available information includes for instance field degradation, outdoor lysimeter, field leaching studies, kinetic evaluations, modelling of persistence and mobility, and monitoring. The information can either be used to derive parameters that can be directly compared with the respective criteria, or they can provide additional information on the substance properties. For example, if a substance is not found in drinking water sources this is a clear indication of non-mobility provided false negatives can be ruled out.

3.14.T-03 Enhancing Regulatory Implementation for PMT and PBT Substances: A Comprehensive Categorization Approach Using the NORMAN SusDat Database
Adriana Sardi[1]*, Valeria Dulio*[2]*, Pierre Boucard*[1] *and Sandrine Andres*[1]*, (1)INERIS, France, (2) INERIS, France*
Following the addition of the PBT/PMT hazard class in the Classification, Labeling and Packaging (CLP) regulation, there is an urgent need to rapidly identify chemicals that will require priority work to confirm or refute these properties. In this work, we propose a categorization framework for identifying substances with persistence (P), mobility (M) and bioaccumulable (B) properties and facilitating the implementation of CLP regulation, which requires industrials to label substances as PMT or PBT substances of human and environmental concern. We applied the categorization methodology to a large dataset, the NORMAN SusDat database, which accounts for more than 120k substances. While generating comparable scores for hundreds of thousands of substances may seem daunting due to varying data availability, our methodology accounts for the data source and attributes the classification to different scenarios that reflect the data quality and quantity, offering a practical solution. The scenarios include a conservative one that selects the highest available score and an average scenario that calculates the average for the scores issued from modeled data. Finally, the robust scenario prioritizes experimental over predicted data. We summarize the three scenarios' categorizations by calculating a global score that considers the classification's severity, the risk, and the substance's data availability. Within the proposed methodology, we prioritized persistency, a shared property for two CLP hazard classifications. Substances classified as vP and toxic with a high and medium level of confidence have a higher global score than PB or PM substances. We assume that vP - also called extremely persistent - substances will sooner or later represent a hazard to the environment or human health. We ranked substances according to their global score and split them into different lists with specific action recommendations for each list, one being substances ready for assessment that includes over 20k substances. Finally, we mapped the substances uses for the assessment list and identified the economic sectors where vPvM/PMT or vPvB/PBT substances occur the most. This work is part of the EU project PROMISCES, which aims to protect the environment, human health, and natural resources from PMT and prevent their impact within the soil-sediment-water system.

Disclaimer/Disclosure: The authors thank the PROMISCES project (EU Horizon 2020, 101036449) for funding.

3.14.T-04 Groundwater Monitoring Insights of 101 PMT/vPvM and PFAS
Till Meier[1]*, Janek Dann*[1]*, Peter Borke*[2]*, Thorsten Reemtsma*[1] *and* ***Qiuguo Fu***[1]*, (1)Helmholtz Centre for Environmental Research (UFZ), Department of Environmental Analytical Chemistry, Germany, (2)Saxon*

State Office for Environment, Agriculture and Geology LfULG, Urban Water Management, Germany
Persistent and mobile chemicals (PMs), including polar per- and polyfluoroalkyl substances (PFAS), pose significant risks to human health and the environment due to their mobility and limited removal by current water treatment technologies. Many PMs remain unregulated, leaving groundwater resources vulnerable to contamination and long-term exposure risks. This study monitored 101 PM chemicals across 180 groundwater wells in Germany, located in various land-use areas, to assess the occurrence and distribution of toxic PMs and their regulatory coverage gaps. Samples were characterized based on hydrological and contamination factors, with analysis using a validated multi-target super-critical fluid chromatography method. High detection of toxic PMs was found. For example, 69% of the total abundance in groundwater was from toxic PMs, with polar PFAS and other organic/inorganic PMs frequently detected at high concentrations. Over 90% of detected PMs were classified as non-persistent under REACH, since aquifers are not considered in persistence testing. This classification fails to address their potential accumulation in groundwater. In addition, mobility and persistence metrics were limited. Standard metrics, like logKoc, showed limited correlation with PM occurrence, whereas emission data better predicted PM abundance, suggesting that emission likelihood should be prioritized in regulation. The findings underscore the need for updated regulatory frameworks that consider emission potential, transformation products, and more realistic environmental compartments to effectively manage PM chemical risks in groundwater.

Disclaimer/Disclosure: This study received funding from the German Research Foundation - DFG (grant agreement No. 437788391).

3.14.T-05 Scoping Unregulated Pollutants in Aqueous Effluents for Circular Water Use in the Netherlands

*Sophie Melchers[1], **Jill April Ramona Soedarso**[2], Nora B. Sutton[3] and Huub H.M. Rijnaarts[3], (1)Utrecht University Centre for Water, Oceans and Sustainability Law, Utrecht University, Netherlands, (2)Wageningen University, Department of Environmental Technology, Netherlands, (3)Wageningen University, Department of Environmental Technology, Netherlands*
During periods with limited precipitation, the indirect reuse of treated municipal effluent via surface water is inescapable in the Netherlands. However, treated municipal effluent contains organic micropollutants (OMPs) such as pharmaceuticals, personal care products, pesticides, and industrial chemicals such as PFAS. Many of these OMPs may be persistent, mobile, and toxic substances (PMTs). EU laws such as the Urban Wastewater Treatment Directive (recast) and policies such as the Circular Economy Action Plans, promote the reuse of treated effluent. Regulation 2020/741 on the minimum requirements for water reuse creates a further legal framework for the reuse of effluent for agricultural irrigation. Despite these regulations, only a few OMPs are well regulated for effluent reuse. Thus, many PMTs and other OMPs may currently fall through the regulatory cracks and may not be sufficiently regulated for safe effluent use.
The Dutch emission registration database WATSON was used to identify OMPs emitted in Dutch effluents that could end up in the environment. The OMPs were grouped per use category (industrial chemicals, pesticides, personal care products, pharmaceuticals and other) and per regulation (EU, Dutch or not regulated). In 2014-2019, over 1000 micropollutants were detected in Dutch effluents. When comparing the EU and the Dutch regulations both regulatory groups have overlaps, but are still missing regulations for most industrial chemicals, pesticides, pharmaceuticals, and personal care products in the context of effluent reuse. Many PMTs and other OMPs are not regulated in Dutch effluents, neither by EU nor Dutch regulation. For the safe reuse of effluent in the Netherlands there is still a need for a regulatory framework for effluent quality. Such future new regulations may be based on exposure scenarios and use profiles (e.g. industrial chemical, pesticide, pharmaceutical, personal care product) or based on chemical structure, in contrast to the currently predominant compound-by-compound approaches.

3.14.P From Persistence to Mobility: Integrating Science with Policy and Bridging Gaps in Understanding Impact and Mobility

3.14.P-Tu236 Is the Organic Carbon Normalised Partition Coefficient the Most Appropriate Measure of Partitioning for Substances that are Highly Mobile in the Environment?

***Adam Peters**, wca environment Ltd., United Kingdom*
Screening level assessment approaches based on log KOC have been used to identify substances that could potentially meet previously defined criteria for the mobility of substances. Due to the lack of

suitable alternative metrics these prioritisation exercises have generally used the Organic Carbon normalised partition coefficient KOC as the indicator of substance mobility in the environment. However, reasonable concerns have been raised about the appropriateness of the KOC concept to indicate to potential for substances to be highly mobile in the environment because, whilst organic matter plays a dominant role in the adsorption of hydrophobic substances to surface soils, it is of considerably less importance for some ionisable substances and because organic matter is a much less important component of subsoils and other sub-surface media than it is in surface soils. Scientists and regulators will need to evaluate whether the KOC parameter is an appropriate descriptor for the partitioning of these highly mobile substances. However, whilst an empirical overall partition coefficient may seem like an appropriate measure the fact that soils, and other sub-surface media are highly variable in their composition, not just in relation to organic matter contents, but also the levels of iron and aluminium (oxy)hydroxides and clay minerals, as well as the many different types of clay minerals, empirical partition coefficients can be highly variable for the same substance in different soils and sub-surface media. The determination of partition coefficients in a standardised test medium could address the issue of variation between different media, although the selection of an appropriate medium composition that is adequately representative of the most relevant environmental media would be problematic. However, the OECD 121 screening test to determine KOC values effectively provides a single test medium in the form of a chromatography column to produce results that are directly comparable between different substances. There are a number of important limitations to the use of the Organic Carbon Normalised Partition Coefficient (KOC) for highly mobile substances, but there are also considerable difficulties associated with defining an appropriate alternative metric that could be used to define the relative mobility of different substances in a diverse range of environmental media.

3.14.P-Tu237 Fate and Transport of Biosolid-Derived PFAS across the Terrestrial-Aquatic Continuum of Agroecosystems

***Diana Oviedo Vargas**[1], Jess Anton[2], Melinda Daniels[1] and Jimmy Murillo Gelvez[2], (1)Stroud Water Research Center, United States, (2)Center for PFAS Solutions, United States*

Per- and polyfluoroalkyl substances (PFAS) are a highly diverse class of contaminants of emerging concern produced intentionally and unintentionally over the past 80 years with an ever-expanding inventory of thousands of unique known structures. Some PFAS have been linked to adverse human health effects, and many are known to bioaccumulate and biomagnify in terrestrial and aquatic species. The application of biosolids (i.e., sludge from wastewater treatment facilities) as a soil amendment on farmland is a widespread practice in the United States (US) and worldwide. While beneficial for soil health and sustainable waste management, this practice may represent a potentially concerning yet understudied pathway for PFAS contamination of soil and water. This study investigates PFAS fate and transport in soils and a freshwater stream on a working farm in Pennsylvania, US with 24 years of regular biosolid use. In January 2023, we began monitoring PFAS concentrations in surface soils (0-15 cm), stream sediments, and stream water using USEPA Method 1633. Preliminary results showed the detection of PFBS, PFOA, PFOS, PFNA, PFDA, PFDS, PFUnA, and PFDoA in soils, with total PFAS concentrations averaging 20±4 ng/g. In addition, soil PFAS concentrations have remained constant over the last 1.5 years since biosolid application ceased. Compounds detected in the stream water differed from those found in the soil and included PFBA, PFBS, PFPeA, PFHxA, PFHxS, PFHpA, PFOA, PFOS, and PFNA, with total PFAS concentrations averaging 126±25 ng/L. Interestingly, despite the presence of various PFAS in the water column, PFAS concentrations in sediments were below the quantification limits for most compounds. This may be related to the low organic matter content of the stream sediments (0.5-1%) and the high hydrophilicity of most compounds detected in the water column. Our results suggest that short-chain PFAS are more readily mobilized from the surface soil to the stream water. Future work will explore high-frequency sampling of stream water and sediments during high-flow conditions to investigate the role of storm events in mobilizing (long-chain) PFAS from the soil to the stream via overland flow. Altogether, these results will improve our understanding of PFAS fate and transport in agroecosystems and the potential implications for human and environmental health.

3.14.P-Tu238 The Leaching Calculator: A Tool for Predicting Leachability Within the Framework of Mobility in the New PMT/vPvM Hazard Class

***Dimitrios Alexander Skodras**[1] and Judith Klein[2], (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

New CLP regulations highlight the importance of mobility assessments for classifying persistent and mobile substances, especially PMT (persistent, mobile, toxic) and vPvM (very persistent, very mobile) compounds. Traditional mobility assessments using the organic carbon partition coefficient (logKoc) can be insufficient, as they overlook degradation processes, solubility, and other transport mechanisms. The proposed LeachingCalculator introduces a robust approach for predicting pesticide leachability to groundwater, complementing logKoc-based evaluations.
The LeachingCalculator builds upon the established FOCUS PELMO model, simulating pesticide movement through soil using variables such as degradation half-life (DegT50) and Koc. By running simulations across representative European scenarios, the tool generates a leachability matrix, interpolating predictions for various combinations of DegT50 and Koc. The model's output includes conservative leachability thresholds (1% and 10%), classifying substances as non-mobile, mobile, or very mobile, aiding in regulatory decision-making.
Evaluation against groundwater monitoring data showed strong alignment between predicted mobility and observed contamination levels, although only 12 substances with sufficient data were analyzed. The LeachingCalculator is available as an open-source, user-friendly tool (https://github.com/IMEDiman/LeachCalc), enabling mobility assessments without requiring advanced modeling expertise. This approach ensures regulatory compliance while addressing critical gaps in current assessment frameworks.

Disclaimer/Disclosure: We thank CropLife Europe for funding this project.

3.14.P-Tu239 Challenges in Assessing the Mobility of Specific Substance Groups

***Marlies Bergheim**, Julia Wilmers and Johannes Tolls, Henkel AG & Co, Germany*

A new CLP revision came into force in 2023 to better safeguarding drinking water resources from harmful substances. With the introduction of the new EU CLP hazard classes, the classification and labeling of chemicals now require the assessment of a completely new hazard property: the mobility of a chemical. This new hazard property focuses on the ability of substances to be transported with water through soil/sub-soils and potentially contaminate groundwater. Up to now, there is little experience in assessing the mobility of substances. The challenge becomes more complex with unstable or reactive substances. They may degrade or react with the soil before they have even reached significant depths. These substances may not follow the same leaching patterns as stable compounds because they break down in soil into transformation products. The mobility of these transformation products may differ from that of the parent compound, and understanding this difference is crucial for assessing the mobility of the parent substance.
Current experimental methods are limited as standard tests typically assume stability and do not consider in-depth how to assess the degradation or reaction of substances during their percolation through soils. The same applies to ionizable substances, which pose a unique challenge because their individual charge density can lead to interactions with soil particles, particularly soil organic matter and soil clay minerals. As such, their mobility in soil is highly dependent on the specific characteristics of the soil.
Existing test methods appear to be inadequate for reactive, unstable, or ionizable substances, and new testing approaches or adaptations seem necessary to ensure reliable prediction of chemical mobility. This poster highlights these challenges, emphasizing the need for scientific innovation and the importance of cross-sector information exchange.

3.14.P-Tu240 Issues Related to the Measurement of Log Koc Using the OECD TG 121

***Marie Collard**[1] and Dushanee Sriyarathne[2], (1)DSM-Firmenich, Belgium, (2)dsm-firmenich, United States*

Recently, new hazard classes for Persistent, Mobile and Toxic (PMT) as well as very Persistent and very Mobile (vPvM) chemicals were included in the European Classification, Labeling and Packaging Regulation (CLP). The assessment information required for the evaluation of a chemical s Mobility (M) is the logarithm of the organic carbon-water partition coefficient (log Koc). Multiple methods are available to measure this parameter, one of which is the OECD TG 121 which estimates the adsorption coefficient using High Performance Liquid Chromatography (HPLC). This method is a comparative approach with a number of standards being used to define the retention time in the column vs. their known log Koc (as defined in the TG) and then estimating the log Koc of the chemical of interest based on its retention time and using the regression established with the standards. However, this method was established over 20 years ago and would benefit from an update to take into consideration the latest scientific knowledge.

Indeed, this method has limitations, particularly for very mobile chemicals, as it is only applicable for substances with a log Koc greater than 1.5. The accuracy of the results is also highly dependent on the choice of standards, which primarily represent Plant Protection Products and Hydrocarbons and do not encompass the diversity of chemicals in databases like REACH. Moreover, some of those standards are now restricted in their use and are difficultly accessible and others are ionizable, hence particular attention is required. Inconsistent log Koc values for the same standards in the literature further raise questions about the method's accuracy. Additionally, there is a lack of proper standards covering the high end of the range. Finally, standards do not always elute in the expected order, complicating interpretation. To address these challenges, we have compiled data on log Koc values and evaluated the variability introduced by different standards. We also propose alternative standards, particularly for fragrance materials, to improve the method's applicability and reliability across a broader range of chemicals.

3.14.P-Tu241 An Approach for Accounting for Structural Similarity in Reference Substance Selection for Highly Mobile Test Substances in OECD TG 121 and Similar Studies

*Adam Peters[1], **Sylwia Kosmala-Grzechnik**[2], Iain Wilson[2] and Graham Merrington[2], (1)wca environment Ltd., United Kingdom, (2)wca, United Kingdom*

Adsorption or partition coefficients such as the organic carbon normalised partition coefficient are a key parameter for assessing the potential mobility of substance in the environment and is a key input into the Persistent, Mobile and Toxic assessment and very Persistent, and very Mobile assessment that are required to be conducted as part of EU Classification and Labelling regulations. An important guideline method for the determination of the KOC value of a substance is the High Performance Liquid Chromatography method detailed in the OECD TG 121 guideline. The current OECD TG 121 guideline states that determined values using this method have improved accuracy if reference substances that are structurally related to the test substance are used for conducting the test. However, the guideline does not provide any further details regarding how structural similarity should be assessed or a potential approach for applying it in practice. Prior to being able to perform a structural similarity assessment, a defined list of substances that could potentially be used as reference substances needs to be compiled. The substances to be used as reference substances are required to have experimentally derived, reliable, partition coefficients. Reference substances are included in the OECD TG 121 guideline. For highly mobile substances that cannot be tested under the OECD TG 121 guideline the retention times in the chromatography system used would need to be known so that reference substances with both shorter and longer retention times could be identified. The OECD QSAR Toolbox has been used to perform an initial assessment for ten substances identified in OECD TG 121 as reference substances to assess their structural similarity to a number of potential test substances. For the structural similarity profiler to operate, both a measure and a molecular feature are required to be selected; this assessment was performed using the Dice coefficient similarity measure and the PubChem molecular features system. Importantly, the results of this assessment demonstrate that the existing reference substances that are recommended for use in the OECD TG 121 test are not suitable reference substances for many of the substances that have been identified as potentially very mobile in the environment. Although the reference substances used may be suitable for diclofenac and benzamide, they are not suitable for EDTA, formamide, N,N-dimethylacrylamide, or sodium trichloroacetate.

3.14.P-Tu242 Finding the Right Way to Address the Potential Mobility – A Case of Fragrance Material

***Aurelia Lapczynski**, Research Institute for Fragrance Materials, United States*

New hazard classification for the European Union (EU) Classification Labelling and Packaging Regulation (CLP) were recently introduced implementing a new hazard class of Persistent (not or hardly degradable in the environment) Mobile (well soluble in water and therefore easily transported through the environment) and Toxic (toxic to ecosystem) - PMT as well as very Persistent and very Mobile (vPvM) chemicals. The combination of intrinsic P and M properties of chemicals enable them to be transported over long distances from the point of emission, pass natural and artificial barriers and enter drinking water sources causing a high concern with consequent exposure to humans and other organisms. To assess the potential of the material to be mobile, standardized methods have been developed and include estimating the adsorption/desorption behavior of chemicals on different soil types (OECD 106) and/or estimating an adsorption coefficient (Koc) in soil and in sewage sludge using HPLC method (OECD 121). In an effort to understand and select the most appropriate approach for evaluating the potential Mobility of a material, a number of fragrance materials with various physical chemical properties will be selected and evaluated using both approaches (OECD 106 and 121). This will allow us to assess the applicability and challenges associated with current approaches when it comes to fragrance materials. In addition, the newly generated data will be compared to Koc values generated by available models (EpiSuite) to evaluate the applicability to fragrance material s predictions.

3.14.P-Tu243 Development of a Screening Test for the Mobility of Polar and Ionisable Substances in the Environment

*Michael Huben[1], **Adam Peters**[2], Benedikt Ringbeck[3], Dieter Hennecke[1], Richard Gibson[4], Steph Jones[4] and Pippa Kate Curtis-Jackson[4], (1)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)wca environment Ltd., United Kingdom, (3)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Environment Agency, United Kingdom*

The partitioning and binding of substances to components of soils and sediments is an important aspect of their environmental fate and mobility. Screening level assessment approaches to identify potentially mobile substances have generally been based on Koc, because organic matter plays a dominant role in the adsorption of many substances to surface soils. However, concerns have been raised about the appropriateness of the Koc concept to indicate the potential mobility of substances, principally because: (1) adsorption to organic matter is a less important adsorption mechanism for some ionisable substances; and (2) levels of organic matter in subsurface soils are much lower than in surface soils, so other interactions may be more dominant in those media. Currently, there is a lack of suitable alternative metrics by which the other interactions between substances and components of soils and sediments can be measured.

The OECD TG 121 screening method for the measurement of Koc on an HPLC system is often carried out as a simple, quick and cheap method that provides directly comparable results. The cyanopropyl stationary phase allows for the interaction of polar and non-polar groups of a test substance, but it does not include other interactions that may be influential in determining the adsorption properties of more polar and ionisable substances, including ion exchange interactions and some polar interactions.

It may be possible to extend the general concept of the OECD TG 121 screening test to consider additional interactions that occur in soils and other subsurface media, which are especially relevant for polar and ionisable substances. This work investigates whether state-of-the-art mixed mode stationary phases might have the potential to act as surrogates for surfaces where adsorption occurs in soils or sediments reflecting such interactions.

The most promising HPLC solid phases for the intended purpose were identified; we are performing tests with 30 substances using strong cation exchange (SCX), weak cation exchange (WCX), strong anion exchange (SAX), and weak anion exchange (WAX) HPLC-columns, each combined with reversed phase material. If the concept works, we will recommend how an extension of the OECD TG 121 could be set up experimentally. The results of the present project are intended to provide a possible solution and improve the mobility assessment of polar and ionic substances in low organic carbon soils and subsurface media.

3.14.P-Tu244 Mobility of Micropollutants that May Occur in Surface Water Used for Irrigation, in Soil

***Radka Kodesova**[1], Vit Kodes[2], Alina Sadchenko[3], Martin Kocarek[4], Miroslav Fer[5], Helena Svecova[3], Ales Klement[6], Antonin Nikodem[4] and Roman Grabic[3], (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)Czech Hydrometeorological Institute, Czech Republic, (3)University of South Bohemia in České Budějovice, Czech Republic, (4)Czech University of Life Sciences Prague, Czech Republic, (5)Czech University of Life Sciences Prague, Prague, Czech Republic, (6)Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Prague, Czech Republic*

Agricultural soil can be contaminated by various micropollutants. One of the sources of these contaminants is agricultural practice, where a variety of pesticides are used for plant protection. Another source of contamination can be river water that is often used for irrigation. River contamination depends on the sources of the compounds, that can be, for example, discharged wastewater, surface water runoff from agricultural or urban land, etc. Compounds occurrence in soils or their leaching from soil and migration towards groundwater depend on the climatic conditions, properties of the vadose zone environment and behavior of a particular compound, i.e., its sorption onto soils and sediments, and stability in the environment.

Based on our previous study focused on micropollutant monitoring in various matrices of intensively irrigated agricultural land, six compounds (1,3-diphenylguanidine, triethyl citrate, napthalene-2-sulfonic acid, benzo(d)thiazole-2-sulfonic acid, 4-acetamidoantipyrine, and fluorinated telomer sulfonate) were

identified as potential contaminants that can occur in surface water and next in soil and ground water. Since they are found in the environment, they are relatively stable compounds. Their sorption in soil is significantly affected by their dissociation in the environment, i.e. by either negative or positive charges of their molecules.
In order to find out their behavior in various soil environments, we conducted standard sorption experiments for each of them in 16 representative soils of the Czech Republic. The Freundlich sorption isotherms were calculated to express relationships between concentrations in solution and sorbed onto soil particles. Multiple linear regressions were used to derive equations for predicting the Freundlich sorption coefficient (KF) using the properties of tested soils. These equations and the maps of soil properties were used to predict the KF value distributions within the irrigated areas and subsequently to delineate classes of compounds mobility in the soil environment. Next, specific groundwater vulnerability maps for each compound were obtained by combining the DRASTIC vulnerability index, mobility index and stability index.

Disclaimer/Disclosure: The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QK23020018 and QL24010384.

3.14.P-Tu245 Developing the New CLP Guidance on PBT/vPvB and PMT/vPvM Properties: Stakeholder Engagement, Key Considerations and Other Discussion Points

*Konstantinos Prevedouros[1], **Kostas Andreou**[1], Anu Maarit Kapanen[1], Jane Caley[1], Romanas Cesnaitis[2], Doris Hirmann[3] and Aiga Latsone[1], (1)European Chemicals Agency (ECHA), Finland, (2)Telakkakatu 6, European Chemicals Agency (ECHA), Finland, (3)European Chemicals Agency (ECHA), Helsinki, Finland*

Commission delegated Regulation (EU) 2023/707 of December 2022 has amended the CLP Regulation ((EC) No 1272/2008) to add new hazard classes and criteria for the classification, labelling and packaging of substances and mixtures. This regulatory action was dictated by the concern of substances possessing endocrine disrupting, as well as PBT (persistent, bioaccumulative, toxic), vPvB (very persistent, very bioaccumulative), PMT (persistent, mobile, toxic) and vPvM (very persistent, very mobile) properties. Related to the PMT/vPvM properties, the concerns refer to the substance's high persistence and mobility, the possibility to enter the water cycle, the potential for transport away from point sources, the ongoing emissions, build-up of environmental concentrations over time, combined with the potential toxicity. The new hazard classes introduced an urgent need to develop guidance on the application of the CLP criteria for these hazard classes. The European Chemicals Agency (ECHA) is managing the process of harmonised classification and labelling for substances and mixtures since the adoption of CLP in 2008 and has led the exercise of the development of CLP guidance for the new hazard classes. In the development of this guidance document, key ECHA stakeholders, namely Member States, the European Commission, Industry and NGOs were involved. The development of guidance on the assessment of PBT/vPvB and PMT/vPvM substances under CLP took place between early 2023 and the guidance publication date of November 2024. Important aspects on the structure of the guidance, the availability and relevance of different assessment methods, study-specific considerations, applicability and uncertainties will be presented for each individual property (P,B,M and T). Importantly, the necessary stages for conducting the weight-of-evidence determination will be presented, namely the collection of the available information, its evaluation and weighing, its integration and reporting, as well as description of the underlying uncertainty. Approaches regarding the combination of several experimental study results of the same study type will also be elaborated on, as well as example cases to specify further how all information lines can be integrated in order to come to a scientifically robust conclusion on the related CLP numerical criteria.

3.14.P-Tu246 From Policy Making to Implementing: First Lessons Learned from the Harmonisation of Classification and Labelling of Persistent and Mobile Substances Under CLP

*Konstantinos Prevedouros, Flavio Marchetto, Marco Mattiuzzo, Marta Sobanska, **Kostas Andreou** and Simon Uphill, European Chemicals Agency (ECHA), Finland*

The Classification, Labelling and Packaging (CLP) Regulation ((EC) No 1272/2008) aims to ensure a high level of protection of human health and the environment, as well as the free movement of substances, mixtures and articles. The European Chemicals Agency (ECHA) has been managing the implementation of CLP via the process of harmonised classification and labelling (CLH), where proposals mainly from Member State Competent Authorities are submitted to ECHA for substances that may warrant a harmonised classification. Commission delegated Regulation (EU) 2023/707 of December 2022 has amended CLP to add new hazard classes and classification criteria. Thus, as of the 20th of April 2023, proposals for harmonised classification can be submitted referring, among others, to a substance s PBT (persistent, bioaccumulative, toxic), vPvB (very persistent, very bioaccumulative), PMT (persistent, mobile, toxic) and vPvM (very persistent, very mobile) properties. Thus, an increasing number of proposals is expected to start entering the regulatory machinery of ECHA for these new hazard classes. The presentation will highlight key CLP considerations and criteria, with a focus on persistent and mobile substances, as well as the protection goal for the new hazard classes. It will introduce the main elements of the CLH regulatory process, including the various stages, timelines and actors. Importantly, it will summarise key messages and discussion points from the processing of the historical first cases on PBT and PMT properties that have been received between April 2023 and May 2025, when the SETAC meeting is due to take place. Relevant implications for Dossier Submitters/Competent Authorities will be elaborated upon that will tackle data availability and quality issues, the structuring of the presented information and the building of the overall weight-of-evidence, in order to come to a robust scientific conclusion when data is compared with the respective CLP numerical criteria. The issues that have been identified by ECHA during the initial stages of the processing of these harmonised proposals will be grouped and presented, aiming to increase transparency and clarity on regulatory processing and opinion-making. Additionally, elements relevant to the opinion-making process by ECHA s Risk Assessment Committee will be discussed.

3.14.P-Tu247 PBT/vPvB and PMT/vPvM as Hazard Classes in the Environmental Risk Assessment of Human Pharmaceuticals

Astrid Wiemann[1]*, Daniela Gildemeister*[2]*, Bernhard Kodritsch*[3]*, Gunther Speichert*[3] *and Sieglinde Zahorszki*[3]*, (1)German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)Pharmaceuticals, German Environment Agency (UBA), Germany, (3)German Environment Agency (UBA), Germany*

According to the draft Directive relating to medicinal products for human use the hazard classes persistent, bioaccumulative, toxic (PBT), very persistent, very bioaccumulative (vPvB) as well as persistent, mobile, toxic (PMT) and very persistent, very mobile (vPvM) should be evaluated according to the criteria of Annex I to the revised Classification-Labelling-Packing (CLP) Regulation (EC) 1272/2008.

PMT/vPvM is a new hazard class that is currently being included in the CLP Regulation along with PBT/vPvB and endocrine active agents. Due to their low adsorption potential PMT/vPvM substances are negligibly retained by soil and sediment and pose a risk to surface water, groundwater and drinking water e.g. by leaching processes. PBT/vPvB substances accumulate in the environmental compartments and biota and can be distributed in the food chains. Ecotoxicological effects are strengthened by bioaccumulation and may also appear in remote areas like marine and polar regions.

The aim of the current research is to identify the PMT/vPvM substances in human pharmaceuticals being of concern for drinking water and groundwater. PBT/vPvB assessment was already specified in the environmental assessment of medicinal products from the outset and this was at best published in the European Public Assessment Reports (EPAR). For the new hazard class PMT/vPvM no assessment for human or veterinary medicinal products has been carried out to date. To get an overview, the German Environment Agency (UBA) evaluates the active substances in human medicinal products based on data from marketing authorisation procedures assessed in DE. From substances with complete data sets, data for just the half are published e.g. in EPARs. To date 10 human active ingredients were identified as PBT or vPvB. The proportion of identified PMT/vPvM substances is higher, but due to data gaps in many cases a definite PBT/vPvB or PMT/vPvM classification was not possible.

Veterinary medicinal products containing PBT/vPvB substances should generally not be authorised as per legal requirements; PMT/vPvM properties are not taken into account yet. For human active substances with PBT/vPvB or PMT/vPvM properties the draft directive relating to medicinal products for human use provides that a medical prescription will be required and the applicant shall sufficiently address the identified risks and propose risk mitigation measures to avoid or limit emissions into water, soil and air where indicated.

3.14.P-Tu248 Development of a Method for Analyzing Persistent, Mobile and Toxic Compounds, from Groundwater to Drinking Water, Using LC-HRMS

Clementine Gavalon[1]*, Frederique Courant*[2]*, Geoffroy Duporte*[2] *and Elena Gomez*[2]*, (1)Montpellier Alliance for Metabolomics and Metabolism Analysis, Platform On Non-Target Exposomics and Metabolomics (PONTEM), Biocampus, CNRS, INSERM, University of Montpellier, France,*

(2)HydroSciences Montpellier, IRD, CNRS, University of Montpellier, France
The growing pressure on water resources is leading to drinking water shortages and increased pollution. Certain persistent, mobile, and toxic (PMT) substances in aquatic environments have intrinsic properties that allow them to remain in the environment, pass through filtration systems, and withstand conventional drinking water treatments. They can accumulate, especially when wastewater is recycled, eventually reaching resources intended for drinking water. Current data on PMT contamination in water resources are limited, raising significant environmental and public health concerns. In this context, this study focuses on analysing PM/PMT substances in groundwater, surface water, and drinking water of 4 locations around the world with a gradient of anthropic pressure on the water resources from no pressure a priori to increasing pressures depending on water treatment and reuse practices. The initial step of this study was to develop a sample preparation protocol and an LC-MS (liquid chromatography-mass spectrometry) method suited to these compounds.
A literature review of 480 PM/PMT molecules resulted in the selection of 59 compounds from various categories (pharmaceuticals, pesticides, and REACH-regulated chemicals) for targeted analytical method development keeping in mind that a broader suspect screening approach will be also conducted. To achieve an optimal sample preparation and analysis of PMT substances, five solid-phase extraction (SPE) protocols with different cartridges (Hydrophilic-Lipophilic Balance [HLB], Weak Anion Exchange [WAX], ENVI-Carb, Mixed-mode Anion Exchange [MAX], and Mixed-mode Cation Exchange [MCX]) were tested on the 59 selected compounds. For LC-MS analysis, four chromatographic columns (Biphenyl, BEHC18, Cortecs T3, and Acclaim Trinity P1) with various mobile phases were also evaluated.
Following evaluation, the Acclaim Trinity P1 chromatographic column demonstrated superior performances in terms of retention of polar analytes and sensitivity. Regarding sample preparation, 2 complementary methods were selected: HLB and WAX. The HLB cartridge achieved superior results, delivering higher recoveries and lower matrix effects for 43 compounds. Additionally, the WAX cartridge enhanced the extraction of 8 additional compounds that were insufficiently retained by the HLB cartridge. Application of this optimised method on real samples collected in the frame of project revealed the presence of various PM/PMT substances.

3.14.P-Tu249 Quantification of Prioritized Persistent Mobile and Toxic Substances in Urban Water of Barcelona: A Cross-Sectional Analysis of Rainfall, Runoff, and Infiltration Water
*Sergio Santana-Viera[1], Marc Teixido[2], **Filippo Chierchini**[2] and Sandra Perez Solsona[3], (1)Instituto Universitario de Estudios Ambientales y Recursos Naturales (i-UNAT), Universidad de Las Palmas de Gran Canaria, Spain, (2)IDAEA-CSIC, Spain, (3)Department of Environmental Chemistry, IDAEA-CSIC, Spain*
Urbanization, climate change, and the increased frequency of extreme weather events are degrading urban water quality, necessitating adaptive water management strategies. Urban stormwater transports anthropogenic contaminants, including Persistent, Mobile, and Toxic (PMT) substances. These PMT substances pose significant threats to groundwater resources due to their persistence and mobility, with standard water treatments often failing in removal. Monitoring these substances is crucial to understand their fate in natural processes and to validate the mobility criterion used in prioritization. This study aims to deploy a robust analytical method using RPLC-ESI-TQ-MS/MS for the quantification of 40 selected PMT substances, prioritized by the German Federal Environment Agency (UBA) under REACH category A, in urban stormwater, groundwater, and Blue-Green Infrastructure (BGI) effluents, collected during two sampling campaigns, conducted during summer-fall 2024 and winter 2025, covering four districts across Barcelona city, with wells located above and below BGI recharge points. Samples undergo initial filtration and are enriched using vacuum-assisted evaporation before analysis. The method demonstrates high sensitivity and robustness, with chromatographic run times of 14 minutes, recoveries between 70% and 120%, relative standard deviations below 20%, and limits of detection below 10?ng/L. Preliminary results from the 2022 stormwater campaign revealed the detection of all 13 prioritized PMT substances in street runoff, with mean concentrations up to 1??g/L, and several in BGI effluents ranging between 0.1 and 1??g/L. The inclusion of groundwater samples in the current study allows for the exploration and evaluation of the extent of contamination resulting from runoff and BGI effluents in direct contact with the aquifer. Data analysis employs statistical methods to identify geospatial patterns and correlations with hydrological parameters and vehicular traffic. Human health risk assessments are performed for substances ubiquitous in groundwater and those with average concentrations exceeding 100?ng/L. This work underscores the significance of mobility in the environmental behavior of PMT substances and highlights the necessity of monitoring to inform management strategies. Understanding the sources,

transport, and fate of PMTs in urban water cycles is essential for protecting water resources and ensuring the safe reuse of groundwater.

Disclaimer/Disclosure: The authors thank the project URBANWAT (WaterJPI-JC-2018_16) for the foundation of the current work. BP 00280)).

3.14.P-Tu250 Integrating Groundwater in the RAIDAR Environmental Fate Model for the Screening of PMT Chemicals

***Alessandro Sangion*[1]**, *Zhizhen Zhang[2], Li Li[3], Liisa Toose[1], Trevor N. Brown[1] and Jon A. Arnot[4], (1)ARC Arnot Research and Consulting Inc., Canada, (2)University of Nevada, Reno and ExxonMobil Biomedical Sciences, Inc, Houston, United States, (3)University of Nevada, Reno, United States, (4)ARC Arnot Research and Consulting Inc. and University of Toronto, Canada*

Persistent, Mobile, and Toxic (PMT) and very Persistent and very Mobile (vPvM) chemicals are of concern to human and ecological health because of their potential for widespread exposure. Current hazard-based regulatory approaches, based on pass/fail bright-line threshold criteria, may not fully capture the exposure potential of these chemicals, potentially introducing biases in decision-making. This presentation outlines a tiered modelling framework to assess the environmental fate and human and ecological exposure of organic chemicals with potential PMT and vPvM concerns.

The Risk Assessment IDentification And Ranking (RAIDAR) model is a multimedia mass balance model combining environmental fate and aquatic and terrestrial bioaccumulation models to represent regional-scale environments. RAIDAR supports simulations for neutral and ionogenic organic chemicals (IOC). In this work RAIDAR was revised to include groundwater compartments increasing capacity to estimate how PMT chemicals may contaminate critical sources of drinking water. Groundwater conditions in the real world are quite variable; thus predictions of chemical transport to and from groundwater compartments are uncertain. The revised RAIDAR model allows users to select different assumptions (scenarios) including options for groundwater recharge from soil, freshwater, or freshwater sediments.

The results of different model assumptions were compared in a series of simulations using hypothetical organic chemicals encompassing a diverse range of chemical properties (e.g., log KOA 1-10, log KOC -2 10, neutrals and IOCs). The results reveal significant differences in multimedia mass distribution as a function of the chemical properties and for the different environmental configurations with mode of entry representing one of the most sensitive input parameters in the model calculations.

The revised RAIDAR model is included in the freely accessible Exposure And Safety Estimation (EAS-E) Suite online platform (www.eas-e-suite.com) to facilitate access and use by interested stakeholders. Future work could consider the refinement of a local scale fate model, such as RAIDAR Point Source in EAS-E Suite, which is more suitable for exploring the impacts of riverbank filtration on groundwater contamination.

3.14.P-Tu251 Development of Experimental Testing for the Mobility Assessment of Chemicals During River-Bank Filtration

***Prasit Shrestha*[1]**, *Stefan Trapp[2], Klaus Mosthaf[2], Dimitrios Alexander Skodras[3] and Dieter Hennecke[1], (1)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

River-bank Filtration (RBF) is a simple and widely accepted technology which utilizes the natural filtration processes of subsurface materials to remove contaminants and improve the quality of the extracted water. However, certain non-degrading and highly mobile chemicals could be transported across RBF and contaminate the drinking water sources. In order to protect drinking water sources from such mobile chemicals, mobility criteria M has been proposed under EU REACH Regulation ((EC) No 1907/2006). The assessment of M criterion in this approach is based on the organic carbon normalised adsorption coefficient (KOC). In particularly, the KOC approach does not account for I) sorption to clay and mineral surfaces, II) non-linear sorption (Freundlich isotherms), III) for aging processes, slow adsorption to the inner particles, entrapment and irreversible sorption (non-extractable residues NER). Especially the sediments characteristics relevant for RBF in most cases are very poor of organic carbon and the adsorption process during bank passage could take weeks to months. Thus, the aforementioned interaction could become a key parameter for mobility considerations for RBF. This study aims to develop a column testing approach with aquifer-like material for the assessment of sorption processes during river-bank filtration accompanied by the modelling approach for evaluation. For this study, two aquifer materials with variable cation exchange capacity, content of organic carbon, texture (hydraulic conductivity between 10-3 and 10-5 m/s), and porosity will be selected. A column test setup with water saturation in up-flow condition similar to DIN 19528 (Leaching of solid materials Percolation method for the joint examination of the leaching behaviour of inorganic and organic substances) will be used as a basis for the development of this testing approach. Tests will be performed with three environmentally relevant test substances with different degree of polarities and at least one of them as 14C-radioactive labelled substance. An introduction to the test setup, selected reference substances and the first results obtained under this study will be presented.

3.15 Co-Occurrence of Contaminants in Urban and Rural Environments

3.15.T-01 Co-Occurrence of Pesticides and PFAS from Agricultural Pesticide Applications

Michelle L. Hladik[1], *Emily Woodward*[1], *James Gray*[1], *James Orlando*[1], *Dana Kolpin*[1], *Zachary Hopkins*[2] *and Andrea Tokranov*[1], *(1)U.S. Geological Survey, United States, (2)U.S. Geological Survey, United States*

Per- and polyfluoroalkyl substances (PFAS) are frequently found in streams with most research focusing on urban sources of PFAS to surface water (e.g., firefighting foams, industrial releases, and wastewater treatment plant discharges). Pesticide applications are an under-investigated source of PFAS to streams in both agricultural and urban areas. Although many PFAS are not applied as pesticides there are concerns of increased PFAS levels in pesticide containers and as inert ingredients not listed on pesticide formulation labels. Additionally, some pesticide active ingredients can be considered PFAS because their structures contain at least one fully fluorinated methyl or methylene carbon atom (Organisation for Economic Co-operation and Development 2021 revised definition). To better understand the potential co-occurrence of pesticides and PFAS in predominantly agricultural watersheds, 10 streams were selected for sampling in northern California, USA. Agricultural inputs included rice, nuts (almonds, walnuts), tomatoes, alfalfa, and various row crops. Water samples were collected in May and July of 2024 and corresponded with peak target pesticide application timings. Water samples were analyzed for more than 180 pesticides and pesticide transformation products and 64 PFAS compounds. To evaluate potential PFAS occurrence associated with agricultural seed treatments, several types of insecticide and fungicide coated seeds (wheat, canola, soybeans, maize) were extracted and analyzed for more than 50 PFAS. This work will (1) compare the occurrence and concentrations of target pesticides (e.g. the insecticide methoxyfenozide) with commonly detected PFAS (e.g., perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate [PFOS]), (2) evaluate the contribution of pesticides that qualify as PFAS (e.g., the fungicide fluopyram) to overall PFAS concentrations, and (3) determine if PFAS are present in pesticide-coated seeds.

3.15.T-02 Co-Occurrence of Heavy Metals (Cu, Zn, Mg) and Pesticides in European Agricultural Soils: A European Assessment

Adelcia Veiga[1] *and Vera Silva*[2], *(1)Wageningen University and Research (WUR), Netherlands, (2)Wageningen University, Netherlands*

Modern agriculture has led to an increasing occurrence and levels of contaminants in soil, which may pose significant risks to environmental and human health. Over the years, an increasing number of studies worldwide have reported data on different soil contaminants, such as pesticides, heavy metals, microplastics, and pharmaceutical products. However, knowledge on effective soil contamination status remains incomplete/fragmented, also because most of the assessments focus on a single type of contaminants. Notably, there is a significant knowledge gap regarding contaminants co-occurrence and on its implications to soil health. The co-occurrence of pesticides and heavy metals is highly likely in agricultural soils and particularly concerning due to their intrinsic relationship, as pesticides contribute to heavy metal accumulation, and as copper based fungicides have a significant expression on conventional and organic farms. Soil serves as a primary sink and key reservoir for these contaminants, and the application of pesticides, particularly copper (Cu)-based fungicides, contributes to Cu being one of the most common heavy metals in agricultural soils.

This study, part of the H2020 project SPRINT, addresses the critical knowledge gap regarding the co-occurrence of contaminants in agricultural soils by assessing the occurrence and levels of multiple pesticide residues and of selected heavy metals (Cu, Zn, and Mn) across organic and conventional farming systems in Europe.

3.15.T-03 Continuous River Monitoring Networks: Understanding Co-Occurrence of Chemical Pollution from Urban and Rural Sources

Jun Li[1]*, Ieuan Roberts*[2]*, Angelica Islas*[2]*, Martha Villamizar*[2] *and Alistair Boxall*[2]*, (1)Department of Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom*

Water quality and freshwater biodiversity are declining globally due to complex mixtures of chemical pollutants from diverse sources. In England, only 16% of surface water bodies achieve good ecological status under the EU Water Framework Directive. To mitigate the impacts of chemical pollutants on UK freshwater biodiversity, a high-resolution monitoring study is needed that accounts for all chemical sources, prioritizes high-risk substances, and provides spatial and temporal insights into mixture profile variations within catchments. The ECOMIX project conducted a comprehensive high-resolution spatial and temporal monitoring study across 19 sampling sites in 9 English catchments to assess chemical contamination dynamics and evaluate chemical mixture impacts on freshwater biodiversity. Weekly composite samples collected over 12 months (March 2024-March 2025) were analyzed for 53 prioritized organic chemicals covering seven classes, selected based on ecotoxicity, bioavailability, and stakeholder input. Nineteen monitoring sites were selected using k-means cluster analysis based on topography, contaminant sources, land uses, and pathways. Preliminary analysis of the first two months revealed significant spatial and temporal variations in chemical concentrations. Urban sites demonstrated higher pollution levels compared to rural areas, with mean cumulative concentrations of 2763 ng/L and 1394 ng/L, respectively. Temporal variation was observed across all 19 sites, with the ratio of maximum to minimum total concentrations over the two-month period ranging from 1.5 at a location on the River Foss to 19.5 for a location on the River Wharfe. Downstream sections consistently displayed higher concentrations than upstream areas, particularly in rivers intersecting urban zones, driven by industrial effluents, urban runoff, and municipal wastewater discharge. Pharmaceuticals, pesticides, and personal care products were the dominant contaminants, with mean concentrations of Metformin (933 ng/L), Cypermethrin (157 ng/L), and Methylchloroisothiazolinone (117 ng/L) as key contributors in each class. This monitoring study has generated a large and systematic dataset, revealing spatial and temporal patterns of chemical contamination in urban and rural environments. The findings support the development of policy-driven strategies for effective pollution management and the mitigation of threats to freshwater biodiversity.

3.15.T-04 Size-Segregated Analysis of Airborne Nano- and Micro-Plastics and their Association with Carbonaceous Species in an Urban Environment

Ankush Kaushik[1]*,* ***Anju Elizbath Peter***[1]*, Manuela van Pinxteren*[1]*, Barbara M. Scholz-Boettcher*[2] *and Hartmut Herrmann*[1]*, (1)Leibniz Institute for Tropospheric Research (TROPOS), Germany, (2)Institute for Chemistry and Biology of the Marine Environment (ICBM), Carl von Ossietzky University of Oldenburg, Germany*

The presence of nano- and micro-plastics (NMPs) in the air has emerged as a significant environmental and health concern. Airborne NMPs have been detected in outdoor environments, but most research is focused on the concentration of deposited particles, while submicron-suspended NMP particles, which directly impact human exposure, are understudied. Extensive studies exploring the interrelationships among polymers and their interactions with other urban pollutants, such as carbonaceous species, are lacking. Initiatives are needed to publish data on the extent of NMP pollution. Hence, the current study fills the gap in data scarcity to understand the dynamics, sources, and degradation of NMP pollutants as PM10 NMPs, coarse microplastics (CMPs) as PM10-2.5 and fine microplastics (FMPs) as PM2.5 and their interaction with other carbonaceous parameters. We analysed synthetic polystyrene (PS), polyethylene (PE), polypropylene (PP), polyethylene terephthalate (PET), polyvinyl chloride (PVC), poly-(methyl methacrylate) (PMMA), polycarbonate (PC), and TWPs in PM10 and PM2.5 samples using pyrolysis-gas chromatography coupled with mass spectrometry (Py-GC-MS). The average total atmospheric NMPs concentration was found to be 0.6±0.1 µg/m3, 0.3±0.1 µg/m3 and 0.3±0.1 µg/m3 in PM10 NMPs, FMPs and CMPs respectively. TWPs contribute ~60% to the NMPs composition in all size fractions. TTT, PMMA, PVC, and PC mostly contribute to FMPs, and PP, PE, PET, and PS contribute more to CMPs. Airborne NMPs exhibit significant interactions with carbonaceous species, influencing their environmental fate and transport. In CMPs, primary organic carbon (POC) and elemental carbon (EC) show direct emission associations with NMPs, whereas correlation with secondary organic carbon (SOC) indicates their secondary formation during the degradation process in the atmospheric environment, especially in FMPs. The current NMPs quantification method is reliable, which includes a large spectrum of analysed polymers and assesses the relation of analysed NMPs with the carbonaceous species to understand their dynamics and environmental behaviour.

Disclaimer/Disclosure: This work is a part of AirPlast project funded by the German Leibniz Association under the project no. K389/2021.

3.15.P-Th240 Modelling Chemical Mixtures for Assessing the Impact on Freshwater Biodiversity in Yorkshire, UK

Martha Villamizar[1]*, Alistair Boxall*[1]*, Sim Reaney*[2]*, Ivo Pink*[2] *and Colin Brown*[1]*, (1)University of York, United Kingdom, (2)Durham University, United Kingdom*

Water quality and freshwater biodiversity are declining due to human-made stressors resulting from a mixture of chemicals from a wide range of sources. Nevertheless, studies often focus on a small number of chemicals from single source types, ignoring the fact that freshwaters are exposed to complex mixtures of hundreds of chemicals originating from multiple sources that interact together to exacerbate impacts. To move forwards, a more integrated approach is required that considers all significant sources of chemicals, focuses on those chemicals that pose the greatest risk, and delivers a spatial and temporal understanding of how mixture profiles vary in the catchment. The ECOMIX project aims to develop innovative approaches for chemical mixture exposure and effects monitoring and modelling using nine catchments in Yorkshire, England as its test system. A stakeholder workshop prioritised 40 chemicals, including pharmaceuticals, pesticides, metals, personal care products, PAHs, and livestock and pet medicines. Source density maps were developed based on spatial data for population, combined sewer overflows, crops, livestock, pet ownership, mines and road emissions, and these were combined with an analysis of dilution potential within the catchment. Density maps of the sources of chemicals were calculated for 50 sub-catchments within the study area. Subbasins with high source density areas are widespread within the catchment. A catchment-scale model was developed to consider inputs from multiple sources, land uses, and pathways. The model was used to generate current (2002-2022) profiles for flow and chemical exposure. Spatially distributed stream flow and nutrients were generated using the terrestrial hydrological and biogeochemical model HYPE for 16,000 separate river reaches. The model runs on a daily time step to capture individual storms. Modelled WWTP-treated effluent concentrations of down-the-drain chemicals were simulated within the same order of magnitude to observed concentrations. Work is ongoing to model exposure concentrations that will provide data for ecological modelling. This presentation provides an overview of the modelling approach, including results of chemical emissions and river concentration of chemical mixtures in the catchment.

Disclaimer/Disclosure: The authors thank NERC Freshwater biodiversity programme for funding the project (Grant number NE/X015637/1)

3.15.P-Th242 ENCORE: A Probabilistic Framework for ENvironmental CO-exposure and Risk Estimation

Karel Viaene[1]*, Frederik Verdonck*[2]*, Karel Vlaeminck*[1]*, Sibren Loos*[3]*, Jos van Gils*[3]*, Jannicke Moe*[4]*, Samantha Eslava Martins*[5] *and Sophie Mentzel*[4]*, (1)ARCHE Consulting, Belgium, (2)ARCHE Consulting, Ghent (Wondelgem), Belgium, (3)Deltares, Netherlands, (4)Norwegian Institute for Water Research (NIVA), Norway, (5)Norwegian Institute for Water Research (NIVA), Oslo, Norway*

The EU's Chemicals Strategy for Sustainability (CSS) aims to incorporate "combined exposure" risks, stemming from unintentional chemical mixtures in the environment, into regulatory risk assessments. Until a suitable predictive tool is available to identify mixtures of concern, it has been suggested to lower all safety limits for single chemicals by the so-called Mixture Allocation Factor (MAF). The general objective of the recently established project ENCORE (ENvironmental CO-exposure and Risk Estimation) is to develop a probabilistic modelling framework that allows to identify the priority chemicals for co-exposure risk at the watershed level.

In modelling, uncertainty (i.e. lack/incompleteness of data) and variability (i.e. known spread on data) is unavoidable, in areas such as usage information, model parameters and processes, monitoring data, and more. Considering environmental risk, there is also uncertainty on the hazard assessment. In ENCORE, a

probabilistic framework will be developed to characterise and propagate the uncertainty throughout the whole risk assessment model. In addition to uncertainty characterisation (allowing for probabilistic risk characterisation), the ENCORE framework allows to combine different sources of information (e.g. monitoring and modelling). More specifically, ENCORE will combine prior probabilities from modeled data with new evidence from monitoring data using Bayesian networks (BN), enhancing robustness of model predictions.
The ENCORE framework builds on an environmental fate model originally developed for large-scale European domains, but adaptable to specific regions, such as the Rhine and Danube river basins. One key part of the ENCORE project is to improve the accuracy of model predictions for specific watersheds through improving the quality of model input data, by integrating chemical use and emission information, tonnage data over time and local monitoring data, in combination with verified hazard data. Ultimately, ENCORE aims to prioritize high-risk co-exposure chemicals by accounting for spatial and temporal exposure patterns across large regions of Europe.

Disclaimer/Disclosure: This project is funded by Cefic (CEFIC-LRI ECO-66).

3.15.P-Th243 An Indicator for Toxic Pressure of Mixtures in the Dutch Pesticide Atlas

Joost Lahr[1]*, Marco Visser*[2]*, Maarten van't Zelfde*[2]*, Jaap Slootweg*[1] *and Leo Posthuma*[1]*, (1)National Institute of Public Health and the Environment (RIVM), Netherlands, (2)Institute of Environmental Sciences (CML), Leiden University, Netherlands*

When the concentrations of chemical substances in the water are lower than the protective standard, it is assumed that this has no unacceptable effects. However, when there are mixtures of substances the risk is potentially increased and an additional assessment step may be performed to determine the combined toxic pressure. Toxic pressure offers a nuanced insight into the extent to which substances and mixtures affect water quality and aquatic life.
A study was conducted to introduce an indicator for (mixture) toxic pressure into the Dutch Pesticide Atlas. This interactive online atlas provides a national picture of pesticides in surface water based on monitoring data from regional and national water managers and from drinking water companies.
The indicator calculates the mixture toxic pressure as the fraction of aquatic species potentially affected by multiple substances (msPAF) using Species Sensitivity Distributions (SSDs). A set of indicators for mixture toxic pressure was developed and built into the Dutch Pesticide Atlas, which is available online for experts and the general public. The atlas contains different indicators that can be used to display and explore spatial and temporal trends in toxic pressure at the national, regional or local scale. There are also indicators to assess the absolute and relative contribution to this toxic pressure by individual pesticides present.
The toxic pressure that is calculated may be an underestimation when pesticides are present below their limit of quantification or when insufficient toxicity data are available to construct SSD s for particular compounds.
The indicators are illustrated with examples on the risk of mixtures. With the indicator and utilities it could be visualised, among others, that the number of sampling stations in the Netherlands with high and very high toxic pressure decreases over time.

Disclaimer/Disclosure: The research was financed by Dutch Ministry of Infrastructure and Water Management.

3.15.P Co-Occurrence of Contaminants in Urban and Rural Environments

3.15.P-Th232 Simultaneous Detection of Nanoplastics and Adsorbed Pesticides by Surface-Enhanced Raman Spectroscopy

Barbara Rani-Borges*, Clara de Jesus Rangel and Rômulo Augusto Ando, Institute of Chemistry, University of São Paulo (USP), Brazil*

One of the most critical characteristics of nanoplastics is their ability to interact with other pollutants in the environment, particularly in water bodies, where they are widely found. This property has raised concerns about their potential to amplify the toxicity of associated pollutants, creating complex and challenging-to-monitor mixtures. A notable example is the interaction between nanoplastics and pesticides, which represent a group of chemical compounds with highly toxic potential widely used in agriculture. In addition to their impact on aquatic organisms, pesticides are known for their harmful effects on human health, such as endocrine-disrupting, carcinogenic, and neurotoxic effects. Diquat is a highly toxic herbicide for aquatic organisms, as it can cause from cellular damage to death at relatively low doses. In this way, the toxic impact of both nanoplastics and pesticide can be exacerbated as they interact, as the presence of nanoplastics may prolong exposure to the pesticide or increase its concentration in specific organisms. Despite the relevance of this interaction, studies on the detection of pesticides adsorbed on nanoplastics have not been reported, mainly due to the analytical challenges involved. In this context, the present study aimed to investigate the use of the Surface Enhanced Raman Spectroscopy (SERS) technique, employing gold nanoparticles as a substrate, to detect polystyrene (PS) nanoplastics (100 nm) and the pesticide Diquat in environmental relevant concentrations (as low as 20 µg/L for the polymer and 66 µg/L for the pesticide). By utilizing the SERS technique, it was possible to obtain the spectra of both compounds simultaneously, demonstrating the method s sensibility to detect both the nanoplastic and the adsorbed pesticide at very low concentrations. The results indicate that SERS is a promising tool for environmental analyses, providing a non-destructive, sensitive and specific alternative for the detection of nanoplastics and pesticides. The simultaneous acquisition of nanoPS and Diquat spectra opens up new possibilities for monitoring these pollutants in the environment and investigating the consequences of their interaction in different environmental scenarios.

3.15.P-Th233 Synergistic Effects of Microplastics and Chemical Residues: Disruption of Soil Microbial Communities

***Lama Ramadan**[1], Emel Topuz[2], Kyle Mason-Jones[3], Tess Van de Voorde[4], Esmer Jongedijk[5] and Ciska Veen[1], (1)Netherlands Institute of Ecology (NIOO-KNAW), Royal Netherlands Academy of Arts and Sciences, Netherlands, (2)Department of Environmental Engineering, Gebze Technical University, Turkiye, (3)Netherlands Institute of Ecology (NIOO-KNAW), Royal Netherlands Academy of Arts and Sciences; Soil Microbial Interactions, Department of Geosciences, University of Tubingen, Netherlands, (4)Wageningen Plant Research, Biointeractions and Plant Health, Netherlands, (5)Wageningen Food Safety Research (WFSR), Netherlands*

Soil is one of the most biologically diverse environments on earth. Soil microorganisms play a key role in driving soil functions, such as the cycling of carbon and nutrients, and thereby contribute to important ecosystem services. However, human activities result in various pollutants entering the soil, which are potentially hazardous to the soil ecosystem. In recent years, studies have typically focused on the toxicity of these pollutants for soil microbial communities by examining each of these compounds individually or limited to a mixture of one group (e.g. pharmaceuticals). However, these compounds are part of more complex mixtures of chemical pollutants and biological hazards. Moreover, the presence of nonbiodegradable particles in the soil matrix such as microplastics may substantially influence the toxicity and persistence of other chemicals in the soil. Diclofenac, terbutryn, ciprofloxacin, 17α -ethynylestradiol (EE2) and diuron were selected for this study and applied as a mixture. These contaminants belong to various groups with distinct chemical structures and physicochemical properties, and are included in respective EU legislations of substances that should be monitored in the environment and the food chain. Polypropylene microplastics (PP-MPs) were selected as a background contaminant applied on its own or in a mixture with the other selected chemicals. PP-MPs are highly resistant to biodegradation due to their robust molecular structure. The presence of PP-MPs with the other chemicals in the tested soil substantially elevated the activity of the soil microbial community as reflected by increased respiration, from 0.40 0.70 µg CO2-C g-1 h-1 in the control, PP-MPs, and mixture of tested chemicals separately, compared to 2.0 µg CO2-C g-1 h-1 in combination ($p = 0.009 - 0.02$). The results demonstrated synergistic effects of chemical pollutants and microplastics on the soil microbial community. These findings underscore the complex interplay between chemical residuals and microplastics particles in natural soil, and the need for further research to understand the combined impacts and long-term implications of these pollutants and non-biodegradable particles on soil health and carbon cycling. This provides an important input for accurate and comprehensive environmental risk assessment of chemical contamination in the terrestrial environment.

mission. However, all scientific contributions made in this project are owned and approved solely by the authors.

3.15.P-Th234 Sorption and Desorption Processes of S-Metolachor in Soil Contaminated with Microplastics

Kassio Mendes[1]*, Maura Brochado*[2]*, Rodrigo Sousa*[1] *and Laura Bordignon*[1]*, (1)University of São Paulo, Brazil, (2)Federal University of ViCosa, Brazil*

The increasing use of plastics in agriculture has resulted in the accumulation of microplastics (MPs), which can interact with residual herbicides and alter their environmental behavior. This study aimed to evaluate the influence of different MP proportions on the sorption and desorption processes of S-metolachlor in soil. The herbicide (1200 g a.i. ha-1) was applied in soil at MPs concentrations of 0% (control unamended soil), 1, 5, 10, 15, 20, and 100% (w w-1) MPs, with the addition of 2 g of material (soil or MPs). Sorption and desorption isotherms were determined using the batch equilibrium method, followed by herbicide analysis via high-performance liquid chromatography (HPLC). The results indicated that the presence of MPs altered S-metolachlor sorption by approximately 10% in soil amended with 5% MPs, with Kd (sorption coefficient) values ranging from 3.20 to 4.85 L kg−1 in unamended soil, suggesting increased herbicide retention in the presence of MPs. The Kd (desorption coefficient) ranged from 3.20 to 33.20 L kg−1, indicating that desorption increases with the MPs proportion, suggesting that S-metolachlor is more firmly retained in the MPs than in the soil. These findings suggest that the presence of MPs in soil can modify the environmental fate of S-metolachlor, potentially affecting their efficacy in weed control and increasing the risk of environmental contamination, particularly in agricultural soils polluted with these polymers.

Disclaimer/Disclosure: The authors would like to thank the São Paulo Research Foundation (FAPESP, 2024/08299-0) and National Council for Scientific and Technological Development (CNPq).

3.15.P-Th235 Exploring the Potential of Earthworms to Accelerate the Degradation of Biodegradable Plastics in Soils

Ke Meng[1]*, Esperanza Huerta Lwanga*[2]*, Davi Munhoz*[2]*, Maarten van der Zee*[2]*, Rong Ji*[3] *and Violette Geissen*[2]*, (1)Wageningen University & Research; Nanjing University, China (Mainland), (2)Wageningen University and Research (WUR), Netherlands, (3)Nanjing University, China (Mainland)*

Plastic products have long been used in agricultural production and the release of plastic additives and plastic fragments has recently caught attention, sparking a trend towards environmentally friendly alternatives. As a consequence, plastics derived from biodegradable polymers have been actively promoted in the market. However, whether the use of biodegradable plastics (BPs) can really solve this problem remains a question. Our previous studies showed that BPs made from polylactic acid (PLA), polybutylene adipate terephthalate (PBAT) and starch can temporarily affect the activity, composition and functional diversity of soil microbial communities, which was synchronized with BPs degradation. Another major finding was that BPs made from PLA and PBAT degraded very slowly in certain soils, which can lead to the accumulation of BPs fragments in soils. Therefore, given the uncertain environmental impacts of BPs and their unsatisfying degradation rate, efforts were made to accelerate the degradation of BPs in soils. The potential of earthworms to reduce BPs in soils was explored under controlled conditions in the lab. *Lumbricus terrestris* was exposed to soils spiked with microplastics (MPs) of different polymer types at a dosage of 1% (dw/dw). The changes of MPs during gut passage and cast aging were investigated. The size distribution of MPs in different niches (soil, gut, cast) was determined by a laser direct infrared (LDIR) chemical imaging system. Recovered MPs (either in the form of MPs by density separation or in the form of polymers by Soxhlet extraction) were characterized by different techniques, e.g., FTIR, GPC, DSC and NMR. Results show that *Lumbricus terrestris* was able to initiate the physical fragmentation of MPs in their gut. Certain BPs (PLA) can be depolymerized to some extent in the gut. After being excreted in the cast, low density polyethylene did not show any changes during cast aging. PLA degradation was accelerated in the cast than in the soil, accompanied by the reduction in particle size. PBAT MPs were fragmented in the gut but no further degradation happened during cast aging. Our studies show that earthworms do have the potential to accelerate the degradation of certain plastics, especially less recalcitrant ones. However, the simultaneous fragmentation of plastics into smaller pieces by earthworms might lead to an input smaller MPs back to soils. The fate of MPs after earthworm gut processed needs further study in the future.

3.15.P-Th236 Levels, Spatial Distributions, and Provision of Petroleum Hydrocarbons and Phthalates in Sediments from Obhur Lagoon, Red Sea Coast of Saudi Arabia

Hattan Alharbi[1]*, Ahmed Rushdi*[2]*, Abdulqader Bazeyad*[1] *and Khalid Al-Mutlaq*[1]*, (1)King Saud University, Saudi Arabia, (2)College of Earth, Atmospheric, Oceanographic Sciences, Oregon State University, United States*

The levels, spatial distribution, and sources of petroleum hydrocarbons and phthalates were assessed in surface sediment samples from the urban lagoon of Obhur near Jeddah, the largest city on the Red Sea Coast of Saudi Arabia. The lagoon was divided into the inner zone (IZ), middle zone (MZ), and outer zone (OZ) based on its geomorphological features and developmental activities. Surface sediment samples were collected and extracted with a mixture of dichloromethane:methanol and total extractable organic matter (TEOM) of each sample was analyzed with gas chromatography-mass spectrometry (GC-MS). n-Alkanes, hopane and sterane biomarkers, and unresolved complex mixture (UCM) were the major petroleum hydrocarbon compounds of the TEOM. Phthalates were also measured in the sediment samples. In the three zones, n-alkanes ranged from 89.3±88.5 ng/g to 103.2±114.9 ng/g, whereas the hopane and sterane biomarkers varied from 69.4±75.3 ng/g to 77.7±69.9 ng/g and 72.5±77.9 ng/g to 89.5±82.2 ng/g, respectively. The UCM concentrations ranged from 821±1119 ng/g to 1297±1684 ng/g and phthalates from 37.4±34.5 ng/g to 65±68 ng/g. The primary origins of these anthropogenic hydrocarbons in the lagoon sediments were petroleum products (boat-engine discharges, boat washing, lubricants, and wastewater flows) and plasticizers (plastic waste and litter). The proportions of anthropogenic hydrocarbons derived from petroleum products in the sediment's TEOM ranged from 43±33% to 62±15%, while the percentages for plasticizers varied from 2.9±1.2% to 4.0±1.6%. The environmental impacts of petroleum and phthalate in coastal sediments are profound and multifaceted. Their persistence, toxicity and ability to bioaccumulate make them critical pollutants of concern for marine ecosystems. Their occurrence in sediments leads to chronic exposure for marine species and potential bioaccumulation across the food web. Addressing these impacts requires a multifaceted approach, including stricter requirements, pollution control measures, and ongoing monitoring to protect and restore coastal health. Understanding these pollutants behavior and effects in marine environments is essential for developing effective strategies to mitigate their negative influence on coastal and marine ecosystems.

3.15.P-Th237 Setting up a National Monitoring Program to Identify Ubiquitous and Potential Harmful Substances in Soil and Sediment in the Netherlands

Louise M. van Mourik[1]*, Timo Brusee*[1]*, Monique Wolters*[1]*, Bertwin Stoffelsen*[1]*, Harm Wismans*[1]*, Arjan Wijdeveld*[2]*, Tom Bosma*[2] *and Arjen Wintersen*[1]*, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Deltares, Netherlands*

Non-standardized substances are substances that currently lack established legal standards regarding permitted concentrations in the environment. The absence of such standards complicates efforts for regulatory authorities and businesses to provide guidelines for the safe use and management of these substances and/or the materials in which they may be present (such as soil and sediment). A well-known example of this challenge is the current PFAS crisis.

Therefore, the pilot Monitoring for Non-standardized Substances (pMNS) was set up in early 2024 with the aim to develop a novel national approach for detecting various non-standardized substances that co-occur and are diffusely spread across both soil and sediment in the Netherlands and may pose environmental risks. To achieve this, 440 soil and 280 sediment samples with different land use types (including urban and rural) are being collected from various locations across the Netherlands. A part of each sample is being analyzed for initially five groups of substances: polychlorinated n-alkanes (also known as chlorinated paraffins), polybrominated diphenyl ethers, glyphosate and its transformation product AMPA, pyrethroids and PFAS precursors. The selection of the five groups of substances was based on their persistence, toxicity, bioaccumulation and emission potential. Variability among the substance groups, including differences in their use and chemical properties, was also taken into account. The rest of the sample is stored under controlled conditions for future analysis of other substances and other purposes. Indicative risk thresholds for health and background levels will be derived for the substance groups that are found to be present, which can be used by regulatory authorities. This poster presents the aim, methodology, challenges, preliminary results and potential next steps of the pilot project.

3.15.P-Th238 A 600-Years Pollution History Reconstruction Using Lake Sediments from Bad Waldsee, Southern Germany

Thomas Schiedek[1]*, Kristin Haas*[1]*, Matthias Hinderer*[1]*, Sara Saeidi Ghavi Andam*[2] *and Elena Marinova*[2]*, (1)TU Darmstadt, Germany, (2)Archeobotany Lab, Baden-Wuerttemberg State Office for Cultural Heritage, Germany*
Annual lake sediments are excellent high-resolution archives for reconstructing historical pollution. Usually, pollution reconstructions date back to the beginning of industrialization in the early 19th century. Here, we present a long-term record from Lake Stadtsee located in the city of Bad Waldsee. Using historical written documents, the history of pollution can be linked to the economic activities in the city. In an absolutely dated sediment core we explored the concentration and composition patterns of Polycyclic Aromatic Hydrocarbons (PAHs) and heavy metals together with macro charcoal record at 1 cm steps. First findings indicate that PAHs were primarily derived from pyrogenic, rather than petrogenic sources throughout the entire time interval. These most probably correspond to urban fire or domestic heating. The general trend observed by using PAH diagnostic ratios indicates a shift of the sources from low temperature pre-industrial combustion processes towards high temperature combustion processes in more recent times. Macro charcoal analysis revealed two main phases of biomass burning, which were separated by a fire free interval for more than 200 years. The first phase in the late Medieval period (653?533 cal BP), shows high proportions of burned grass and monocot leaves, whereas in the second phase in the early Modern Times (313 cal BP until today) wood was the main fire fuel. The molecular ratio pattern of specific methylated-phenanthrene isomers also indicates a change of fuel sources. Heavy metal analyses revealed an increasing Pb sediment concentration over time (more than 2x), while V, Ni, Cu and Zn were present in the same concentration order. Interestingly, during the 30-year war all heavy metals analyzed showed a remarkable decrease in concentration, which returned to the previous level after the war.

3.15.P-Th239 Determining the Impact of Pyrolytic Conversion on the Exposure and Mobility of Organic Pollutants, Metals and Nutrients in Biochar

Clara Lade, Kristin Kostadinova*, Raissa Rossi, Heidi Birch, Wolfgang Stelte and Philipp Mayer, Technical University of Denmark, Denmark*
The Danish Government has presently a strong focus on pyrolysis as part of the green transition in Denmark. This is due to its potential and increasing applications within circular economy, carbon sequestration, soil improvement, and contaminant removal. However, while organic contaminants present in the feedstock can be broken down during pyrolysis, new contaminants, like PAHs, can be formed, and metals can be concentrated in the produced biochar. Consequently, the agricultural application of biochar derived from waste materials such as sewage sludge could potentially contaminate our environment. This raises the critical question: How does the pyrolytic conversion of feedstock to biochar affect the exposure, mobility and potential impact of pollutants in the environment? The first aim of this study is to determine the combined impact of the pyrolytic conversion on (1) the pollutant concentrations in the matrix and (2) the corresponding distribution coefficients. Digested sludge from WWTPs is used as model feedstock, with carefully matched samples of sludge and biochar obtained from a full-scale pyrolysis plant in Denmark. Aqueous concentrations in equilibrium with sludge and biochar are then measured across a broad range of organic chemicals, metals and nutrients, utilizing advanced analytical techniques such as LC-MS and SPME-GC-MS. We hypothesize that pyrolysis markedly decreases aqueous concentrations for most if not all pollutants. Special focus is given to extending this work to non-targeted chemical analysis to comprehensively assess the impact of pyrolytic conversion on various pollutants, including PFAS. The outcomes of this study will be used to provide further information to the Danish EPA on the potential environmental impact of biochar application in agriculture.

3.15.P-Th240 Modelling Chemical Mixtures for Assessing the Impact on Freshwater Biodiversity in Yorkshire, UK

Martha Villamizar[1]*, Alistair Boxall*[1]*, Sim Reaney*[2]*, Ivo Pink*[2] *and Colin Brown*[1]*, (1)University of York, United Kingdom, (2)Durham University, United Kingdom*
Water quality and freshwater biodiversity are declining due to human-made stressors resulting from a mixture of chemicals from a wide range of sources. Nevertheless, studies often focus on a small number of chemicals from single source types, ignoring the fact that freshwaters are exposed to complex mixtures of hundreds of chemicals originating from multiple sources that interact together to exacerbate impacts. To move forwards, a more integrated approach is required that considers all significant sources of chemicals, focuses on those chemicals that pose the greatest risk, and delivers a spatial and temporal understanding of how mixture profiles vary in the catchment. The ECOMIX project aims to develop innovative approaches for chemical mixture exposure and effects monitoring and modelling using nine catchments in Yorkshire, England as its test system. A stakeholder workshop prioritised 40 chemicals, including pharmaceuticals,

pesticides, metals, personal care products, PAHs, and livestock and pet medicines. Source density maps were developed based on spatial data for population, combined sewer overflows, crops, livestock, pet ownership, mines and road emissions, and these were combined with an analysis of dilution potential within the catchment. Density maps of the sources of chemicals were calculated for 50 sub-catchments within the study area. Subbasins with high source density areas are widespread within the catchment. A catchment-scale model was developed to consider inputs from multiple sources, land uses, and pathways. The model was used to generate current (2002-2022) profiles for flow and chemical exposure. Spatially distributed stream flow and nutrients were generated using the terrestrial hydrological and biogeochemical model HYPE for 16,000 separate river reaches. The model runs on a daily time step to capture individual storms. Modelled WWTP-treated effluent concentrations of down-the-drain chemicals were simulated within the same order of magnitude to observed concentrations. Work is ongoing to model exposure concentrations that will provide data for ecological modelling. This presentation provides an overview of the modelling approach, including results of chemical emissions and river concentration of chemical mixtures in the catchment.

Disclaimer/Disclosure: The authors thank NERC Freshwater biodiversity programme for funding the project (Grant number NE/X015637/1).

3.15.P-Th241 Assessing Emerging Contaminants and Biodegradation Potential in the Atlantis Aquifer's Managed Aquifer Recharge Scheme

Maposholi Mokhethi[1]*, Luke Towers*[2]*, Alakendra Roychoudhury*[1] *and Reynold Chow*[3]*, (1)Stellenbosch University, South Africa, (2)ECC Environmental Compliance Consultancy, Namibia, (3)Wageningen University, Netherlands*

Managed aquifer recharge (MAR) using treated effluent and stormwater (TES) is an important strategy for sustaining urban aquifers used for potable water supply in water-scarce regions. However, there are concerns about the introduction of emerging contaminants (ECs) present in TES. This study aims to assess the presence and spatial distribution of various multi-group ECs including pharmaceuticals, pesticides and industrial chemicals in the Atlantis Aquifer. Twenty samples, including MAR source water, groundwater, and surface water, were analysed for 289 compounds. Preliminary results show that 120 compounds were detected, with TES having the highest number of detections, followed by MAR-impacted groundwater, while naturally recharged groundwater had the lowest number of detections. The results suggest that ECs are introduced to the aquifer through MAR, that some ECs may be attenuated, and that there is a baseline level of contamination in naturally recharged groundwater, likely from atmospheric deposition and agricultural runoff. A three-tiered health risk assessment revealed that fewer than 10% of detected compounds pose health risks (RQ >1). Further investigations will consider the behaviour and health risks of co-occurring compounds. To assess natural attenuation via biodegradation in the aquifer, traditional contaminants and parameters (e.g., redox, nitrate, dissolved oxygen, manganese) will be analysed using data collected between 2018 and 2024 from 253 sites. The outcomes of the study will guide the development of an EC monitoring framework for the Atlantis Aquifer water supply scheme, which can also be adapted to South Africa s other MAR schemes in development, as well as other schemes across Africa.

Disclaimer/Disclosure: The project received a Water4All 2022 grant.

3.15.P-Th242 ENCORE: A Probabilistic Framework for ENvironmental CO-exposure and Risk Estimation

Karel Viaene[1]*, Frederik Verdonck*[2]*, Karel Vlaeminck*[1]*, Sibren Loos*[3]*, Jos van Gils*[3]*, Jannicke Moe*[4]*, Samantha Eslava Martins*[5] *and Sophie Mentzel*[4]*, (1)ARCHE Consulting, Belgium, (2)ARCHE Consulting, Ghent (Wondelgem), Belgium, (3)Deltares, Netherlands, (4)Norwegian Institute for Water Research (NIVA), Norway, (5)Norwegian Institute for Water Research (NIVA), Oslo, Norway*

The EU s Chemicals Strategy for Sustainability (CSS) aims to incorporate "combined exposure" risks, stemming from unintentional chemical mixtures in the environment, into regulatory risk assessments. Until a suitable predictive tool is available to identify mixtures of concern, it has been suggested to lower all safety limits for single chemicals by the so-called Mixture Allocation Factor (MAF). The general objective of the recently established project ENCORE (ENvironmental CO-exposure and Risk Estimation) is to develop a probabilistic modelling framework that allows to identify the priority chemicals for co-exposure risk at the watershed level.

In modelling, uncertainty (i.e. lack/incompleteness of data) and variability (i.e. known spread on data) is unavoidable, in areas such as usage information, model parameters and processes, monitoring data, and

more. Considering environmental risk, there is also uncertainty on the hazard assessment. In ENCORE, a probabilistic framework will be developed to characterise and propagate the uncertainty throughout the whole risk assessment model. In addition to uncertainty characterisation (allowing for probabilistic risk characterisation), the ENCORE framework allows to combine different sources of information (e.g. monitoring and modelling). More specifically, ENCORE will combine prior probabilities from modeled data with new evidence from monitoring data using Bayesian networks (BN), enhancing robustness of model predictions.
The ENCORE framework builds on an environmental fate model originally developed for large-scale European domains, but adaptable to specific regions, such as the Rhine and Danube river basins. One key part of the ENCORE project is to improve the accuracy of model predictions for specific watersheds through improving the quality of model input data, by integrating chemical use and emission information, tonnage data over time and local monitoring data, in combination with verified hazard data. Ultimately, ENCORE aims to prioritize high-risk co-exposure chemicals by accounting for spatial and temporal exposure patterns across large regions of Europe.

Disclaimer/Disclosure: This project is funded by Cefic (CEFIC-LRI ECO-66).

3.15.P-Th243 An Indicator for Toxic Pressure of Mixtures in the Dutch Pesticide Atlas

Joost Lahr[1]*, Marco Visser*[2]*, Maarten van't Zelfde*[2]*, Jaap Slootweg*[1] *and Leo Posthuma*[1]*, (1)National Institute of Public Health and the Environment (RIVM), Netherlands, (2)Institute of Environmental Sciences (CML), Leiden University, Netherlands*

When the concentrations of chemical substances in the water are lower than the protective standard, it is assumed that this has no unacceptable effects. However, when there are mixtures of substances the risk is potentially increased and an additional assessment step may be performed to determine the combined toxic pressure. Toxic pressure offers a nuanced insight into the extent to which substances and mixtures affect water quality and aquatic life. A study was conducted to introduce an indicator for (mixture) toxic pressure into the Dutch Pesticide Atlas. This interactive online atlas provides a national picture of pesticides in surface water based on monitoring data from regional and national water managers and from drinking water companies.
The indicator calculates the mixture toxic pressure as the fraction of aquatic species potentially affected by multiple substances (msPAF) using Species Sensitivity Distributions (SSDs). A set of indicators for mixture toxic pressure was developed and build into the Dutch Pesticide Atlas, which is available online for experts and the general public. The atlas contains different indicators that can be used to display and explore spatial and temporal trends in toxic pressure at the national, regional or local scale. There are also indicators to assess the absolute and relative contribution to this toxic pressure by individual pesticides present.
The toxic pressure that is calculated may be an underestimation when pesticides are present below their limit of quantification or when insufficient toxicity data are available to construct SSD s for particular compounds.
The indicators are illustrated with examples on the risk of mixtures. With the indicator and utilities it could be visualised, among others, that the number of sampling stations in the Netherlands with high and very high toxic pressure decreases over time

Disclaimer/Disclosure: The research was financed by Dutch Ministry of Infrastructure and Water Management.

3.15.P-Th244 How PFAS End up in High Concentrations in Home Produced Chicken Eggs at Ambient Background Levels in Soils

***Tessa Pancras** and Laura Vredenborg, Arcadis, Netherlands*

In an area downwind from a fluorochemical plant in the Netherlands, high concentrations of PFAS have been found in home produced chicken eggs. The concentrations of PFOS and PFOA exceed the Maximum Level for eggs (EU, 2022) in 80% of the eggs. This is in contrast to the level of PFAS found in commercial eggs, which is very low. Although the eggs are sampled in an area surrounding a fluorochemical plant, the detection of high amounts of PFOS is remarkable, since the plant predominantly emitted PFOA and GenX. PFOS is the dominant PFAS detected, whereas this compound has not been used by the fluorochemical plant in their production process. Furthermore, PFOS concentrations in the soil are at approximately the same level as ambient background levels in the Netherlands in urban areas. Based

on the results it was concluded that direct consumption of soil by the egg-laying chickens was not the source of the high concentrations of those PFAS found in the eggs.
This resulted in a quest for finding the source of these high concentrations of PFAS. At a selection of the sites, the chicken housing was sampled for possible PFAS sources - feed (including insects), soil (near the feeding unit), drinking water, packaging of the feed, bedding, vitamins, medicines and worms.
The PFAS, especially PFOS, concentrations detected in the worms were very high, in contrast to the other possible sources analyzed. This led to the conclusion that bioaccumulation of PFAS via worms is the most likely source of PFAS for the chicken and the eggs, even at the relatively low concentrations of PFAS measured in the soils.
In the presentation we would like to show the results and put them in the perspective of (background) concentrations measured in soils and eggs on a national level.
The risk of consuming the eggs was evaluated by RIVM (National Institute for Public Health and the Environment). They gave a negative consumption advice for the eggs in the area. RIVM is now working on a national inventory on PFAS in home produced chicken eggs.
The project was conducted for the local municipalities (Dordrecht, Papendrecht, Sliedrecht, Molenlanden), by Arcadis, RIVM, WFSR (Wageningen Food Safety Research) and Tritium Advies, in cooperation with the OZHZ (Environment Agency South-Holland South) and GGD ZHZ (Public Health Service South-Holland South).

3.15.P-Th245 Co-Occurrence Patterns of Semi-Volatile Organic Compounds in Urban and Rural School Environments in the Czech Republic

*Chijioke Olisah[1], Rozarka Jilkova[1], **Lisa Melymuk**[2], Ondrej Mikes[3], Jana Klanova[1] and Petra Pribylova[1], (1)RECETOX, Masaryk University, Czech Republic, (2)Masaryk University, Brno, Czech Republic, (3)Recetox, RECETOX, Masaryk University,Czech Republic*
Exposure to SVOCs in schools has gained growing attention from researchers and the public. Many schools were built when legacy SVOCs were used as additives in building materials. With some SVOCs now banned, it is hypothesized that newer or recently renovated schools will have lower concentrations of these legacy compounds. Here, we evaluated ten schools of different ages located in urban and rural areas in a single region in the Czech Republic to compare levels of SVOCs in indoor and outdoor air and indoor dust. Legacy industrial compounds (e.g., polychlorinated biphenyls PCBs; polybrominated diphenyl ethers PBDEs) and organochlorine pesticides (OCPs) were detected in 60 to 100% in air and dust samples, indicating their widespread presence in school environments. Dechlorane Plus and alternative bromobenzene flame retardants (bromobenzene) were also detected in 60 to 100% of all air and dust samples. BDE 209 dominated the PBDE distribution profile in air and dust samples, accounting for over 50% of the total PBDEs. y-HCH (lindane) was the dominant OCP, with concentrations reaching up to 116 ng/g in indoor dust and 9.12 ng/m^3 in indoor air. Concentrations in indoor air were dominated by flame retardants and PCB-11, while DDT and PCBs dominated in outdoor air. In both urban and rural locations, the indoor air concentrations were substantially higher than outdoor, e.g., 6 to 50 times higher for PCBs and 4-400 times higher for HCHs. This indicates that the SVOCs primarily originate from indoor sources, regardless of outdoor levels. Older, more urban schools had the highest concentrations of both DDTs and HCHs and moderately high PBDE concentrations in both air and dust. Less urban schools were generally newer buildings and showed lower OCP and PBDE levels. SVOC presence appears to be related to emissions from specific construction materials and the continued presence of hazardous SVOCs in schools raises concerns about children's potential exposure.

3.15.P-Th246 Soil Health and Food Quality in Horticultural Systems: A Case Study in the Metropolitan City of Naples

***Ghada Arbi**[1], Francesco A. Carbone[2], Paola Adamo[3], Antonio G. Caporale[3] and Nicoleta Suciu[4], (1)Department for Sustainable Food Process, Università Cattolica del Sacro Cuore, Department of Agricultural Sciences, University of Naples Federico II, Italy, (2)Department of Agricultural Sciences, University of Naples Federico II, Italy, (3)Department of Agricultural Sciences, University of Naples Federico II, Italy, (4)Department for Sustainable Food Process, Università Cattolica del Sacro Cuore, Italy*
Urban areas, covering over 25% of Europe's territory and hosting 75% of its population, a figure projected to rise to 80% by 2050, face pressing challenges, including urban sprawl, green space decline, and soil degradation. As a cornerstone of the urban ecosystem, soil supports biodiversity, provides ecosystem

services, and contributes to citizen well-being. In the last decades, the metropolitan city of Naples (a densely populated area with 3 million inhabitants) was interested in significant soil consumption and infrastructure sprawl. The urban soil used for residential and productive activities currently covers approximately 35% of the metropolitan area (ISPRA, 2023).
Although many of the remaining soils are used for farming and food production, only scant information is available on the fertility and health of these soils, and the quality/safety of their food products. The 2-year HealthySoil4QualityFood project (CUP-E53D23011040006, financed in the frame of European Union Next Generation EU), intends to encompass this gap, with research activities aimed at providing insight on the: i) soil fertility and possible chemical contamination in vegetable gardens of Naples metropolitan area; ii) irrigation water quality; iii) crop biodiversity and sustainability of cultivation practices, and chemical quality of edible biomasses; iv) risks associated to possible contamination, throughout integrated environmental and human exposure modelling; v) public awareness about soil ecosystem services and social benefits of urban farming.
Five case studies were recently selected based on geographical distribution and proximity to potential sources of contamination, type of stakeholders, and scope of cultivation (arable soils split in plots and assigned to citizens, or green spaces used as educational gardens for school, etc); in these areas, sited in the districts of Capodimonte, Ponticelli and Vomero of Naples and in the municipality of Portici, we started assessing the soil physicochemical properties and fertility and irrigation water quality. The first results evidenced an overall good quality of urban soils, showing a sandy-loam texture, neutral-to-sub-alkaline pHs, good nutrient bioavailability, and low-to-moderate occurrence/bioavailability of contaminants. Food products' nutritional value and safety will be monitored in different growing seasons. Realistic exposure scenarios to possible contaminants in each case study will be developed by the MERLIN-Expo tool.

3.15.P-Th247 Aliphatic and Cyclic Hydrocarbons in Urban Street Dust from Riyadh City, Saudi Arabia: Levels, Distribution, and Sources

Hattan Alharbi[1]*, Abdulqader Bazeyad*[1]*, Khalid Al-Mutlaq*[1] *and Ahmed Rushdi*[2]*, (1)King Saud University, Saudi Arabia, (2)Oregon State University, United States*

Dust particles contain diverse natural and anthropogenic organic compounds and act as local collectors of pollutants, particularly in urban settings. Street dust samples were collected from various sites in Riyadh City, Saudi Arabia in 2023. These were extracted using dichloromethane methanol mixture, and the resulting extracts were subjected to analysis through gas chromatography mass spectrometry (GC MS). The primary compounds identified included n-alkanes, methyl n-alkanoates (FAMEs), hopanes, steranes, polycyclic aromatic hydrocarbons (PAHs), plasticizers, tobacco miscellanies, and an unresolved complex mixture (UCM). Vegetation detritus constituted the primary natural source of organic compounds, ranging from 7.4±3.5% to 15.0±4.0%, and comprised fractional n-alkanes and FAMEs. Petroleum-related products from vehicular emissions, and oil combustion were predominant, accounting for 73.3±5.1% to 87.5±4.8%, and included partial n-alkanes, hopanes, steranes, PAHs, and UCM. Littering inputs from discarded plastics and tobacco smoking varied from 5.2±1.3% to 12.0±5.3% and included phthalates, nicotine, and cotinine, as well as recreational drinking (coffee and tea beverages containing caffeine). The occurrence and distribution of natural and anthropogenic extractable organic matter in this arid urban area were influenced by local vegetation and human activities. The prevalence of anthropogenic organic compounds in Riyadh city's street dust depended on locations and types the location and type of urban activities, with elevated levels observed in high-traffic and industrial zones. Aliphatic and cyclic hydrocarbons are of significant concern due to their potential impact on public health, especially in urban areas with high levels of vehicular traffic and industrial activities, which contribute significantly to air and soil pollution. The health effects of exposure to these hydrocarbons can range from respiratory issues to carcinogenic risks, particularly for vulnerable populations such as children, elderly individuals, and those with pre-existing health conditions. Consequently, further investigations are necessary to understand the potential health effects of anthropogenic inputs on the city's residents.

3.15.P-Th248 Measuring and Modelling Deposition and Washoff of Particulate Matter in Tree Leaves in an Urban Forest Ecosystem Gradient

Hamed Dadkhah-Aghdash[1]*, Elisa Terzaghi*[1]*, Corinne Bertipaglia*[1]*, Pietro Anzini*[2]*, Matteo Bessega*[2]*, Fabio Ferri*[2]*, Cristina Corti*[3]*, Laura Rampazzi*[3]*, Kimberly J. Hageman*[4] *and Antonio Di Guardo*[1]*, (1)Environmental Modelling Group, Department of Science and High Technology, University of Insubria,*

Italy, (2)To.Sca.Lab, Department of Science and High Technology, University of Insubria, Italy, (3)Department of Human Sciences, Innovation and Territory, University of Insubria, Italy, (4)Department of Chemistry and Biochemistry, Utah State University, United States
Urban and rural forests are known to improve air quality by contributing to the removal of particulate matter (PM) from the air. The deposition rate of PM on tree leaves depends on several parameters, including particle size and concentration, plant species, leaf traits, and meteorological conditions. While many previous studies have investigated PM deposition and accumulation on leaves, there is still little information about removal mechanisms and dynamics, such as washoff. We selected Laurel (*Laurus nobilis* L.) for this study because it is found at many temperate latitudes and since it is an evergreen, it is ideal for investigating the long-term deposition and removal rates of PM. Here, we investigated PM deposition and washoff from its leaves with different chemical and imaging techniques. Leaves were collected at a control site in a relatively remote area along Lake Como and an urban site near a busy road in Como, Italy. Leaves were washed at different intensities (gently rinsed to simulate precipitation and sonicated to obtain the total PM deposited). The mass of unwashed, gently washed, and sonicated leaves were then determined gravimetrically to obtain the amounts of deposited PM and their release rates at different washing intensities. Leaves were then analyzed with an optical microscope, a scanning electron microscope (SEM), and a white light interferometer to study number, size, and spatial distribution of particles. The results showed the relationships among deposited and accumulated PM, PM air concentration (obtained from the Regional Environmental Protection Agency/ARPA Lombardia), rainfall intensity and amount, and washoff rates at different conditions and different pollution levels. The imaging techniques allowed us to gain insight into particle density, their size and count at different resolutions, further evidencing the role of plant leaves in aggregating small atmospheric PM and later, in part, returning them to the soil environment.

3.15.P-Th249 Sustainable Green Roofs for the Implementation of the Sponge City: Determination of Ecotoxicologically Safe Construction Products for Green Roofs ***Elena Perabo** and Christoph Hafner, Hydrotox - Labor fur okotoxikologie und Gewasserschutz GmbH, Germany*
The consequences of climate change pose enormous challenges for urban regions. In addition to prolonged periods of heat, climate change also affects the availability of water in particular: both heavy rainfall events with flooding and droughts lead to significant damage to buildings, infrastructure and ecosystems, among other things. The sponge city concept offers various advantages for meeting these challenges: in addition to retaining rainwater, preventing flooding and relieving the burden on wastewater systems, it reduces the urban heat island effect through evaporative cooling and reduces drought.
To a large extent, this concept is to be implemented using green roofs, which utilize construction products that are regularly exposed to rainwater. These construction products may have negative impact on the retained water due to the leaching of hazardous substances, which are subsequently discharged into surface water and/ or groundwater. Thus the leaching of substances may cause ecotoxic and human-toxic effects. In the research project, building materials used for the construction of green roofs are eluted in leaching tests and the eluates are analyzed for potential negative effects on the aquatic environment using a standardized bioassay battery. Biotests offer an integrative approach to detecting the effects of undesirable substances, capturing the cumulative impact of complex mixtures, including unidentified or unexpected compounds. In contrast, analytical methods rely on a targeted approach, requiring prior knowledge of specific substances to be identified and quantified. In the further course, a model roof is constructed on a reduced scale with positively evaluated building products and the retained and discharged rainwater is examined with regard to its ecotoxic effects. In comparison, roof run-off water from practical projects will also be examined. The aim is to define building materials that can be used safely for the environment as part of the sponge city concept for green roofs.
The ecotoxicological assessment follows the CEN/TS 17459 framework, which combines standardized leaching tests with ecotoxicological evaluations. Depending on the product type, two different leaching methods are applied: for flat and monolithic products, the Dynamic Surface Leaching Test (DSLT, as per DIN EN 16637-2) is used, while granular products are assessed with the upflow percolation test (DIN EN 16637-3).

Disclaimer/Disclosure: The results of this contribution were developed within the project Implementation of the sponge city: Identification of the 10 most effective levers for the necessary transformation and sustainable model solutions for roofs of the blue-green city, commissioned by the German Environment Agency (Funding code: 3723 48 201 0).

3.15.P-Th250 Road Runoff in Urban Areas: Monitoring and Evaluation of a Raingarden Through One Year of Sampling

Elisabeth Støhle Rødland[1], *Mari Gjeitnes*[1], *Anne Luise Ribeiro*[1], *Ashenafi S. Gragne*[1], *Uta Brandt*[1], *Sondre Meland*[1], *Stina K. Karlstrom*[2], *Pedro N. Carvalho*[3] *and Vaidotas Kisielius*[3], *(1)Norwegian Institute for Water Research (NIVA), Norway, (2)Oslo Municipality, Bymiljoetaten, Norway, (3)Department of Environmental Science, Aarhus University, Denmark*

The negative impact of road pollution, especially tire wear particles (TWP), has gained attention due to new studies on their chemical content, leaching capabilities, and effects on organisms. This study investigated the seasonal variation of pollutants in road runoff, including TWP, organic compounds, metals, and water quality parameters, to assess the mitigation efficiency of a raingarden. Online sensors monitored the inlet and outlet of the raingarden continuously, providing data on water level, temperature, turbidity, and conductivity. Seven rainfall events were monitored: June (01), September (02, 03), October (04), November (05) 2023, and May (06), July (07) 2024. TWP was analysed PYR-GC/MS, organic compounds were analysed using HPLC-MS/MS and metals using ICP-MS. TWP levels varied between rainfalls but were higher at the inlet (2.57 ± 2.30 mg/L) compared to the outlet (0.488 ± 0.188 mg/L), resulting in an 81% reduction. For selected organic compounds (6PPD-Q, Benzothiazole (BT), Methylthiobenzothiazole (MTBT), Hydroxybenzothiazole (OHBT), Aminobenzothiazole (ABT), and Mercaptobenzothiazole (MBT)), levels varied between rainfall events, with the highest levels in Rainfall 01. The highest inlet level was for BT (9.73 ± 6.76 µg/L), followed by OHBT (9.29 ± 7.72 µg/L), MTBT (1.23 ± 1.08 µg/L), ABT (0.380 ± 0.247 µg/L), and 6PPD-Q (0.227 ± 0.160 µg/L). Comparing inlet to outlet values suggests retention rates of 90% for MTBT, 81% for 6PPD-Q, 71% for OHBT, 68% for BT, and 56% for ABT. For all rainfall events, the highest metal levels were for Na (77.8 mg/L), likely due to road salt (NaCl) entering the raingarden during winter. This is supported by high Cl levels (94.2 mg/L) and negative retention for both Cl (-248%) and Na (-215%), as well as high conductivity observed by the sensors. Another interesting result is the negative retention of Zn (-245%), with higher Zn levels in the outlet compared to the inlet. Zn is often used as an inorganic marker for TWP, but the high Zn levels in the outlet do not match TWP or organic tire-related compound levels. High correlation ($R>0.8$) was found between 6PPD-Q and ABT (0.86), BT (0.94), and OHBT (0.86). No correlation was found between TWP or TSS and tire-related compounds. Further analysis, including sensor data, will be presented at the conference. This data is important for understanding the presence of these compounds in road runoff and assessing raingardens as urban nature-based solutions.

Disclaimer/Disclosure: This study is part of the project Multisource, funded by Horizon H2020, grant 101003527.

3.15.P-Th251 Review of Three Years Environmental Pollutant Monitoring Along Railway Tracks in Germany

Sabrina Michael[1], *Gina Bode*[1], *Silvio Klugel*[2], *Thomas Grischek*[3], *Alexander Oy*[3], *Martin Sonntag*[4] *and Markus Zingelmann*[4], *(1)German Centre for Rail Traffic Reasearch at the Federal Railway Authority, Germany, (2)GEPRO Ingenieurgesellschaft mbH,Germany, (3)University of Applied Sciences Dresden, Division of Water Sciences, Dresden, Germany, (4)Beak Consultants GmbH, Germany*

In general, rail transport emits lower levels of pollutants than other modes of transport, but rail operations still have an impact on the environment. Inorganic and organic substance inputs come from rail operations, e.g. abrasion processes, and associated infrastructure maintenance work, such as vegetation control measures. The aim of the study is to summarize the results of three years pollutant monitoring and to categorize the dispersion of pollutants along the route into the adjacent environment. The results allow to close knowledge gaps and provide a basis for an environmental risk assessment.

Since 2021, the pollutant input from railway operations has been recorded at five long-term monitoring sites and their transport behavior was characterized. The investigation program includes the analysis of heavy metals, herbicides (incl. metabolites) and PAHs in water and soil samples. As part of the investigations, the depth-dependent herbicide and heavy metal contamination was determined in various soil horizons and track areas. In addition, the pollution potential at different distances from the track axis (2.5 m and 5.0 m) was also investigated. All sampling and analyses were carried out using standardized methods.

The results show a site-specific pollutant distribution with a clear decrease in pollutant concentrations from the middle of the track to its surroundings. The highest pollutant load was detected in the upper soil layers (0 - 0.30 m). Herbicides such as glyphosate and its metabolite AMPA, pelargonic acid and flumioxazine can be detected in the soil and leachate, especially after vegetation control. In a direct comparison of samples from upstream and downstream groundwater in the track area, arsenic, iron and zinc concentrations were found to increase, with none of the values exceeding the regulated limits. The aim of the study is to combine, bundle and categorize the knowledge obtained to date and thus, improve our understanding of the potential release of pollutants caused by rail traffic. The results contribute to an initial risk assessment and a further sustainable development of rail transport.

3.16 Photochemical Transformation of Contaminants in Aquatic Environments

3.16.T-01 Following the Photochemical Fate of Fluorinated Compounds

William Arnold*, Thomas Mundhenke, Akash Bhat, Cole Scholtz and William Pomerantz, University of Minnesota, United States*

Rachel Carson brought to light the dangers of persistent chlorinated chemicals in 1962, and we have spent decades dealing with these pollutants. Rather than learn from this lesson, we have incorporated another halogen, fluorine, into numerous industrial, agricultural, medical, and consumer chemicals. This includes numerous pesticides and pharmaceutical compounds, which are continuously released into the environment and thus are present in sunlit surface waters. Upon direct or indirect photolysis in aquatic systems, persistent fluorinated byproducts or fluoride from pesticides and pharmaceuticals are formed depending on the type and stability of the fluorine-containing functional group. Byproduct quantification is required to fully evaluate potential impacts of these compounds, and our methodology uses a combination of quantitative fluorine nuclear magnetic resonance spectroscopy (19F-NMR) and high-resolution mass spectrometry to track the persistence and transformation of fluorinated molecules. The 19F-NMR measurements allow a mass balance on fluorine to be performed, and density functional theory calculations can be used to estimate NMR shifts of compounds found via mass spectrometry to allow their quantification. Some motifs are persistent, generating compounds that are polyfluorinated alkyl substances (PFAS), while others degrade to fluoride. More oxidizing conditions (e.g., reaction with hydroxyl radical) often leads to a higher yield of fluoride as an end product, but also trifluoroacetic acid which is persistent. These results will assist in the evaluation of the fate of the large suite of fluorinated pesticides and pharmaceuticals in the environment and in the development of pharmaceutical/pesticide structures to limit persistent byproduct formation.

3.16.T-02 The Role of Photochemistry in the Environmental Fate of a New Antimicrobial Peptide

Owen Daniel[1]*, Thomas Thiebault*[2]*, Fabrice Alliot*[2] *and Elodie Guigon*[2]*, (1)Sorbonne University, Paris, France, (2)Ecole Pratique des Hautes Etudes, France*

Antibiotics are molecules used to treat bacterial infections that have contributed to the increase of human life-span over the last century. Widely used in human and veterinary medicine, these drugs have led to the development of antimicrobial resistance (AMR), a major global health threat. Antibiotics and their transformation products can reach the environment via various pathways, and have impact on human and environmental health by developing AMR in the environment or by exerting other deleterious effects. Therefore, the environmental fate of antimicrobials needs to be characterized. Their fate depends on various natural attenuation mechanisms, including photodegradation. In order to tackle AMR, new efficient antibiotics less susceptible to create resistance are needed. A promising antimicrobial peptide, Pep16, was synthetized. Its environmental fate and its transformation products need to be characterized to ensure that the possible wide use of this compound will not present risks to human and environmental health. Photodegradation and water stability of these compounds were assessed in the laboratory in batch scale. Hydrolytic degradation was studied in deionized water and in sterilized Seine River water in the dark at different pH. Direct and indirect photolysis were investigated using solar sunlight. Solutions were placed in quartz tubes on the roof of Sorbonne University (Paris, France). Pep16 and its transformation products were analyzed via HPLC-HRMS. In deionized water, Pep16 was not hydrolyzed, although it was degraded in complex environmental matrix. Since the degradation did not follow pseudo first-order kinetics, it is likely that metals or inorganic species contribute to the hydrolysis of Pep16. Pep16 was not phototransformed at pH = 4 and pH = 7; however a 39% degradation was observed at pH = 9, associated with a low quantum yield determined via PNAP/Pyr actinometry. Indirect photolysis of Pep16 appeared to be faster than direct photolysis. 1O2 seems to be the main contributor in this degradation, hence further experiment using sensitizers and probes will be conducted to study it. Phototransformation products will be used to propose degradation pathways and their potential toxicity will be predicted using existing models. This work contributes to the evaluation of the environmental fate of Pep16, which is essential for assessing the potential impact of this compound on human and environmental health should it be commercialized.

3.16.T-03 Photochemical Degradation of Diclofenac and Cimetidine in Natural Aquatic Environments: A Comparative Study of Laboratory and Field Experiments

Sofia Ambrogetti[1]*, Juliana Laszakovits*[1]*, Sarah Partanen*[2] *and Kristopher McNeill*[1]*, (1)Institute of Biogeochemistry & Pollutant Dynamics, Department of Environmental Systems Science, ETH Zurich, Switzerland, (2)Department of Environmental Chemistry, Eawag, Switzerland*

Photochemical transformations are critical for mitigating pharmaceutical contamination in natural aquatic systems, yet translating laboratory findings to real-world conditions remains challenging. While the photodegradation mechanisms of compounds like diclofenac and cimetidine are well understood under controlled laboratory conditions diclofenac undergoing direct photolysis and cimetidine degrading through singlet oxygen-mediated indirect photolysis environmental variability complicates predictions. To bridge the gap between laboratory-based measurements and real-world observations, we investigated the photodegradation of these pharmaceuticals in an outdoor experimental wetland pond through four two-day field experiments. We added 10 µg L? of diclofenac and cimetidine to the pond and monitored their degradation hourly, alongside measurements of water quality (dissolved organic carbon, UV-visible spectroscopy, and pH) and photochemical reactivity (singlet oxygen, hydroxyl radicals, carbonate radicals, and hydrogen peroxide concentrations). The field experiments revealed discrepancies between laboratory-based predictions and observed degradation rates, with diclofenac and cimetidine displaying half-lives of 48.3 (lab) to 73.5 (field) hours and 62.7 (lab) to 95.8 (field) hours, respectively. These slower observed degradation rates in the field suggest that environmental factors such as light attenuation, seasonal changes, and reactive species substantially influence degradation in natural settings. Notably, hydroxyl radicals contributed more significantly to cimetidine degradation than previously recognized. Our findings contribute to the broader effort to manage pharmaceutical contaminants in aquatic ecosystems more effectively by improving the accuracy of photodegradation predictions. In this presentation, we will discuss critical knowledge gaps in moving from the laboratory into the environment and the importance of refining predictive models to incorporate environmental variability.

3.16.T-04 POLITE: Photomodification of Low-Sulfur-Fuel-Oils, Investigations of Toxic Effects

Benjamin Patrick de Jourdan[1]*, Christoph Aeppli*[2] *and Danielle Philibert*[3]*, (1)Huntsman Marine Science Centre, Canada, (2)Bigelow Laboratory for Ocean Sciences, United States, (3)Huntsman Marine Science Centre, St. Andrews, NB, Canada*

The 2010 Deepwater Horizon oil spill changed our understanding of the significance of photomodification as a fate pathway following an oil spill. It revealed a considerable portion of non-volatile, non-soluble surface oil was rapidly oxidized by sunlight, resulting in the formation of complex mixtures of tens of thousands of water-soluble oxygenated compounds. The toxicity of these photo-products is largely unknown, and their propensity to form varies with oil type, however for new fuels like very low-sulfur fuel oils (VLSFO) it is not known whether they will behave in the same manner as traditional crude and fuel oils.

The POLITE project sought to improve the understanding of the photomodification potential of VLSFOs and their relative toxicity to species that are important to aboriginal, commercial and recreational fisheries. We determined the toxicity of 13 VLSFOs both with and without photomodification to a variety of early-life stages of marine organisms including, American lobster (*Homarus americanus*), Atlantic cod (*Gadus morhua*), and green-sea urchin (*Strongylocentrotus droebachiensis*).

A total of 31 bioassays were conducted with 17 products, using low energy water accommodated fractions (WAFs, n = 150) that were prepared and mixed either in the dark or under full spectrum UV light exposures for an 18-hr period using an Atlas Solar Constant lamp.

Following irradiation, the exposure metrics for many of the products tested significantly increased, suggesting that there were photoproducts being formed. The amount of photoproducts formed varied between oil samples, with some of the tested VLSFOs not showing any detectable changes following irradiation. In nearly all cases the observed toxicity in the UV treated WAF was equal or greater than the WAF prepared in the dark. Larval lobster immobilization was the most sensitive endpoint across the tested species.

Using waterborne PAC concentrations, toxic units were calculated, and predictions were compared against the observed responses. The toxic units had good agreement with observed effects; however they were underpredicting the toxicity of many of the VLSFOs products, both with and without UV irradiation. These results suggest that there are other components within VLSFOs which are contributing towards the toxicity.

3.16.T-05 Next Generation PhotoFate: A Technique for Simultaneous Determination of Indirect Photochemical Degradation Rates, Transformation Products, and Second-Order Rate Constants

William Fahy *and Scott A. Mabury, Department of Chemistry, University of Toronto, Canada*

Indirect photochemistry is an important transformation pathway for environmental contaminants in surface waters. However, the rates of indirect photochemistry can vary significantly between contaminants and surface waters depending on the reactivity towards and concentration of photochemically produced reactive intermediates such as hydroxyl and carbonate radicals, singlet oxygen, and excited triplet state organic matter. Significant strides have been made in understanding the reactivity of these species, but accurately measuring rates of indirect photochemistry still requires careful experiments to determine second-order rate constants with respect to each reactive intermediate, comprehensive assessment of the role of surface water components on indirect photochemistry, or sampling and testing of many genuine surface water samples. This variability and a lack of a standardized procedure for measuring the rates of indirect photochemistry has limited its inclusion in chemical fate and exposure assessments by regulatory bodies and industry.

Here we propose and validate a standardized method for assessing the role of indirect photochemistry in the fate of environmental surface water contaminants. Our approach couples a detailed kinetic model with a streamlined version of the PhotoFate technique, where the indirect photodegradation rates of a compound are tested in a series of synthetic surface water mixtures created by combining surface water constituents at various concentrations. The experimental half-lives in the synthetic surface waters provide a range of possible indirect photochemical reaction rates in surface waters globally. With the same dataset and the modelled steady-state concentration of photochemically produced reactive intermediates, second-order rate constants between the environmental contaminant of interest and each reactive intermediate can also be estimated by fitting to the experimentally measured pseudo first-order rate constants in each solution. Finally, a comprehensive and reproducible distribution of possible photoproducts can be identified from the synthetic surface water solutions. This technique is simple to perform and standardized to ensure results will be reproducible between laboratories, allowing interlaboratory comparison, benchmarking of the rates of indirect photochemistry in sampled surface waters, standardized testing of new compounds, and regulatory assessment.

3.16.P Photochemical Transformation of Contaminants in Aquatic Environments

3.16.P-Mo246 Sunlight-Responsive Photocatalytic Membrane for the Treatment of Emerging Contaminants

Venkateshwaran Gopal[1] *and Ambika Selvaraj*[2]*, (1)Department of Civil Engineering, Indian Institute of Technology Hyderabad, India, (2)Faculty, Department of Civil Engineering, Indian Institute of Technology Hyderabad, Adjunct Faculty, Department of Climate Change, Indian Institute of Technology Hyderabad, Adjunct Faculty, Greenko School of Sustainability, Indian Institute of Technology , India*

The availability of clean water is a global concern due to the usage of multiple chemicals, which tend to be persistent in day-to day life. Similarly, conventional water or wastewater treatment plants could not remove the recalcitrant and emerging contaminants completely and thus require advanced treatment. Photocatalysis is seen as one of the most advanced treatment techniques due to the stable and powerful oxidant generation that degrades pollutants. However, at the end of the treatment, it is tedious to collect the photocatalyst particles for reuse, which makes the treatment costly and unsustainable. These facts suggest attaching the photocatalyst particles to a surface and applying it for that purpose. In the same aspect, if the photocatalyst particles are merged with the membrane, the resultant photocatalytic membrane reactor (PMR) was observed to have the advantages of (i) complete utilization of photocatalysis; (ii) membrane-based filtration and photocatalysis as a single unit; (iii) no escape of particles, so no worry of having the nano-photocatalysts in the treated water. Having this understanding of the PMR, in this talk, the different configurations of the PMRs, operational parameters, and influencing factors on the treatment of emerging pollutants-contaminated water from different sources will be discussed.

The 2,4-dichlorophenoxyacetic acid (2,4-D) is an agrochemical used to remove weeds in paddy fields. Due to the toxicity associated, 2,4-D containing water needs treatment. Thus, herein, a sunlight-responsive ZrO2-Bi2O3 photocatalyst was prepared by green synthesis using cow urine and tested for its efficiency in degrading 2,4-D. The prepared ZrO2-Bi2O3 was then characterized in detail. The experimental results showed that 40% ZrO2-Bi2O3 showed the best photocatalytic activity and stable even after five cycles of reuse. Furthermore, the sustainability of the studied technique that was analysed by the newly developed weightage-based ranking method showed that the present work addressed 14 of 17 SDGs. In addition, the mechanisms of different photocatalysts during the adsorption and catalysis stages that were observed in the laboratory and how the performance and mechanisms vary with sunlight-based experiments compared to the controlled environment will also be explained.

3.16.P-Mo248 Understanding the Role of Photolysis in the Aquatic Fate of Antimicrobial Transformation Products

Paul Loffler[1]*, Valentina Ugolini*[2]*, Harold Flores Quintana*[2]*, Karin Wiberg*[3] *and Foon Yin Lai*[3]*, (1)Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Swedish University of Agricultural Sciences (SLU), Sweden*

The global proliferation of antimicrobial resistance (AMR) presents a complex concern, impacting the well-being of humans, animals, and the environment, within the One Health framework. Current environmental risk assessments of AMR primarily focus on antimicrobial parent compounds, with limited consideration given to their transformation products (TPs). However, antimicrobial TPs can be ubiquitously found in aquatic environments due to incomplete or even absent removal in effluent wastewater with conventional wastewater treatment. Thus, natural processes, such as photolysis, may substantially influence the distribution and persistence of these compounds in surface waters.
This study investigates the role of photochemical processes in the degradation of seven antimicrobial TPs derived from various antibiotic classes: hydroxy-metronidazole, hydroxy-trimethoprim, N-acetylsulfamethoxazole, clindamycin sulfoxide, erythromycin A enol ether, anhydro-erythromycin, and 4-epianhydrotetracycline. Experiments were conducted under controlled irradiation intensities (250 and 600 W m-2, across 300-800 nm) to simulate different seasonal and/or altitudinal conditions, and considered different water matrices (MQ, surface and sea water) as well as the influence of other water parameters (e.g., pH, salinity, dissolved solids). All compounds were degraded to different extents over the course of the 56 h experiment. Most TPs followed first-order kinetics, with indirect photolysis and hydrolysis seemed to have a stronger influence than the irradiation intensity. Overall, several of the investigated TPs (N-acetylsulfamethoxazole, clindamycin sulfoxide, hydroxy-trimethoprim, and anhydro-erythromycin) have provided limited photodegradation potential, highlighting the persistence of these organic micropollutants in different water matrices, hence the importance of considering them in environmental risk assessments.

Disclaimer/Disclosure: This study is funded by the Swedish Research Council (project number: 2020-03675).

3.16.P-Mo249 Photodegradation of Trifluoromethyl-Substituted Aromatic Compounds: Effect of Nitrogen Presence in Aromatic Rings

Mattia Balestra[1]*, Thomas Mundhenke*[2]*, Juliana Laszakovits*[1]*, Sofia Ambrogetti*[1]*, Kristopher McNeill*[1] *and William Arnold*[2]*, (1)Institute of Biogeochemistry and Pollutant Dynamics (IBP), Department of Environmental Systems Science, ETH Zurich, Switzerland, (2)Department of Civil, Environmental, and Geo- Engineering, University of Minnesota, United States*

Several pharmaceuticals and pesticides containing trifluoromethyl-aromatic moieties, such as fluoxetine, TFM, flupyrsulfuron-methyl, and trifluridine, have faced regulatory scrutiny due to their classification within the large and problematic PFAS group. Some of these compounds photodegrade both directly and indirectly producing trifluoroacetic acid and fluoride anion as final products. To predict their degradation rates in the environment, assess the byproducts formed, and to ultimately design less persistent products, it is important to understand which structural features drive photochemical degradation. Here, we characterized the photodegradation of trifluoromethyl substituted aromatic and heteroaromatic model compounds, including benzoic acid, pyridine, pyrimidine, pyrazine, imidazole, pyrazole, and triazole. We determined their quantum yields and radical reactivity through a combination of direct and indirect photolysis experiments. Furthermore, using 19F NMR, mass spectroscopy and computational methods, we attempt to determine intermediates and final products formed by photodegradation and uncover the mechanisms at play. Our results reveal that an increased presence of nitrogen in the aromatic ring diminishes photodegradation rates. This reduction is due to a decrease in quantum yield, resulting in a lower efficiency of direct degradation processes. Moreover, an increased number of nitrogen atoms in the structure also hinders reaction rates with hydroxyl radicals. Additionally, we observe that the presence of nitrogen in the ring also increases the yield of trifluoroacetic acid and leads to less defluorination. The intermediate products formed and the final trifluoroacetic acid yield also depend on the reaction pathway, with indirect photolysis increasing trifluoroacetic acid formation for some compounds. Overall, these findings contribute to a deeper understanding of the photodegradation mechanisms of trifluoromethylated heteroaromatic compounds and highlight critical structural properties that may inform environmental risk assessment and regulatory considerations for such chemicals.

3.16.P-Mo250 Photochemical Degradation of Dimethylsilanediol in Fluvial Environments: Effects of Dissolved Organic Matter

Aleksandar I. Goranov[1]*, Jaeshin Kim*[2]*, Debra Ann McNett*[2]*, Marc-Andre Courtemanche*[2] *and Joseph Vasquez*[2]*, (1)Old Dominion University, United States, (2)The Dow Chemical Company, United States*
Dimethylsilanediol (DMSD) is the major degradation product of silicone polymers found in sealants, adhesives, lubricants, medical devices, cooking utensils, thermal insulation, electrical insulation, and other products. Interest in DMSD increased after it was detected in the potable water of the International Space Station. It is a challenging compound to quantify and thus, its concentrations and dynamics are poorly understood in the aquatic environment. This presentation will show findings from a comprehensive study of DMSD photochemical degradation in fluvial settings. Simulated sunlight was used to irradiate DMSD in water from four aquatic sources: Great Dismal Swamp (Virginia, USA), Suwannee River (Georgia, USA), Lake Ocklawaha (Florida, USA), and the Everglades (Florida, USA). Quantitative 1H NMR spectroscopy determined that DMSD degrades following pseudo-first-order kinetics (i.e., rate = k [DMSD]), with the rate constants k being similar for the experiments with Suwannee River, Lake Ocklawaha, and Everglades media. The degradation of DMSD was much faster in the Great Dismal Swamp media likely due to the high iron loadings stimulating photo-Fenton oxidation of DMSD. NMR relaxometry (measurements of spin-lattice relaxation times, T1, of DMSD) revealed that DMSD does not bind to fluvial molecules through non-covalent pathways such as hydrogen bonding or Van der Waals forces. Ultrahigh resolution mass spectrometry (10-Testa FT-ICR-MS) indicates the formation of new Si-containing compounds during photo-irradiation. This implies the formation of covalent bonding between DMSD fragments to fluvial organic molecules, however, this mechanism for DMSD removal appears to be insignificant in fluvial environments (as determined by kinetic experiments). Additional experiments showed that hydroxyl radical and superoxide species oxidize DMSD in significant amounts, suggesting these oxidation pathways as predominant. By contrast, it was revealed that DMSD did not degrade upon exposure to sunlight in pure water or to singlet oxygen species. Lastly, solid-state 29Si NMR revealed that photo-flocculation may also be responsible for sequestering DMSD to some extent in fluvial settings. Collectively, these laboratory experiments expanded the knowledge on how DMSD degrades environmentally and further point to reactive oxygen species as responsible for DMSD losses in the environment (i.e., secondary photochemical degradation).

Disclaimer/Disclosure: Funding for this work was provided by CEFIC CES - SILICONES EUROPE.

3.16.P-Mo251 Comparative Investigation of Microplastic Fiber Formation from Five Synthetic Textile Fabrics Under UV-A Exposure

A. Angel Jessieleena, Iniyan K.E. and ***Indumathi M. Nambi****, Indian Institute of Technology Madras, India*
Microplastic fibers (MPFs) are the dominant form of microplastics ubiquitously present in the environment, with textile fabrics being the largest source of MPFs. Though several research works have been conducted previously to understand the transformation of plastic products under photo radiation, not much research have been undertaken to investigate the fate of textile fabrics which is the major source for MPFs pollution. In Asian countries like India, a huge number of clothes are discarded every year in the water bodies as part of religious rituals, leaving the water body contaminated. These clothes eventually enter the ocean while being constantly exposed to sunlight. Therefore, to mimic this scenario, five different fabrics, namely polyester, georgette, satin, nylon, and lycra, were chosen for the study. These fabrics were cut into 5x5 sq. mm sized square and subjected to sacrificial photo radiation studies in aquatic suspension for 1, 3, 5, 7, 14, 21, and 46 days of UV-A radiation in an annular photoreactor fitted with a 400 W 365nm UV lamp. The fresh and aged fabrics were then characterized using X-Ray Diffractometer (XRD), micro-Fourier Transform Infrared Spectroscopy (μ-FTIR), and Scanning Electron Microscopy (SEM). Besides, after each experiment, the suspension media was completely filtered onto a Whatman glass fiber filter (GF/C, 47 mm diameter, 1.2 μm pore size) to quantify the number of released MPFs. The entire filter was then observed under an optical microscope in a zig-zag manner to capture and characterize the whole set of released MPFs. Notably, nylon fabric has become brittle, eventually breaking down into tiny, uncountable numbers of particles at 7d of exposure. Among the remaining fabrics, the number of released MPFs was highest in satin (>1000 MPFs), followed by lycra, PET, and georgette. The obtained estimation correlates with the surface characteristics analysis, with satin showing a greater number of long and wider cracks compared to other fabrics. μ-FTIR analysis has confirmed the occurrence of aging, with aged fabric possessing varying intensity of peaks and peak shifts. However, no changes can be seen in the crystallinity of the aged fabrics, as confirmed by XRD analysis. Overall, the

outcome of this study would enable policymakers to understand the need for the management of textile fabrics that are discarded into the water bodies.

3.16.P-Mo252 Role of Direct and Sensitized Photolysis in the Photomineralization of Dissolved Organic Matter and Model Chromophores to Carbon Dioxide

Shelby Buckley[1], *Frank Leresche*[2], *Kari Norris*[2] *and Fernando Rosario-Ortiz*[2], *(1)ETH Zurich, Switzerland, (2)University of Colorado Boulder, United States*

This study addresses the fundamental processes that drive the photomineralization of dissolved organic matter (DOM) to carbon dioxide (CO2), deconvoluting the role of direct and sensitized photolysis. Here, a suite of DOM isolates and model compounds were exposed to simulated sunlight in the presence of various physical and chemical quenchers to assess the magnitude, rate, and extent of direct and sensitized photomineralization to CO2. Results suggest that CO2 formation occurs in a biphasic kinetic system, with fast production occurring within the first 3 h, followed by slower production thereafter. Notably, phenol model chromophores were the highest CO2 formers and, when conjugated with carboxylic functional groups, exhibited a high efficiency for CO2 formation relative to absorbed light. Simple polycarboxylated aromatic compounds included in this study were shown to be resistant to photomineralization. Quencher results suggest that direct photolysis and excited triplet state sensitization may be largely responsible for CO2 photoproduction in DOM, while singlet oxygen and hydroxyl radical sensitization may play a limited role. After 3 h of irradiation, the CO2 formation rate significantly decreased, and the role of sensitized reactions in CO2 formation increased. Together, the results from this study advance the understanding of the fundamental reactions driving DOM photomineralization to CO2, which is an important part of the global carbon cycle.

3.16.P-Mo253 The Role of Lipids in the Photoinactivation of Enveloped Viruses

Eliane Ballmer[1], *Juliana Laszakovits*[1], *Alexandria B. Bohem*[2] *and Kristopher McNeill*[1], *(1)ETH Zurich, Switzerland, (2)Stanford University, United States*

Aquatic ecosystems can serve as important reservoirs for enveloped viruses such as influenza viruses. Due to the possibility of virus transmission via contaminated waters, knowledge on the persistence of enveloped viruses in these matrices is decisive to better understand transmission pathways and risks. So far, it has been established that factors such as temperature, biological activity, virus subtype and water characteristics (e.g., pH, salinity) impact the decay rates of enveloped viruses. While only few studies have investigated the fate of enveloped viruses upon exposure to sunlight, recent experimental evidence suggests that enveloped viruses have lower photoinactivation rates compared to non-enveloped viruses, questioning the role of the envelope in the photoinactivation pathway. The envelope, consisting of a lipid membrane and associated glycoproteins, contains unsaturated lipids, which may be reactive towards photochemically produced reactive intermediates such as singlet oxygen. We therefore hypothesize that the lipid membrane presents a target for the photoinactivation of enveloped viruses in DOM-influenced surface waters. To test this hypothesis, we synthesize lipid vesicles of different lipid compositions and degrees of unsaturation via extrusion, expose them to sunlight in presence of DOM and trace their degradation using high performance liquid chromatography-mass spectrometry (HPLC-MS). By evaluating the photochemical degradation kinetics of the lipid membrane of enveloped viruses, our work aims at enhancing the understanding of virus persistence in aquatic environments, eventually allowing for better estimates of transmission routes and risks.

3.17 Combined Effects of Contaminants and Global Change Stressors in Estuarine and Marine Environments

3.17.T-01 Inferring Exposure to PFAS Over Time in the French Atlantic Coast by Sediment Core Analysis

Javier Castro-Jimenez, *Emma Junca, Nadege Bely, Charles Pollono and Anne Grouhel-Pellouin, IFREMER, Chemical Contamination of Marine Ecosystems (CCEM), France*

Per- and polyfluoroalkyl substances (PFAS) have been reported as wieldy distributed in oceanic environments. However, the occurrence of these highly persistent chemicals in the sedimentary compartment of marine regions is very little studied, despite the fundamental role of marine sediments in biogeochemical cycles, being both a compartment of storage of pollutants and the main route of exposure of benthic organisms. The study of vertical profiles of contaminants in sediment cores represents a unique retrospective environmental approach to infer their deposition and exposure history. In this work we (1) investigated the occurrence of PFAS in sediment core horizons covering the last 50-100 years in the Gulf of Biscay (North-East Atlantic Ocean), and (2) assessed the PFAS historical and present concentrations and exposure trends in the study area by investigating their vertical profiles in the sediment cores. Three sediments cores were collected in sites subject to different anthropogenic pressures by using an interface corer equipped with stainless steel tubes on board of the R/V Thalia (IFREMER) in May 2022 (ROCCHSED2022, DOI: 10.17600/18002069.). Once in the lab, the cores were sliced into 1 cm horizons and dated. PFAS were microwave-extracted from the sediments, the extract cleaned-up by sequential solid phase extraction and PFAS quantified by isotopic dilution LC-ESI-MS/MS. A significantly higher loading of sumPFAS (Wilcoxon, $p = 0.0001$) was recorded in the accumulation area of sedimentary material drained by the Gironde River (west Gironde mud patch), where core 22-20 was collected, with median concentrations of 314 pg g-1 dw. The fact that core 22-24 was sampled closer to the coast, in a touristic area and under the influence of some urban/industrial areas from Spain, did not seem to have a big influence in the median sumPFAS levels in the area, which were more than 6-fold lower (~50 pg g-1 dw). The vertical profiles in core 22-20 allowed us to trace back the PFAS presence in the study area to the early 50 s. The first detections were observed in year 1952, although only one compound was found in this period and at very low concentration (few pg g-1 dw). Even if the total PFAS concentrations increased by a factor of 30 since first detections to modern times, the PFAS fingerprint, and therefore the exposure pattern, seems to have been quite homogeneous over time. Perfluorooctane sulfonic acid (PFOS) was one of the predominant compounds across time.

3.17.T-02 Field and Laboratory Studies Assessing the Transport Behaviour of Priority Pollutants in the Tidal Elbe

Pascal Hoppe[1]*, Victoria Ortiz*[2]*, Tristan Zimmermann*[3] *and Daniel Profrock*[3]*, (1)Helmholtz-Zentrum Hereon, Germany, (2)Federal Waterways Engineering and Research Institute (BAW), Germany, (3)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany*

Sediment management in the Elbe estuary serves to expand and maintain the waterway. As fluvial Elbe sediments are contaminated, their relocation and natural transport can lead to pollutant accumulation as well as their widespread distribution. Old legacy pollutants can be distributed between water, suspended particulate matter (SPM) and sediment. The physicochemical dynamics that control the transport of pollutants between these compartments are sometimes inadequately reflected in prediction models. In order to generate more reliable data and optimize forecasts for the Elbe estuary, an interdisciplinary approach based on field and laboratory studies was used to investigate the distribution behavior of selected pollutants. These data are used to parameterize a new numerical model that integrates interactions between sediment, SPM and pollutant transport.

This contribution provides current and discrete data for legacy pollutants in the tidal Elbe SPM with a spatial distribution and corresponding KD values. The samples were collected on a sampling campaign with the research vessel Ludwig Prandtl in April 2023, prepared in the laboratory, digested according to Zimmermann et al. (2022) and measured via ICP MS/MS. In addition, monthly pooled samples provided by the Lower Saxony State Agency for Water Management, Coastal Defence and Nature Conservation (NLWKN) were subjected to sequential extraction according to the Community Bureau of Reference (BCR) to provide the model with valuable data on remobilization behavior under different environmental conditions.

The trace element mass fractions of the sediment samples range from 0.14 ± 0.07 mg kg-1 to 3.9 ± 0.3 mg kg-1 to 35.9 ± 2.3 mg kg-1 to 162 ± 8 mg kg-1 for Cd and Zn, respectively. The mass fractions of the SPM samples range from 0.26 ± 0.16 mg kg-1 to 3 ± 0.4 mg kg-1 to 83.0 ± 10.0 mg kg-1 to 552 ± 29 mg kg-1 for Cd and Zn, respectively. Overall measured mass fractions in SPM are significantly higher than the corresponding sediment samples. To support a precise modelling of pollutants in the Elbe catchment the data was used further to calculate KD values which are used as input parameters in various numerical models.

3.17.T-03 Distribution and Occurrence of Emerging Organic Compounds in the Estuary of Plentzia

Maddi Salvoch Vilches[1]*, Belen Gonzalez-Gaya*[1]*, Juan Francisco Ayala Cabrera*[1]*, Amaia Callejo-Rubio*[2]*, Ailette Prieto*[1]*, Oihane Diaz de Cerio*[1]*, Ibon Uriarte*[1]*, Amaia Leunda*[1] *and Nestor Etxebarria*[1]*, (1)Research Centre for Experimental Marine Biology and Biotechnology, University of the Basque Country (PiE-UPV/EHU) & Department of Immunology, Microbiology and Parasitology, University of the Basque Country (UPV/EHU), Spain, (2)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain*

This study, conducted within the One Health framework, analysed contaminants of emerging concern (CECs) in the Plentzia estuary and Butroe River basin (Biscay, Basque Country) to understand their distribution, occurrence, and role in coastal ecosystem health. CECs include diverse substances such as pharmaceuticals, PFAS, plasticizers, pesticides, and personal care products, many of which occur at trace levels but pose risks due to chronic exposure. Their varied physicochemical properties challenge their measurement and understanding of their environmental fate, requiring advanced analytical techniques like high-resolution mass spectrometry and extensive spatial and temporal monitoring. The research involved a year-long sampling campaign in the estuary and river basin, areas influenced by industrial activity, wastewater discharges, and significant seasonal population changes. Effluents from two wastewater treatment plants (WWTPs) were sampled alongside surface and bottom waters from various estuarine points, accounting for salinity and tidal conditions. Samples were filtered, extracted using Oasis HLB cartridges, and analysed on a Dionex UltiMate 3000 UHPLC coupled to a Q Exactive Focus quadrupole-Orbitrap (Thermo Scientific) equipped with a heated ESI source (Thermo, CA, USA). A selection of around 300 compounds, including many different CECs families, was used for a target analysis. A clear correlation was observed between WWTP effluents and estuarine waters, with similar contaminant patterns regardless of salinity or depth. The highest concentrations and frequencies of occurrence were found in intermediate salinity zones, where seawater dilution is reduced. Additionally, seasonal trends have also been observed, suggesting that the distribution may be influenced by temporal variations throughout the year. These findings highlight the need for continuous monitoring and advanced analytical approaches to address the environmental and health impacts of CECs in dynamic coastal systems, particularly under the pressures of human activity.

3.17.T-04 Following the Mixtures of Organic Micropollutants with In-Vitro Bioassays in a Large Lowland River from Source to Sea

***Elena Hommel*[1]**, *Maria Konig[2], Georg Braun[2], Beate Escher[3], Martin Krauss[4], Norbert Kamjunke[5], Werner Brack[4], Anna Matousu[6], Tina Sanders[7], Ingeborg Bussmann[8], Eric P. Achterberg[9] and Bjorn Raupers[9], (1)UFZ, Germany, (2)Department of Cell Toxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Department of Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (4)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (5)Department of River Ecology, Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Biology Centre, Czech Academy of Sciences, Institute of Hydrobiology, České Budějovice, Czech Republic, (7)Institute for Carbon Cycles, Helmholtz Centre Hereon GmbH, Germany, (8)Departments of Shelf Sea System Ecology, Alfred-Wegener-Institut, Helmholtz Zentrum fur Polar- und Meeresforschung, Germany, (9)GEOMAR Helmholtz Centre for Ocean Research, Germany*

Human-impacted rivers often contain a complex mixture of organic micropollutants, including pesticides, pharmaceuticals and industrial compounds, along with their transformation products. Combining chemical target analysis for exposure with in vitro bioassays for effect assessment offers a holistic view of water quality. This study targeted the River Elbe in Central Europe, known for its anthropogenic pollution exposure, to obtain an inventory of micropollutant contamination during base flow and to identify hotspots of contamination. We identified tributaries as sources of chemicals activating the aryl hydrocarbon receptor quantified with the AhR-CALUX assay, including historically contaminated tributaries and a newly identified Czech tributary. Increased neurotoxicity, detected by differentiated SH-SY5Y neurons cytotoxicity and shortened neurite length, was noted in some Czech tributaries. While effect-based trigger values (EBT) for oxidative stress response, xenobiotic metabolism and neurotoxicity were not exceeded, estrogenicity levels surpassed the EBT in 14% of surface water samples, posing a threat to fish reproduction. Target analysis of 713 chemicals resulted in the quantification of 487 micropollutants, of which 133 were active in at least one bioassay. Despite this large number of quantified bioactive chemicals, the mixture effects predicted by the concentrations of the quantified bioactive chemicals and their relative potency explained only 0.002-1.2% of the effects observed in the surface water extracts, highlighting a significant unknown fraction in the chemical mixtures. This case study established a baseline for understanding pollution dynamics and spatial variations in the Elbe River, offering a comprehensive view of potential chemical effects in the water and guiding further water quality monitoring in European rivers.

3.17.T-05 Assessment and Prioritization of Aquatic Contaminants of Concern on Florida's Coral Reef

*Ellen Regina Englert Skelton[1], **Dorothy-Ellen Abigail Renegar**[2], Carys Louise Mitchelmore[3] and Bernhard M. Riegl[2], (1)Nova Southeastern University, United States, (2)National Coral Research Institute, United States, (3)University of Maryland Center for Environmental Science, Cambridge, United States*

Florida's Coral Reef (FCR) is the third largest barrier reef in the world and faces significant stress from localized, land, water, and air-based sources of pollution. Several chemical contaminants have been found in waters surrounding reefs and within corals, including pesticides, hydrocarbons, personal care products, pharmaceuticals, and trace metals. However, for most current and emergent environmental contaminants, little to no consistent information exists regarding environmental concentrations or toxicological effects on corals. Assessment of the levels of contaminants in coral reef environments is needed to conduct risk assessments to guide management, restoration, and recovery strategies, and the coral reef resource management community has recognized the need for improved, readily available comprehensive information.

Concentration data for metals, non-metals, and various organic compounds, consisting of over 72,000 marine data points for water and sediments, and covering over 800 sites in the five counties encompassing FCR (Broward, Miami-Dade, Palm Beach, Martin, and Monroe), were compiled from two main portals, the National Water Quality Monitoring Council Water Quality Portal and NOAA's National Status and Trends, and peer-reviewed literature. Concurrently, toxicological data for scleractinian corals was compiled from the EPA ECOTOX knowledgebase and peer reviewed literature for the same contaminant classes. These two datasets were then compared to establish existing knowledge gaps in both environmental monitoring data and toxicological effects on corals, and to identify any emerging contaminants of concern along the FCR. Where environmental data were not available, then potential sources and likelihood of occurrence for key contaminants were evaluated to estimate exposure risk, for example examining the most commonly used pesticides in Florida. The data, analysis, and evidence-based recommendations will support informed conservation management decisions and will be widely disseminated via incorporation into Florida s Department of Environmental Protection s (FDEP) coral reef decision support system (CRDSS).

3.17.P Combined Effects of Contaminants and Global Change Stressors in Estuarine and Marine Environments

3.17.P-Th252 Evaluation of Elevated Temperature Effects on Pollutant Toxicity in *Artemia salina*

*Yakinthi Kontou[1], **Danae Patsiou**[2], Maxime Pontie[3], Kalliopi Bormpoudaki[4], Dionysios Raitsos[1], Christina Zeri[2] and Catherine Tsangaris[2], (1)Department of Biology, National and Kapodistrian University of Athens, Greece, (2)Institute of Oceanography, Hellenic Centre for Marine Research (HCMR), Greece, (3)Group of Analysis and Processes, Chemistry Departement, Faculty of Sciences, University of Angers, France, (4)Association for the Solid Waste Management of Crete (ESDAK), Greece*

In the context of climate change, the increasing frequency and intensity of environmental stressors like marine heatwaves necessitate understanding their biological impacts, particularly when combined with pollutant exposure. This study investigates the acute toxicity of a landfill leachate sample collected from a leachate treatment plant in Crete, Greece, alongside two environmental pollutants, copper (Cu^{2}?) and bisphenol A (BPA), on *Artemia salina nauplii* under ambient (25°C) and elevated (30°C) temperatures, simulating marine heatwave conditions. Mortality, expressed as lethal concentration 50 (LC50), and sublethal biochemical responses, including glutathione S-transferase (GST) and electron transport system (ETS) activity, were assessed.
At 30°C, LC50 values for Cu and BPA were significantly reduced compared to 25°C, indicating increased toxicity at elevated temperatures. For Cu, LC50 decreased from 104.94 mg/L to 79.27 mg/L, while for BPA, LC50 dropped from 54.73 mg/L to 10.71 mg/L. In contrast, leachate LC50 values were unaffected by temperature changes. Biochemical assays revealed that GST activity peaked at lower Cu concentrations and increased significantly with elevated temperatures, with activity doubling for Cu exposure at 30°C compared to 25°C. BPA exposure induced GST activity at the highest concentration tested, while no GST

response was observed for leachate exposure. ETS activity in control groups was temperature-sensitive, increasing significantly at 30°C; however, pollutant exposure did not significantly alter ETS activity at either temperature.
These findings show the complex interplay between temperature and pollutant toxicity, with elevated temperatures intensifying the adverse effects of Cu and BPA on marine organisms. The results highlight the vulnerability of marine and aquatic ecosystems to compounded stressors, suggesting that rising global temperatures and pollution may synergistically threaten biodiversity and ecosystem stability.

Disclaimer/Disclosure: This study was funded by the HORIZON project iMermaid - Safeguarding the Mediterranean Sea from contaminants of emerging concerns, financed by the European Union (GA No 101112824).

3.17.P-Th253 Toxicological Evaluation of Plastic and Antifouling Paint Leachates on Two Life Stages of an Estuarine Copepod: *Nitokra spinipes*, in the Context of Global Change

***Juliette Grandjean**[1], Maria Kazour[2] and Ana I. Catarino[1], (1)Flanders Marine Institute (VLIZ), Belgium, (2)Thomas H. Gosnell School of Life Sciences, Rochester Institute of Technology, Rochester, United States*

Plastic production soared to 400 million tons with a substantial proportion finding its way from inland areas to riverine and coastal environments. Within aquatic environments, plastics and biocide boat coatings undergo physical and chemical degradation, leaching chemicals from the polymer's matrix. These leachates have been found to have deleterious effects on aquatic organisms, such as copepods, crustaceans or fish. Furthermore, global change is currently increasing the frequency and magnitude of environmental stressors (i.e., increased temperatures), inducing negative effects in organisms. To the best of our knowledge, the combined effects of plastic-associated chemicals and global change remain largely unexplored. So, this study aims to evaluate the effects of leachates from plastic debris and boat coatings on *Nitokra spinipes*, a harpacticoid copepod key-species to estuarine food webs, in the context of global change. First, the most common observed plastics in an estuarine environment was established by sampling plastic items from the water column of the Iser estuary in Nieuwpoort, Belgium, via a manta net coupled to an aquatic drone; and from the banks using three quadrats of 50 x 50 cm randomly deployed along the tide line. After identifying polyethylene (PE) and polypropylene (PP) as the most abundant polymers as well as coating particles, leachates were produced using pristine PP and a Hemper's boat coating (7 days, at room temperature, in the dark). The toxicity of the leachates was then assessed by exposing *N. spinipes* adults and nauplii at 22°C and 25 °C (+3 °C, RCP 8.5 scenario, IPCC 2021). A significant toxicity was observed from the coating's leachates on nauplii development and mortality, whereas none was observed for the PP-leachates. Our results on adults showed a synergistic negative effect of the coating s leachates when combined to higher temperature (after 72 h, EC50 at 22°C = 44.7 ± 16.88% and EC50 at 25°C = 6.52 ± 10.73%). To conclude, coating's leachates exhibited significant toxicity in both life stages affecting greatly the adults when combined with elevated temperature. Our findings suggest that the predicted increase in temperature will aggravate the leachates toxicity on copepods and could lead to a cascading effect on the food web. Our results contribute to the risk assessment of plastic and coatings related litter in regional estuaries and help filling the knowledge gap on combined stressors effects on organisms.

3.17.P-Th254 Combined Effects of Plastic Pollution and Global Change on a Benthic Primary Consumer, *Nitokra spinipes*

***Juliette Grandjean**[1], Jana Asselman[2] and Ana I. Catarino[1], (1)Flanders Marine Institute (VLIZ), Belgium, (2)Ghent University, Laboratory of Environmental Toxicology and Aquatic Ecology, Faculty of Bioscience Engineering and Blue Growth Research Lab, Ghent University, Belgium*

In estuarine waters, organisms are subject to multiple stressors in the environment, including anthropogenic pollutants such as plastic, and fluctuating physical-chemical parameters due to tidal and freshwater inputs. However, due to global change, physical-chemical parameters are predicted to be shifted towards new extremes in estuaries. For example, recurring extreme salt intrusion events will increase due to a higher frequency in heatwaves and draughts, more acidic water events will happen. Alongside these stressors, estuaries are considered reservoirs of plastic pollution, but the assessment of the combined effects of these parameters on primary benthic consumers, along generations, is lacking. Therefore, we aim to assess the combined effects of multiple stressors (pH, salinity, plastic particle forms) on a benthic estuarine primary consumer, *Nitokra spinipes*, across multiple generations. Using both experimental results and coastal ecosystem knowledge, we aim to model the coastal ecosystem responses, already impacted by multiple stressors (e.g. fishery activities, pollutants, global change), to a shift in a benthic primary consumer group. We expect that sublethal effects will be observed when one of the physical stressors approaches the species tolerance limit, and that particle ingestion will potentiate these effects along generations. Expected effects can be the reduction of number of offspring to decrease or impaired growth and development, due to energy reallocation (food dilution) and population decline over multiple generations. Within the ecosystem, if the primary consumers are impacted, a cascade effect could be predicted with a shift in the access to food items on high food web levels, potentially leading to negative impacts on economic activities leaning on fisheries.

3.17.P-Th255 Small Microplastics and Microlitter Components (<100 µm) in the Invasive Blue Crab *Callinectes sapidus* from a Mediterranean Lagoon

Beatrice Rosso[1]*, Matteo Zucchetta*[1]*, Luisa Patrolecco*[1]*, Francesca Spataro*[1]*, Piero Franzoi*[2]*, Carlo Barbante*[3]*, Andrea Gambaro*[3] *and Fabiana Corami*[1]*, (1)CNR ISP, Italy, (2)Ca Foscari University Venice Italy, Italy, (3)Ca Foscari University of Venice, Italy*

Small microplastics (SMPs <100 ?m) can be ingested by organisms at the lower layers of the trophic web, leading to bioaccumulation and biomagnification in the higher trophic levels, with potential health risks associated with seafood consumption and the seafood industry. Additionally, the presence of MLCs (micro-litter components such as plastic additives, artificial fibers, and other micro-components), can further increase the potential threat to organisms, including humans. Invasive species, like the fast-growing blue crabs (*Callinectes sapidus*), originally from the western Atlantic coasts and now found in coastal environments like lagoons, may be particularly prone to ingest SMPs and MLCs, due to their predatory feeding habits and benthic lifestyle in transitional environments. Blue crabs (*Callinectes sapidus*) were collected from various sites in the Venice Lagoon in August 2024 as part of the PNRR spoke 1 Biodiversity project. The samples were dissected in a Clean Room (ISO7) and subjected to pseudodigestion process involving optimized mild pre-treatment, purification, and filtration procedures based on a previously established method A rigorous Quality Assurance and Quality Control (QA/QC)) protocol was followed throughout. Filters were analyzed using Micro-FTIR, enabling both quantification and identification of SMPs and MLCs. The specific methodologies employed for these samples proved crucial for targeting these emerging pollutants and providing reliable, replicable data. These preliminary findings will contribute to the limited knowledge of SMPs and MLCs ingestions by invasive species and shed light on potential health risks associated with their consumption, with implication for seafood and production.

3.17.P-Th256 Microplastic and Phthalate-Screening in Wild *Mytilus galloprovincialis*

Ilaria Savino[1]*, Beatrice Rosso*[2]*, Khaled Fouad Elrawy Abdelrahman*[3]*, Jose Paulo Da Silva*[3]*, Giuseppe Corriero*[4]*, Vito Felice Uricchio*[5] *and* ***Fabiana Corami***[2]*, (1)Water Research Institute, Italian National Research Council, Italy, (2)Institute of Polar Sciences, CNR-ISP, Ca Foscari University of Venice, Italy, (3)Centre of Marine Sciences (CCMAR/CIMAR LA), University of Algarve, Portugal, (4)Department of Biosciences, Biotechnologies and Environment, University of Bari Aldo Moro, Italy, (5)Construction Technologies Insitute, Italian National Research Council, CNR-ITC, Italy*

Additives associated with microplastics pose a double threat to the environment and aquatic organisms' health. Many of these compounds, such as phthalates, are classified among the most hazardous contaminants. These additives can be readily released into the environment, due to their lack of covalent bonds with synthetic polymers, potentially causing toxic effects, including immunotoxicity, neurotoxicity, and oxidative stress in exposed organisms. *Mytilus galloprovincialis* emerges from research as a potential bioindicator of microplastic pollution, playing a key role in monitoring the health of the marine ecosystem and the implications for human health. In this context, this study aims to detect microplastics and phthalates in the soft tissues of wild *Mytilus galloprovincialis*, evaluating a potential correlation between contaminants and the use of bivalve species to monitor microplastic and additive pollution. Several analytical methods were applied. On the one hand, the pre-treatment method was based on pseudo-digestion at temperatures below 40°C thus avoiding polymer degradation, which could lead to an underestimation of particle abundance. This methodological approach enabled the characterisation of microplastics with a high yield by micro-Fourier Transform Infrared Spectroscopy. On the other hand, the screening of phthalates was performed by Liquid Chromatography/High-Resolution Mass Spectrometry. Polyamide was the most widely detected polymer with a prevalence of ellipsoidal shape and an average length of 50.95 ?m and width of 22.01 ?m. The phthalate analysis detected Diisobutyl phthalate (DIBP) in all samples. The applied methodology allowed the identification and quantification of microplastics and phthalates in mussel tissues, providing indication on their possible sources and environmental fate, and predicting the potential risks of transporting these contaminants throughout the food chain. Furthermore, *M. galloprovincialis* has great potential for monitoring microplastic pollution and exposure levels of organisms, allowing for the prediction of adverse effects on biodiversity and ecological stability associated with the presence of microplastics and additives in the marine environment.

3.17.P-Th257 Plastic Leachates Stimulate Feeding Responses in Sea Anemones

Zoie Taylor Diana[1]*, Sophia McGee*[2]*, Chingakham Chinglenthoiba*[3]*, Suresh Valiyaveettil*[4]*, Jan Tebben*[5]*, Tilmann Harder*[5] *and Daniel Rittschof*[2]*, (1)Duke University Marine Laboratory, Nicholas School of the Environment, Duke University, Canada, (2)Duke University Marine Laboratory, Nicholas School of the Environment, Duke University, United States, (3)Centre for Research Impact and Outcome, Chitkara University, India, (4)Department of Chemistry, 3-Science Drive, National University of Singapore, Singapore, (5)Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Section Ecological Chemistry, Germany*

Plastic pollution is accumulating in the marine environment and being consumed by marine animals. Marine animals are hypothesized to consume plastic in part due to the chemosensory cues emitted by plastic. We leached plastic (pre-production pellets and knives) in high-performance liquid chromatography (HPLC) water for 24 hours. Sea anemones (*Exaiptasia pallida*) were fed pre-combusted glass fiber filters with 7.5 µL of leachate and HPLC grade water (controls), and the time from ingestion to egestion was measured. Anemones fed filters with plastic leachates had feeding retention times 3.5 to over 4-fold longer than controls. Subsequent feeding of the same filters to new anemones resulted in decreased feeding retention times. We characterized the polymer of the knives and pre-production pellets used in the leachate with Fourier transform infrared spectroscopy and determined both were polystyrene. We used liquid chromatography-mass spectrometry to determine leachate chemistry but the concentrations of chemical compounds fell below detection levels despite concentrating the leachate 25-fold. This study provides evidence that molecules leaching from polystyrene pre-production pellets and knives contain feeding stimulants for sea anemones. Reducing the amount of plastic entering the ocean and limiting or altering flavors that leach from plastics may reduce plastic consumption by marine animals.

3.17.P-Th258 Polycyclic Aromatic Hydrocarbons Levels in Corals Exposed to an Oil Spill Simulation: Physiological and Ecological Implications

Fung Chi Ko[1]*, Jing-O Cheng*[2]*, Yu-Han Cheng*[3] *and Chun-Wen Chang*[4]*, (1)National Museum of Marine Biology and Aquarium, Taiwan (Greater China), (2)National Musuem of Marine Biology and Aquarium, Taiwan (Greater China), (3)Institute of Marine Biology, National Dong Hwa University, Taiwan (Greater China), (4)General Research Service Center, National Pingtung University of Science and Technology, Taiwan (Greater China)*

To investigate the effects of oil pollution on coral health, a 72-hour exposure experiment was conducted utilizing the stony coral *Euphyllia paraancora*. The corals were exposed to varying concentrations of motor oil: 10 g/L and 1 g/L. The study focused on assessing the bioaccumulation of polycyclic aromatic hydrocarbons (PAHs) in the corals and its impact on lipid content, density and chlorophyll levels of symbiotic algae (zooxanthellae). The results revealed a significant accumulation of PAHs in corals exposed to the higher oil concentration (10 g/L). Although coral lipid content remained largely unaffected by oil exposure, both the density and chlorophyll content of symbiotic algae showed significant declines under higher pollution conditions compared to the lower pollution group. These findings suggest that oil pollution may disrupt the symbiotic relationship between corals and the zooxanthellae, which could threaten coral survival and reef health.

Disclaimer/Disclosure: This study is gratefully supported by the National Science and Technology Council (NSTC) of Taiwan, under project numbers NSTC 112-2611-M21-005 and NSTC 113-2611-M-020-002.

3.17.P-Th259 Examining Export and Bioaccumulation of Methyl Mercury in a Wetland Impacted by Avian Guano and Water Table Restoration

Nelson J. O'Driscoll[1]*, Holly Turner*[2]*,* ***Gretchen Marie McPhail***[2]*, Mark Mallory*[3]*, Nick Hill*[4] *and Kirk Hillier*[2]*, (1)Acadia University,Canada, (2)Acadia University, Canada, (3)Department of Biology, Acadia University, Canada, (4)Southwest Nova Biosphere Reserve Association, Canada*

Big Meadow Bog (Brier Island, NS) underwent water table restoration in 2018 that returned the bog to its original water levels prior to ditching. The Northern bog hosts a cluster of 4000-6000 herring gulls that

feed at nearby mink farming and aquaculture sites. Previous research in our group has shown that bird biomass and waste products are increasing the trace metals and nutrients measured in groundwater. Analyses have shown that gull guano is very high in water soluble PO43- but low in total mercury (THg) and methylmercury (MeHg). Research from various studies examining terrestrial freshwater catchment flooding indicates that MeHg increases over a multi-year time span. An examination of water quality and lower trophic level biota was initiated to set a baseline for MeHg concentrations in the base of the food web. Water from the primary surface outflow was collected over five years (2018-2023) and invertebrate samples were collected over three summers (2021, 2022, and 2023). Mean concentrations of MeHg, DOC, PO43-, and NO3- in water were significantly higher in the first-year post-flooding and decreased through subsequent years. MeHg, DOC, and NO3- concentrations were all strongly correlated and significantly higher in the summer months than the winter months. MeHg concentrations in water were correlated with those in resident Gammaridae (benthic invertebrate) tissues, suggesting that this environment is conducive to MeHg bioaccumulation in gammarids. Recent installation of hydrological weirs to track surface outflow volumes show hypereutrophic concentrations of nutrients and elevated MeHg at the weir nearest the gull colony. Mercury dynamics in this local system are complicated by biovector introduction of various elements as well as past and recent anthropogenic activities, but serve as a case study for coastal wetland habitats situated near various types of industries.

Disclaimer/Disclosure: This research was supported by the Nova Scotia Habitat Conservation Fund and NSERC.

3.17.P-Th260 Methylmercury Concentrations of Freshwater and Coastal Invertebrates from the Jijuktu'kwejk Estuary, Nova Scotia, Canada

Gretchen Marie McPhail[1]*, Mark Mallory*[2]*, Ian Spooner*[1] *and Nelson J. O'Driscoll*[1]*, (1)Department of Earth and Environmental Science, Acadia University, Canada, (2)Department of Biology, Acadia University, Canada*

Methylmercury (MeHg) is a toxic contaminant that bioaccumulates and biomagnifies in food webs; however, differences in mercury (Hg) retention and bioaccumulation between freshwater and coastal environments are not well understood. Inland rivers and estuaries transfer Hg and MeHg from anthropogenic terrestrial sources to coastal environments where MeHg accumulates in sediments and food webs. Identifying sediments and organisms with high Hg accumulation within an ecosystem is critical to the assessment of MeHg biomagnification in sensitive areas. This study examines the Jijuktu'kwejk estuary, Nova Scotia, Canada. Invertebrates, porewater, and sediment samples were collected from freshwater, estuarine, and coastal sites to assess environmental contamination. A total of 37 invertebrate families were collected. Apart from two families, estuarine invertebrates were of coastal origin. Mean MeHg concentrations in both coastal and estuarine invertebrates (13.2 ± 11.7 ng/g dry weight (dw) and 12.3 ± 11.4 ng/g dw, respectively) were ~10 times below the Canadian guideline for the protection of wildlife consumers (174.3 ng/g dw for 81% moisture). The mean MeHg concentration for freshwater invertebrates (125.2 ± 116.9 ng/g dw) was much higher, with two groups, water striders (Gerridae spp.) and a freshwater mussel, above the guideline (213.1 ± 223.0 ng/g dw and 191.8 ng/g dw, respectively). Several other freshwater invertebrate groups had mean MeHg concentrations near the guideline, including fishing spiders (*Dolomedes* spp.) (168.4 ng/g dw), water boatman (Corixidae) (153.9 ± 27.8 ng/g dw), and damselflies (Zygoptera) (150.5 ng/g dw). Mean MeHg concentrations for coastal and estuarine invertebrates did not exceed 40 ng/g dw, though species with the highest concentrations for these locations were bamboo worms (Maldanidae) (37.43 ng/g dw), eastern mudsnails (*Ilyanassa obsoleta*) (29.86 ± 16.45 ng/g dw), and European green crabs (*Carcinus maenas*) (28.09 ± 2.20 ng/g dw). These values in combination with stable isotopes of ?13C and ?15N will allow us to compare MeHg bioaccumulation slopes for invertebrates between freshwater, estuarine, and coastal environments. Though further analyses for porewater and sediment Hg concentrations are needed, these initial results suggest that MeHg accumulation in low-trophic freshwater food webs is significant compared to that of estuarine and coastal environments within the Jijuktu 'kwejk estuary.

3.17.P-Th261 Progressing Short-Term Methods to Estimate Chronic Marine Toxicity for Regulatory Use in the North-East Atlantic Region

Kirit Wadhia[1] *and Mathijs Smit*[2]*, (1)NOV, United Kingdom, (2)Shell Global Solutions International BV, Netherlands*

Introduction
Within the North-East Atlantic region, reliable risk- and hazard-assessments are crucial for the management and permitting of offshore chemicals, produced water and other wastewater discharges. Assessments mostly rely on regulatory required acute Whole Effluent Toxicity (WET) and chemical toxicity tests, performed with a limited number of species, potentially leading to overly precautionary risk estimates due to the application of conservative assessment factors
Chronic toxicity data potentially reduce this uncertainty, but application of such data in regulatory context is limited, e.g. not regulatory required, practical limitations, availability and associated costs.
Risk-based approaches increase demand for chronic marine toxicity data to reliably assess chemicals and wastewater discharges both offshore and from land-based sites to coastal environments. There is a need to further develop and deploy short-term tests to assess chronic marine toxicity for regulatory use for both WET and chemical testing.
Objective
Identify suitable methods for estimating chronic marine toxicity based on existing protocols and global practices that would be applicable to the management of both offshore and coastal chemical use and discharges.
Deliverables
A set of well validated protocols that estimate chronic toxicity, selected based on their availability, regulatory acceptability and efficiency in terms of costs and executability.
Implementation Plan
- Review and analysis of existing protocols
- Protocol selection and testing plan design
- Pilot testing
- Dissemination

3.17.P-Th262 Occurrence of OPEs and PFAS in Surface Sediments from the French Atlantic Coast and Loire Estuary
***Javier Castro-Jimenez**[1], Emma Junca[1], Putu Yolanda Yulikayani[2], Nadege Bely[1], Charles Pollono[1] and Anne Grouhel-Pellouin[1], (1)IFREMER, Chemical Contamination of Marine Ecosystems (CCEM), France, (2)ILVO, Belgium*
Organophosphate esters (OPEs) flame retardants and plasticizers and per- and polyfluoroalkyl substances (PFAS) are among the most widely distributed contaminants of emerging concern (CECs) in the marine environment. Both CECs reach marine coastal areas at high rates due to their non-stop emissions. There is high global concern due to their hazardous properties. While no regulations are in place or planned to limit production and emissions of most OPEs, a global restriction process has just been launched at European level by the European Chemicals Agency (ECHA). However, the occurrence of these CECs in marine sediments, considered global sinks of many organic contaminants, are still little studied compared to other environmental compartments. In this work we investigated the occurrence of parent OPEs (tri-OPEs), their major degradation metabolites (di-OPEs), and PFAS in various sampling locations along the French Atlantic coast (Gulf of Biscay), including the Loire estuary. The selected sites are under the influence of different anthropogenic pressures. Sediments were collected in intertidal areas from the Loire estuary in February 2022 and along the coast on board of the R/V Thalia (IFREMER) in May 2022 (campaign ROCCHSED2022, DOI: 10.17600/18002069.) One gram of dry material was extracted by sonication (OPEs) and microwave (PFAS). The extracts were cleaned up by solid phase extraction and quantified by isotopic dilution LC-ESI-MS/MS. PFAS were detected in all samples, with values varying from 0.03 to 0.6 ng g-1 dw (?PFAS) in sites along the coast. Tri-OPEs were detected in 93% of samples and exhibited one order of magnitude higher concentrations than PFAS, with levels ranging from 0.2 to 2.8 ng g-1 dw (?tri-OPEs) in costal sites. Di-OPEs showed lower detection frequency (73%) and concentrations. Higher levels of both PFAS and OPEs were found in sites from the Loire estuary under harbour and/or industrial activities. Our results show the overall occurrence of both families of CECs pointing to industrial areas inside the estuary as relevant sources. Tris(chloro-2-propyl) phosphate (TCIPP), tris(2-ethylhexyl) phosphate (TEHP), and perfluorooctane sulfonic acid (PFOS) were among the most abundant CECs found in the study area. The influence of the sediment total organic carbon and granulometry on their spatial distribution in the study area is under evaluation.

3.17.P-Th263 Fate and Behaviour of Contaminants in Estuarine Systems: An Example from Southampton Water, UK
***Jana-Sophie Appelt**[1], Andrew Cundy[2], Sargent Bray[2] and Jessica Whiteside[3], (1)University of Southampton, Southampton, United Kingdom, (2)Ocean and Earth Science, University of Southampton, United Kingdom, (3)San Diego State University, United States*

Estuaries are important, often heavily urbanized ecosystems, acting as sinks for contaminants and moderating their input into marine environments. Many of these contaminants, including legacy contaminants and contaminants of emerging concern (CECs), pose significant ecological risks. The heterogenous composition of estuarine sediments and the variety of contaminant groups make predicting their fate and behaviour in estuaries challenging, especially under changing environmental conditions. This study examines the role of estuarine sediments in contaminant adsorption processes by assessing CECs and conventional contaminants in an estuary and conducting controlled batch adsorption experiments.
Surface sediment samples and a sediment core were taken from Southampton Water, a large estuary in southern England. The spatial and temporal distribution of trace metals, polycyclic aromatic hydrocarbons (PAHs), and hormones were assessed using x-ray fluorescence analysis and targeted gas chromatography mass spectrometry (GC-MS). In addition, non-targeted analysis was conducted with a two-dimensional GC-MS. Sediment properties including total organic carbon and stable isotopes (d13C, d15N) were measured. Furthermore, the adsorption patterns of hormones on different types of estuarine organic matter at varying salinities are investigated.
Results of the estuarine samples show increasing contaminant concentrations close to point sources such as the port (e.g. Hg up to 2.4 mg/kg, PAHs up to 5600 ng/g). The dated sediment core documents historical waste discharges into the estuary over the past 60+ years. Core profiles from trace metals (e.g. Cu, Ba, Pb) show distinct discharge events, whereas organic contaminants (e.g. PAHs, Bisphenol A, phthalates) are present throughout the depth of the core, indicating their persistence and potential mobility. Hormones such as estrone were detected at concentrations between 1.8 13.2 ng/g in surface samples, but no trends or correlations with sediment properties were observed. Batch adsorption experiments are ongoing to give a more detailed insight into the adsorption behaviour of hormones onto different types of estuarine organic carbon under changing salinities.
This work will help to better understand hormone adsorption mechanisms under changing environmental conditions and contribute to a more comprehensive understanding of contaminant dynamics in estuarine systems which is crucial for effective risk assessment and management.

3.17.P-Th264 Prioritisation of CECs in the Marine Environment Using Hazard-Based Filtering and Ranking Approaches
Putu Yolanda Yulikayani[1]*, Bavo De Witte*[1]*, Aasim Ali*[2]*, Jonathan Barber*[3]*, Juan Bellas*[4]*, Nicolas Briant*[5]*, Steven Brooks*[6]*, Are Saele Bruvold*[2]*, Megan Anne French*[7]*, Ketil Hylland*[2]*, Helen Kaberi*[8]*, Victor M. Leon*[9]*, Samantha Eslava Martins*[10]*, Aourell Mauffret*[5]*, Francesca Molinari*[11]*, Malcolm Reid*[6]*, Joachim Sturve*[11]*, Stig Valdersnes*[2] *and Aina Charlotte Wennberg*[6]*, (1)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Belgium, (2)Institute of Marine Research (IMR), Norway, (3)Centre for Environment, Fisheries and Aquaculture Science (Cefas), United Kingdom, (4) Instituto Español de Oceanografía (IEO), CSIC, Spain, (5)French National Institute for Ocean Science and Technology (IFREMER), France, (6)Norwegian Institute for Water Research (NIVA), Norway, (7)National Institute of Oceanography and Applied Geophysics (OGS), Italy, (8)Hellenic Centre for Marine Research, Insititute of Oceanography (HCMR), Greece, (9) Instituto Español de Oceanografía (IEO), CSIC, Spain, (10)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (11)University of Gothenburg, Sweden*
The increase in the use and production of chemicals has led to a growing number of contaminants of emerging concern (CECs) in the marine environment. A prioritisation strategy is necessary to study the environmental occurrence and effects of the most impactful chemicals in the marine ecosystem, guiding decisions on which compounds should be included in routine monitoring. To address the lack of marine-specific prioritisation schemes, a hazard-based prioritisation tool was developed for CECs within the European Union (EU) project An Integrated Approach for Assessing Impacts on the Marine Environment (CONTRAST). A comprehensive literature review identified the most frequently used criteria for prioritising CECs. Subsequently, the outcomes of an internal survey among project partners on the most important criteria to be included in the prioritisation scheme were used as a basis. CECs were filtered using three parallel schemes: persistence and bioaccumulation (PB), toxicity (T), and persistence and mobility (PM) using cut-off values adapted from the EU regulatory framework for PBT and PMT assessments. The filtering of chemicals was aided by a tool developed in the PikMe project, which was funded by the Norwegian Environment Agency. The PikMe tool contains a database regarding physical, chemical, and PBT properties, tonnage, and EU regulations of approximately 1.1 million chemical substances gathered from different data sources. The filtered chemicals were assessed further and scored based on their modes of action, occurrence in the marine and freshwater environments, and emission. A ranking based on the final score resulted in a list of around 8500 chemicals with high diversity regarding their functional use (e.g., pharmaceuticals, flame retardants, plasticisers, personal care products, and

biocides). The top 100 contains the compounds that will be selected for use within CONTRAST for the distribution, fate, and effects studies, determining their impacts on the marine biodiversity and providing an effective integrated monitoring framework to monitor their impacts on marine life.

3.17.P-Th265 A Paleolimnological Assessment of Environmental Degradation and Legacy Pollutants in a Back-Barrier Lagoon at Pictou Landing, Nova Scotia, Canada

***Ian Spooner**[1], Kirklyn Davidson[2], Baillie Holmes[3] and Dylan Wyles[4], (1)Earth and Environment, Acadia University, Canada, (2)SCG Industries, Canada, (3)Acadia University, Canada, (4)WSP Inc., Canada*

Sitmu'k is a marine lagoon located in an Indigenous community in Nova Scotia, Canada. Boat Harbour is a former estuary located 2 km from Sitmu'k that was converted to a pulp mill and chlor-alkali plant effluent impoundment in 1970. Boat Harbour contains > 577,000 m3 of contaminated sediment including metal(loid)s and a variety of persistent organic pollutants. A limnological assessment of Sitmu'k indicated significant water quality degradation, which residents suspected was associated with Boat Harbour effluent. A paleolimnological assessment was undertaken to provide a spatiotemporal perspective on legacy pollutants. Sediment gravity cores were collected from Sitmu'k and Boat Harbour and the estuary at the outlet of Boat Harbour, two nearby estuaries and a freshwater pond served as reference sites. Sediments were characterised using X-ray fluorescence (XRF); total Carbon (C), total Nitrogen (N) and stable carbon (?13C) and nitrogen (?15N) isotopes.

Boat Harbour effluent contains elevated Cu, Zn, Pb that increase up-core and exceed marine sediment guidelines, top-bottom core analyses indicated elevated geogenic As, also present at other sites in the study. Most Cu, Zn and Pb bioaccumulated in the pulp feedstock. Cores obtained at the outlet of Boat Harbour also contained elevated metals that decline seaward. All sites in this study contained elevated Pb, a legacy atmospheric pollutant from regional coal fired power generation and steel production. Total C, N and stable isotope values for the effluent reflect a terrestrial carbon source. In contrast, isotope analyses at Sitmu'k and reference estuaries indicated marine carbon sources and metal concentrations that decrease up-core and do not exceed guidelines. Elevated ?15N in Sitmu'k sediments compared to all other sites is likely associated with residential development and effluent from local water treatment. Landward migration of the barrier-beach complex and reduction in water depth and circulation likely contribute to water quality degradation. Collectively the paleolimnological data indicate that the pulp mill and chlor-alkali plant effluent is not impacting Sitmu'k. This study demonstrates that the paleolimnological approach coupled with the use of reference sites can provide clarity on the impact of a variety of legacy pollutant sources in dynamic marine environments.

3.18 Chemical Emissions and Associated Environmental Impacts from Offshore Energy Production

3.18.T-01 Chemical Emissions from Offshore Wind Farms: Compound Identification and Prioritisation for Risk Assessment

***Genevieve Deviller**[1], Pablo Zapata-Corella[2], Elena Hengstmann[3], Lisbet Sorensen[4], Javier Castro-Jimenez[2], Andy Booth[4], David Vanavermaete[5], Torben Kirchgeorg[3] and Bavo De Witte[5], (1)DERAC, France, (2)IFREMER, Chemical Contamination of Marine Ecosystems (CCEM), France, (3)BSH, Germany, (4)SINTEF, Norway, (5)ILVO, Belgium*

Offshore wind farms (OWFs) are a source of chemical emissions to the marine environment. A wide variety of compounds can enter the marine environment, from inorganics to dissolved organic chemicals and even plastic polymer particles. Before characterising the extent, distribution and impact of non-particulate emissions, it is essential to identify the individual compounds that can be emitted and to prioritise those compounds that might exert the largest negative impacts to the marine ecosystem and humans consuming marine products. Here, we provide a comprehensive overview of potential chemical emissions from OWFs, using a combination of literature data and non-target screening (NTS) by GCxGC-HRMS of paint leachates. This resulted in a long list of >400 individual chemicals representing a wide variety of compound groups including metals, alkylphenols, bisphenols, diisocyanates, alkyl and aromatic amines, diamines, benzotriazoles, organophosphate esters and BTEX compounds. Additional data was gathered, including information on the properties of concern at regulatory level (e.g. priority listing, classification) and the frequency of the release (intermittent vs continuous) to set a list of 51 candidate priority compounds. A second prioritisation step based on persistence, bioaccumulation, toxicity (PBT) and endocrine disrupting (ED) properties on humans and aquatic organisms was performed on the candidate list; leading to a categorization into (1) officially recognised PBT and/or ED substances, (2) potential PBT/ED substances or equal level of concern, (3) not PBT/ED but medium level of concern

substances and (4) not PBT/ED and low level of concern substances.
The combined literature overview and GCxGC-HRMS NTS offers valuable insights into the potential chemical emissions from OWFs. However, it is only a first step to identify the substances of potential concern. The prioritisation exercise based on the PBT and ED properties of the substances allows us to focus on substances that require a full risk assessment of OWF chemical emissions. Although the properties of these compounds are sometimes well-defined, we have already identified the need for additional data on bioaccumulation in aquaculture products and on ecotoxicity. Determination of environmental concentrations at OWFs will be necessary to complete the risk assessment of chemical emissions on the marine ecosystem.

Disclaimer/Disclosure: This study was performed as part of the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union.

3.18.T-02 Untargeted Screening of Marine Sediments in Offshore Wind Farms: Tracking Chemical Emissions

David Vanavermaete[1]*, Pablo Zapata-Corella*[2]*, Karien De Cauwer*[3]*, Javier Castro-Jimenez*[2]*, Elena Hengstmann*[4]*, Koen Parmentier*[3]*, Christof Van Poucke*[1]*, Putu Yolanda Yulikayani*[1] *and Bavo De Witte*[1]*, (1)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO-Marine), Animal Sciences Unit - Aquatic Environment and Quality, Belgium, (2)IFREMER, Chemical Contamination of Marine Ecosystems (CCEM), France, (3)Royal Belgian Institute of Natural Sciences, Operational Directorate Natural Environment, Belgium, (4)Federal Maritime and Hydrographic Agency (BSH), Marine Sciences Department, Germany*

Offshore wind farms (OWFs) play a crucial role in reducing carbon emissions and the dependency on fossil fuels. The biological effects of OWFs on the marine ecosystem have systematically been monitored. However, chemical emissions have often been overlooked. As it is expected that current OWFs will further be expanded to comply with European energy and climate goals, it is paramount to understand and characterize the potential chemical emissions of these OWFs. This is not an easy task, as many activities are taking place in a limited area at sea, rendering it difficult to identify the specific emission sources. Sediment samples were taken in and near four OWFs within the Belgian and German parts of the North Sea to identify potential emissions. Three types of reference locations were considered: offshore reference samples in an area where low human impact is expected, aiming to capture background concentrations; ship reference samples, taken offshore near a shipping lane, aiming to correct for effects of ship traffic; and near-shore references, where a larger impact of multiple human activities taking place within 12 nautical miles of the shoreline can be expected. Sample extracts were analyzed on a Vanquish Orbitrap Exploris 120 LC-HRMS(/MS) and on a GC-triple quadrupole MS, allowing for the detection of a wide variety of compounds and covering both the polar and non-polar chemicals. More than 150 compounds were detected by GC-MS. Most of these compounds were present in both impact and reference samples. To identify compounds that might be leaching from OWFs, the relative intensity was calculated between impact and reference samples, and peaks with an intensity of at least five times the measured intensity at all three reference locations were withheld. Besides using the relative peak intensities, machine learning was also applied to identify potential peaks. A random forest model, for example, allows the identification of peaks that are associated with impact, nearby, or reference areas. After building a random forest model, the most important compounds that contributed to the impact or nearby areas were also selected. For the Belgian part of the North Sea, this consisted of more than 30 potential compounds (for the GC-MS method). Further identification with MS libraries allowed us to identify, to the greatest extent possible, these compounds and characterize, for the first time, the potential chemical emission of OWFs.

Disclaimer/Disclosure: The authors acknowledge the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union.

3.18.T-03 Offshore Chemical Emissions (OffChEm): Six Years of Environmental Research In and Around Offshore Wind Farms in the German North Sea

Dominik Wippermann[1]*, Anna Ebeling*[1]*, Tristan Zimmermann*[1]*, Ole Klein*[2]*, Torben Kirchgeorg*[3]*, Ingo Weinberg*[3]*, Simone Hasenbein*[3]*, Anna Plass*[3] *and Daniel Profrock*[1]*, (1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Helmholtz-Zentrum Hereon, Germany, (3)Federal Maritime and Hydrographic Agency (BSH), Germany*

Offshore wind farms (OWFs) are pivotal for fulfilling the EU's goal to a sustainable energy transition and achieving climate neutrality by the year 2050. Different corrosion protection systems are commonly applied, including galvanic anodes, which dissolve over time and could therefore be a relevant source of metal emissions to the marine environment related with OWFs. Tracer elements for OWF-induced emissions from galvanic anodes consisting of six elements: Al and Zn as main components, the technology-critical elements (TCEs) In and Ga and as ecotoxicologically relevant legacy pollutants: Cd and Pb, have been previously published.
Sediment and water samples were taken over six years in the German North Sea. Sediments were processed by microwave assisted acid digestion following the protocol of Zimmermann et al. and subsequent multi-element analysis by an inductively coupled plasma tandem mass spectrometer (ICP-MS/MS) (Agilent 8800, Agilent Technologies, Tokyo, Japan).
Water samples were pressure filtrated and acidified with double sub-boiled nitric acid. An online preconcentration and matrix removal system was coupled online to an ICP-MS/MS system (Agilent 8900, Agilent Technologies, Tokyo, Japan) for quantification of the water samples.
The data show that mass fractions of the selected tracer elements in sediment are currently predominantly within the range of the known variability in the study areas. Locally elevated mass fractions were found occasionally in the sediment, especially for Pb and Cd. Based on the Ga and In elemental mass fraction data and the prevailing dilution and distribution processes, there are currently no direct effects discernible due to the use of galvanic anodes.
Elevated In concentrations were found in this study, while Ga concentrations were found to be within the known variability. The combination of In concentrations measurements, Gd anomaly calculations and drift trajectory modeling of water masses showed a high potential for an in-depth source assignment. The release of In caused by the dissolution of galvanic anodes seems to be associated to OWFs corrosion protection for at least one area within two different years.
Overall, the data do not prove direct impact of OWF emissions on elemental mass fractions, but galvanic anodes are per se a continuous source of metal emissions and thus are a new source of pollution within the marine environment.

3.18.T-04 Anticipate the Environmental Impact of Brine from the Desalination Process for Offshore Green Hydrogen Production on the Fish Model, *Scophthalmus maximus*

Tiphaine Labed-Veydert[1]*, Karine Pichavant-Rafini*[2]*, Michael Theron*[2]*, Marie Robert*[1] *and Matthieu Dussauze*[1]*, (1)France Energies Marines, France, (2)Laboratoire ORPHY EA4324, Universite de Bretagne Occidentale, France*
In the pursuit of enhancing energy production from Offshore Renewable Energies (ORE), the production of hydrogen (H2) integrated within the large-scale deployment of Offshore Wind Farms (OWF) appears to be a promising green energy vector. At sea, producing H2 through freshwater electrolysis necessitates seawater desalination, which results in chronic brine discharge. This brine, consisting of hypersaline, warm water for the thermal desalination process, contains chemical residues, such as phosphonates and chlorination by-products. Discharging this brine into the marine environment induces local physicochemical changes, exposing marine organisms to osmotic, thermal, and chemical stress. In the context of the environmental integration of OREs, the environmental impact of chronic brine discharge into the offshore ecosystem is, to date, inadequately documented to anticipate potential environmental effects. The R&D project OPHARM2 aims to conduct an environmental impact assessment of the offshore H2 production through a synergistic and transdisciplinary approach with three objectives: (1) evaluating acute toxicity across multiple trophic levels; (2) investigating the intrinsic and chronic toxicity of brine through cellular and sublethal approaches on a fish model; (3) mapping exposure gradient to brine discharge within OWFs using multi-scale hydrodynamic modeling.
This study presents preliminary acute toxicity results on the benthic model fish species, *Scophthalmus maximus*. These results allow us, on the one hand, to estimate the impact of salt stress through the LC10 of exposure to brine at different temperatures (18°C to 30°C) and, on the other hand, to identify the ecotoxicological specificities of each brine constituent (salt and chemicals) via a cellular approach on two key organs (gill and liver). This comprehensive and ecotoxicological approach offers the first data and insights

on the offshore toxicity of brine, enhancing the knowledge of the potential environmental impact of offshore green H2 production.

3.18.P-Mo259 Ecological Impacts of Wind Turbine Blade Erosion on Blue Mussels (*Mytilus edulis*)

***Daria Bedulina*[1]*, Spela Korez Lupse*[1]*, Lars Michael Hildebrandt*[2]*, Yaqing Duan*[3]*, Ole Klein*[2]*, Sebastian Primpke*[3]*, Christian Bock*[1]*, Stefan Krause*[4]*, Steffen Czichon*[4]*, Daniel Profrock*[2]*, Gunnar Gerdts*[3] *and Gisela Lannig*[1]*, (1)Department of Integrative Ecophysiology, Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany, (2)Department for Inorganic Environmental Chemistry, Institute of Coastal Environmental Chemistry, Helmholtz Centre Hereon, Germany, (3)Department of Shelf Sea System Ecology, Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany, (4)Department Rotor Blades, Fraunhofer Institute for Wind Energy Systems, Germany*

Offshore wind farms (OWFs) introduce novel anthropogenic pressures to marine ecosystems, including the release of organic and inorganic particles from turbine blade erosion, which may impact marine life. This study investigated the potential effects of these particles and their additives on the metabolic profile of the blue mussel (*Mytilus edulis*) using 1H-NMR spectroscopy. Mussels were exposed in the laboratory to microplastic (MP) particles derived from cryo-milled rotor blade coatings and core materials (glass fiber polymer, GFP) under a simulated worst-case scenario of extensive blade erosion. Enrichment factors (EFs) for metals and metalloids (e.g., Ba, Cu, Cd, Cr, Ni) ranged from 0.93 to 6.1, indicating a potential chemical load from the rotor blade materials. Untargeted metabolic profiling of mussel tissues revealed no significant disruptions to metabolic pathways, however trends in metabolite levels suggested potential short-term effects on neuroendocrine systems and possible long-term impacts on energy metabolism. Further research is essential to comprehensively evaluate the potential impacts of OWF erosion on marine environments, particularly in light of the planned expansion of wind farm construction as part of the EU-wide energy transition.

3.18.P-Mo260 Analysis of Coating Particles from Offshore Wind Farms in Sediment Samples

***Elena Hengstmann*[1]*, Marten Fischer*[1]*, Torben Kirchgeorg*[1]*, Karien De Cauwer*[2] *and Coline De Schrijver*[2]*, (1)Federal Maritime and Hydrographic Agency (BSH), Germany, (2)Royal Belgian Institute of Natural Sciences, Belgium*

Offshore energy production has risen sharply in the last decades. Consequently, the number of offshore wind farms (OWFs) is growing and chemicals may be released by the construction and operation of these structures. However, resulting impacts on the marine environment are still largely unknown. Within the EU Interreg project Anemoi, chemical emissions from OWFs and their effects are investigated. One source of emission is the particulate release of corrosion protection coatings and paints, as well as leading edge erosion of rotor blades leading to an introduction of microplastic particles into the marine environment.

Currently, only a small number of studies have investigated these paint and coating particles in marine samples. One reason for this is methodical challenges to analyse these particles in environmental samples and therefore, missing adapted protocols.

We tested different methodical approaches for separating paint and coating particles from OWFs from the sample matrix. On the one hand, different digestion protocols were compared. On the other hand, the density separation to separate the particles of interest from the sediment was adapted and improved. To do so, sediment (sandy or silty) was spiked with coating particles derived from six coatings commonly used on offshore wind turbines (four epoxy-based and two polyurethane-based) from two manufacturers. Two salt solutions with different densities were used and recovery rates calculated. Furthermore, procedures for the identification of particles by FTIR (ATR and FPA) and Pyrolysis GC/MS were optimized for the analysis of paint and coating particles and both approaches were compared. Finally, environmental samples from the North Sea were analysed using the developed protocol.

Tests showed that digestion chemicals have to be chosen with caution not to cause any harm to the paint and coating particles. With respect to the density separation, the solution with higher density resulted in higher recovery rates for paint and coating particles. The optimization of identification methods especially included the development of an adapted library for FTIR spectra of paint and coating particles. The adapted protocol was successfully applied to a first sample set of North Sea sediment samples.

Disclaimer/Disclosure: This study was performed as part of the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union.

3.18.P-Mo261 Settling Velocities of Particle Emissions from Offshore Wind Farms

Niklas Czerner, *Christian Windt and Nils Goseberg, TU Braunschweig, Germany*

The technology of offshore wind is undergoing a period of rapid growth, with an enormous expansion of installed capacity expected in the coming decades. To protect offshore wind turbines against corrosion, the structures are coated with organic coatings, which deteriorate over time and subsequently detach, either through corrosion or by accidental damage during operation. The environmental impact of these detaching coatings is not investigated yet. In order to address this knowledge gap, this work focuses on the investigation of the transport of coating particles through the water column by investigating the terminal settling velocity of particles manufactured from common coating materials. Particles from epoxy and polyurethane were made as single and double-layered particles with dimensions ranging from 1 to 3 cm in flat, regular shapes such as disks and squared plates. The particles were released into an acrylic glass tank in order to determine their terminal settling velocity, using both fresh and saltwater. The double-layered particles exhibited the highest settling velocity, followed by epoxy particles, and polyurethane particles, which demonstrated the lowest settling velocity. The experiments at different salinities showed that salt water as surrounding fluid led to a decrease in settling velocities. The findings of this study represent a significant initial step towards a more comprehensive understanding of the environmental transport of corrosion protection coatings and can inform the development of strategies to mitigate adverse environmental effects associated with all types of coated marine artificial structures.

Disclaimer/Disclosure: The authors gratefully acknowledge funding through the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union.

3.18.P Chemical Emissions and Associated Environmental Impacts from Offshore Energy Production

3.18.P-Mo254 Regulation of Chemical Emissions from Offshore Wind Farms: An Overview and Comparison for the North Sea Region

Elena Hengstmann[1], Matthias Hasenbein[1], Anna Plass[1], Bavo De Witte[2], David Vanavermaete[2], Dorothy J. Dankel[3], Karien De Cauwer[4], Tom Baur[5], ***Ingo Weinberg***[1] *and Torben Kirchgeorg[1], (1)Federal Maritime and Hydrographic Agency (BSH), Marine Sciences Department, Germany, (2)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO-Marine), Animal Sciences Unit - Aquatic Environment and Quality, Belgium, (3)SINTEF Ocean, Norway, (4)Royal Belgian Institute of Natural Sciences, Belgium, (5)POM West-Vlaanderen, Belgium*

Due to great environmental goals to increase the production of renewable energy and its advantages, offshore wind energy is a fast-growing sector. The current rise in construction of offshore wind farms (OWFs) in Europe makes comprehensive regulations for their construction, operation and decommissioning necessary to monitor and minimize potential effects. However, it is the task of national and/or local authorities to regulate OWFs which may result in differences between countries and missing overarching rules. In addition, some potential effects of OWFs are still largely unknown and are therefore difficult to be addressed in current regulations. For example, effects of chemical emissions from OWFs are not yet fully understood but research has already started. Effects on the marine environment of chemicals released from different parts and processes of OWFs cannot be excluded and should consequently be considered in regulatory documents to provide guidance for operators and limit possible negative environmental effects in advance.

National regulations for OWFs were reviewed and analyzed with respect to rules for chemical emissions from these structures (e.g. during approval/licensing procedures and the operational phase). The focus was on EU countries bordering the North Sea, including Norway. In a first step, national authorities and stakeholders were contacted to gather information on existing regulations in the respective country. In a second step, OWF regulations for chemical emissions were evaluated in detail and analyzed for the first positive steps and gaps in order to compare countries and identify similarities and differences.

The analysis showed that, overall, regulations for chemical emissions from OWFs are not yet fully developed even though first attempts have been made. Also, major differences were found between the countries with respect to the level of detail describing the conditions and limitations related to the use of chemical compounds and focus on the effects of OWFs to the marine environment. Our assessment reveals the need to increase the knowledge on applied techniques and effects of chemical emissions from OWFs to improve rules and accelerate the development of guidelines practicable for both environmental protection and OWF operators.

Disclaimer/Disclosure: This study was performed as part of the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union.

3.18.P-Mo255 Techniques to Avoid or Minimize Chemical Emissions from Offshore Wind Facilities

Wiebke Pape, Anna Plass, ***Ingo Weinberg*** *and Torben Kirchgeorg, Federal Maritime and Hydrographic Agency (BSH), Marine Sciences Department, Germany*

Offshore wind energy is a key element in the renewable energy sector and essential to reduce greenhouse gas emissions in Europe. The entity of Offshore Wind farms (OWFs) consists of different offshore facilities like offshore wind turbines for energy generation and offshore platforms such as substations and converters (HVDC stations) for energy collection, transformation, and subsequent energy transmission to shore by sea cables. All offshore facilities are complex technical structures, consisting of many various components and technical systems. To sustain their operability the use of operating materials and techniques is required which can lead to chemical emissions into the marine environment by accidents and in some cases also during regular operation. Impact on the marine environment can be minimised if offshore wind facilities are designed and conducted in a manner that they do not cause any avoidable emissions (precautionary principle). This approach can be achieved by using state of the art techniques. However, when it comes to emission control it is not easy to define state of the art techniques explicitly for offshore wind facilities, as only very few detailed recommendations or guidelines for OWFs are currently available but no best available techniques (BAT). However, techniques to avoid or minimize emissions from other (maritime) industrial fields (e.g. shipping, offshore oil and gas industry) may be appropriate and are already used to some extent.
Here, we present a comprehensive overview of relevant emission sources of chemicals into the marine environment by OWF and how chemical emissions can be avoided by using state of the art techniques (e.g. for cathodic corrosion protection, seawater cooling systems (biocides), sewage). This overview could be used as a first guideline for planners, windfarm operators, and administrations.

3.18.P-Mo256 Strategies for Emission Monitoring in Offshore Renewable Energy

Anna Ebeling[1]*, Dominik Wippermann*[1]*, Alexa McCormick Zonderman*[1]*, Ole Klein*[2]*, Tristan Zimmermann*[1]*, Torben Kirchgeorg*[3]*, Ingo Weinberg*[3]*, Simone Hasenbein*[3]*, Anna Plass*[3] *and Daniel Profrock*[1]*, (1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Helmholtz-Zentrum Hereon, Germany, (3)Bundesamt fur Seeschifffahrt und Hydrographie, Germany*

Offshore wind farms (OWFs) are pivotal for fulfilling the EU's goal to a sustainable energy transition and achieving climate neutrality by the year 2050, as well as the 2023 UN Climate Change Conference (COP28) agreement to triple renewable energy capacity by 2030. By 2023, a total of 75.2 GW of offshore wind capacity had been installed worldwide, with 38 GW in Chinese waters and 34 GW in European waters. Moreover, recent advancements are aiming to produce green hydrogen and secondary products such as ammonia, methanol, and synthetic fuels offshore.
The poster will showcase the developed monitoring approach for metal emissions from galvanic anodes used for corrosion protection of offshore structures: from the identification of metal tracers through analysis of these galvanic anodes to the development of analytical methods and their application to field samples. This comprehensive approach includes measurement of (tracer) metal concentrations, determination of stable metal isotope ratios, calculation of element ratios and the integration of water mass modeling to support interpretation of results. In past and current research projects, water, sediment, and biota samples from the North Sea were analyzed. Key findings from eight years of sampling will be highlighted, emphasizing trends in metal concentrations and the effectiveness of monitoring strategies. Additionally, lessons learned will be discussed to support future research and policy decisions.
This poster aims to contribute to the ongoing dialogue on sustainable offshore energy production and its environmental implications, providing valuable insights for researchers, policymakers, and industry stakeholders.

3.18.P-Mo257 Occurrence of Organophosphate Esters, Benzotriazoles, Phenols and Primary Sromatic Fiamines in Offshore Windfarm Areas from the North Sea

Pablo Zapata-Corella[1]*, David Vanavermaete*[2]*, Charles Pollono*[1]*, Nadege Bely*[1]*, Elena Hengstmann*[3]*, Bavo De Witte*[2] *and Javier Castro-Jimenez*[1]*, (1)French National Institute for Ocean Science and Technology (Ifremer), Atlantic Center, Chemical Contamination of Marine Ecosystems Unit (CCEM), France, (2)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO-Marine), Animal Sciences Unit - Aquatic Environment and Quality, Belgium, (3)Federal Maritime and Hydrographic*

Agency (BSH), Marine Sciences Department, Germany
The number of offshore windfarms (OWF) in Europe has been strongly increased during last years and will continue growing as a part of the efforts to reduce the CO2 emissions. While various environmental effects have been described, the release of organic pollutants is still largely unknown. Target compounds were selected as they are used as additives or components of the polymers most frequently used in protective coatings of OWFs: polyurethane (PU) and epoxy resins (EP). Four chemical families, namely organophosphate esters (OPEs), phenolic compounds, benzotriazoles (BTRs) and derivate UV filters and primary aromatic diamines (PAAs), were selected as target compounds.
Two sampling campaigns took place in April 2024 collecting a total of 45 seawater samples from 4 different OWFs located in the Belgian and German parts of the North Sea (BPNS and GPNS respectively). Sampling design included sampling points from inside and nearby the OWF installations as well as reference areas with different anthropogenic pressures around them. Subsamples of 3 L of seawater were immediately extracted onboard by C18-polar SPE disks for the determination of phenols while for the rest of the compounds, 2 L seawater were extracted with HLB SPE cartridges. SPE sorbents were transported and eluted in the laboratory to be analyzed by LC-MS/MS.
Preliminary results from the BPNS showed the widespread presence of OPEs, with various aryl tri- and diphosphates being detected in all samples along with BTR and 4Me-BTR. The levels of both BTR and 4Me-BTR were 10 to 15 times higher in the high anthropogenic influence reference area (up to 10 ng/L). The most polluted sample was collected from the nearby area of OWF B and showed a differential pollution profile dominated by chlorinated OPEs. Triethyl phosphate (TEP) was the compound detected at the highest concentrations in most samples. Eight out of 12 analyzed phenols were detected in at least one sample and PAAs were in all cases below the limit of detection.
Even though no clear patterns have been found for this sample subset, the analysis of the remaining samples as well as further data analysis may provide more information about the sources releasing pollutants in OWF areas.

Disclaimer/Disclosure: This study was performed as part of the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union. We also acknowledge the captaincy and crew from the RV Belgica and the VWFS Atair for their collaboration on sampling campaigns.

3.18.P-Mo258 Microplastics and Offshore Wind: Context and First Data from the Belgian North Sea

***Alexa McCormick Zonderman*[1]**, *Lars Michael Hildebrandt*[2] *and Daniel Profrock*[1], *(1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany* Renewable energy is a clear priority, both for the EU and for governmental and industry organizations globally. While the end of reliance on fossil fuels is indisputably a positive goal, the necessity of regulation and monitoring of the impacts of new energy generation techniques is necessary to avoid the introduction of new, unknown sources of contamination. A relevant example of developing technology is offshore energy generation, which currently exists primarily in the form of offshore wind turbines for generating electricity. Structures placed in the offshore environment require corrosion protection, including coatings in the form of paints. Recent studies have shown that a large proportion of marine particulate contaminants, or microplastics, consist of coatings that may originate from protective coatings on ships and other structures. The large coated surface area introduced to the marine environment by an offshore wind farm represents an additional source of these particles.
Seven locations in the Belgian North Sea were sampled for particulates in seawater in April 2023 as part of the Anemoi project. Samples originate from two offshore wind farms in addition to references areas with varying anthropogenic stressors. Particles were obtained by use of a filtration cascade attached to the ship seawater system with filter sizes of 300 µm, 100 µm, and 10 µm. A minimum of 1 m3 for the smallest size fraction was sampled per location. Preparation of the samples following reduction of sample volume was conducted via a two-step digestion and density separation with ZnCl2. Analysis with laser direct infrared (LDIR) imaging constitutes the first analytical step. Further analyses and a larger dataset over two years are expected to result from work currently in progress within Anemoi.
The projected increase in offshore energy generation and marine area reserved for large structures speaks to a need for understanding and monitoring of the various types of contaminants that can be released from these structures. Currently, the behavior of particulate, or coating, particles originating from offshore wind farms is virtually unknown. Furthermore, the reliability of data concerning paint particles in the marine

environment requires improvement. This and other knowledge gaps highlight the need for the Anemoi project and further related research into emissions from new technologies associated with renewable energy, with the goal of minimizing unwanted side effects.

Disclaimer/Disclosure: This study was performed as part of the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union. We acknowledge the crew of the RV Belgica for their collaboration.

3.18.P-Mo259 Ecological Impacts of Wind Turbine Blade Erosion on Blue Mussels (*Mytilus edulis*)
***Daria Bedulina**[1], Spela Korez Lupse[1], Lars Michael Hildebrandt[2], Yaqing Duan[3], Ole Klein[2], Sebastian Primpke[3], Christian Bock[1], Stefan Krause[4], Steffen Czichon[4], Daniel Profrock[2], Gunnar Gerdts[3] and Gisela Lannig[1], (1)Department of Integrative Ecophysiology, Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany, (2)Department for Inorganic Environmental Chemistry, Institute of Coastal Environmental Chemistry, Helmholtz Centre Hereon, Germany, (3)Department of Shelf Sea System Ecology, Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Germany, (4)Department Rotor Blades, Fraunhofer Institute for Wind Energy Systems, Germany*
Offshore wind farms (OWFs) introduce novel anthropogenic pressures to marine ecosystems, including the release of organic and inorganic particles from turbine blade erosion, which may impact marine life. This study investigated the potential effects of these particles and their additives on the metabolic profile of the blue mussel (Mytilus edulis) using 1H-NMR spectroscopy. Mussels were exposed in the laboratory to microplastic (MP) particles derived from cryo-milled rotor blade coatings and core materials (glass fiber polymer, GFP) under a simulated worst-case scenario of extensive blade erosion. Enrichment factors (EFs) for metals and metalloids (e.g., Ba, Cu, Cd, Cr, Ni) ranged from 0.93 to 6.1, indicating a potential chemical load from the rotor blade materials. Untargeted metabolic profiling of mussel tissues revealed no significant disruptions to metabolic pathways, however trends in metabolite levels suggested potential short-term effects on neuroendocrine systems and possible long-term impacts on energy metabolism. Further research is essential to comprehensively evaluate the potential impacts of OWF erosion on marine environments, particularly in light of the planned expansion of wind farm construction as part of the EU-wide energy transition.

3.18.P-Mo262 Assessing the Environmental Risks of Offshore Hydrogen Production using Energy from Offshore Wind Farm: An Anticipatory Approach

Matthieu Dussauze[1], ***Tiphaine Labed-Veydert[1]****, Romain Wlodarczyk[1], Karine Pichavant-Rafini[2], Michael Theron[2] and Marie Robert[1], (1)France Energies Marines, France, (2)Laboratoire ORPHY EA4324, Universite de Bretagne Occidentale, France*

In the context of the extensive deployment of offshore wind farms (OWF), hydrogen (H2) is emerging as a promising energy vector to enhance electricity production from Offshore Renewable Energies (ORE). In this context, the OPHARM2 project aims to advance the knowledge on renewable H2 production from OWF through a transdisciplinary approach including the study of energy networks integration, technology aspects and the assessment of environmental impacts. A key objective of this last point is to identify and characterise the different environmental pressures specifically generated by the development of H2 production within an OWF.

In addition to potentially intensifying existing environmental pressures already generated by OWF (e.g. electromagnetic emissions, noise emissions, chemical pollution), offshore H2 production could introduce new environmental issues, leading to an increase in some accidental and chronic risks to the surrounding ecosystem. A major environmental concern is the discharge of produced waters which is formed by the brine - the byproduct from desalination required to produce freshwater for electrolysis- and the cooling waters resulting from heat exchangers. For gigawatt scale OWF, discharges could exceed 10^4m3 day-1 in certain scenarios. Such chronic discharges will lead to increased salinity and temperature on a local scale. In addition, the main accidental risks involve the potential explosion of stored H2 and substantial spills of chemicals used for desalination.

This work highlights the critical lack of empirical data and scientific resources regarding some environmental pressures, which severely hampers our ability to anticipate the potential impacts of offshore H2 production. To address these limitations, the OPHARM2 project has undertaken a range of experimental approaches. These include the physico-chemical and ecophysiological characterization of produced water, alongside hydrodynamic modeling of plume diffusion. Collectively, these research efforts, by advancing our understanding, aim to develop procedures for implementing a relevant Avoid, Reduce, Compensate (ARC) framework, thereby enhancing the environmental integration of offshore H2 production.

3.18.P-Mo263 Microbial Assays for Risk Assessment to Evaluate Toxicity of Chemicals and Environmental Samples

***Kirit Wadhia**[1], Carole Devine[2] and Michelle Robertson[3], (1)NOV, United Kingdom, (2)NCIMB, United Kingdom, (3)Energy & Enviromental Microbiology Services, NCIMB, United Kingdom*

Benefits of microbial bioassays

Bacteria are good candidates for ecotoxicity testing because of number of factors that include small size, rapid growth rate and ease of handling. The best-known tests make use of the naturally luminescent bacteria *Aliivibrio fischeri* (previously known as *Vibrio fischeri*). These tests are based on the rationale that exposure to toxins disrupts the bacterial respiratory processes, which in turn results in a reduction in light output. Reduction in light output is a relatively simple response to measure, which can then be calibrated to convey toxicity of the test sample.

MARA and LumiMARA bioassays with the incorporation of a genetically diverse multiple strains combination have significantly advanced microbial assays from single species utilisation.

Bacterial testing is generally based around assessment of the acute toxicity response of a single marine species. In contrast, testing using both MARA and LumiMARA gives a measure of acute and chronic toxicity, encompassing marine, freshwater and terrestrial species of prokaryotic microrganisms (bacteria) and additionally eukaryotic single-celled microrganism (yeast).

MARA: The MARA test assesses toxicity by measuring the growth of ten bacterial species and one yeast, following 18 hours of incubation in the presence of a concentration gradient of the test sample. As a eukaryote inclusion of a yeast species gives a valuable additional dimension to test results.

LumiMARA: LumiMARA assesses toxicity on the basis of the reduction in luminescence of 11 species of bacteria following exposure to a concentration gradient of the test sample. The test includes nine marine and two freshwater species from a variety of habitats. Two of the strains in the array are of *A. fischeri*, one of which is an equivalent to NRRL B-11177 referenced in ISO 11348-3 (Water quality Determination of the inhibitory effect of water samples on light emission of *A. fischeri* (Lumiescent bacteria test) Part 3: Method using freeze-dried bacteria.

Application in the oil and gas industry: The Oslo and Paris Commission (OSPAR) Recommendation 2012/5 requires contracting parties, of which the UK is one, to implement a risk-based approach for the management of produced water from offshore oil and gas installations. MARA and LumiMARA bioassays are recommended as part of the UK s Department for Energy Security and Net Zero (DESNZ) preferred approach to achieving this.

3.18.P-Mo264 Possible Ecotoxicological Effects of Wind Turbines

***Joachim Sturve**[1], Karin Mattsson[2] and Helen Karlsson[3], (1)Department of Biological and Environmental Sciences, Gothenburg University, Sweden, (2)Department of Marine Sciences, University of Gothenburg, Fiskebäkskil, Sweden, (3)Occupational and Environmental Medicine Centre, Linkoping University, Sweden*

Due to problems we are facing as a result of climate change, important work is ongoing to replace fossil fuels with alternative renewable energy sources, such as wind energy and wind turbines. Besides providing new energy, offshore wind farms have been shown to have potentially positive effects in terms of reef and reserve effects and protecting them from trawling and fishing. Positive ecological effects have also been observed in terrestrial ecosystems. However, impact analyses for many energy sources are still lacking, including wind power. There is a growing concern that wind farms may contribute to an increased pollution due to leakage of particles eroding from the blades. In addition, it has been shown that the turbines also leak different kinds of oils such as hydraulic and gear oils. The aim of this study was to investigate possible ecotoxicological effects of wind turbines.

Particles were collected from moss, water and sediment from lakes adjacent to wind turbine areas as well as from control lakes for particle analysis. To get an indication of possible ecotoxicological effects, perch from lakes in these areas were collected and samples taken for gene expression and histopathological studies. In addition, turbine blades were milled for controlled trials in aquariums with cultured perch. Analyses of particle characterization and chemical content in collected particles is ongoing but particles have been found in environmental samples. Exposure to particles in controlled laboratory experiments had limited effects on the gene expression analyzed in perch but showed effects of thyroid metabolism genes. Similar results were observed in the field collected fish that also displayed unusual fat incorporation in the livers, further analyzed with histopathology.

In order to assess negative effects of wind mill relevant oils, the water accommodated fraction (WAF) of a hydraulic and a gear oil were tested on several relevant models. We exposed fish liver cells (in vitro cell line), zebrafish embryos (FET test) and copepods to a concentration range of both WAFs. Both WAFs showed toxicity with the gear oil derived WAF being much more potent leading to 100% mortality of copepods also when diluted to 0,1% and zebrafish embryos exposed to 5% of the WAF.
Results show that particles and oils potentially leaking from wind turbines might have negative effects on the ecosystem. This information will hopefully aid the industry to invest in more sustainable materials.

3.18.P-Mo265 Applying Frameworks for Risk Assessment of Hydrocarbon Streams and Feeds to Alternative Non Crude Oil-Based Feeds

Mark Lampi[1], Lize Deferme[2], Ming Kung[1] and ***Louise Camenzuli***[2]*, (1)ExxonMobil Biomedical Science, Inc., United States, (2)ExxonMobil Petroleum & Chemical BV, Belgium*

Hazard and risk assessment of complex petroleum-derived substances has been in a state of continuous improvement since the 1970s, with the development of approaches that continue to be applied and refined. Alternative feeds are defined here as those coming into a refinery or chemical plant that are not hydrocarbons from oil and gas extraction such as biologically derived oils, pyrolysis oil from biomass or other, and recycled materials. These feeds are increasingly being used for production of liquid hydrocarbon streams, and hence, there is a need to assess these alternatives, subsequent manufacturing and refining processes and end products for potential risk to humans and the environment. Here we propose a tiered, problem formulation-driven framework for assessing the safety of hydrocarbon streams and products derived from alternative feedstocks in use. The scope of this work is only focused on petrochemical safety assessment, though the principles may be applicable to other chemistries. The framework integrates combinations of analytical chemistry, in silico and in vitro tools, and targeted testing together with conservative assumptions/approaches to leverage existing health, environmental, and exposure data, where applicable. The framework enables the identification of scenarios where new hazard and/or exposure assessments may be needed and incorporates tiered approaches to do so. It can be applied to enable decisions efficiently and transparently and can encompass a wide range of compositional space in both feedstocks and finished products, with the objective of ensuring safety in manufacturing and use.

3.19.A Legacy and Emerging Organic Contaminants in the Global Ocean and Polar Regions: Long-Range Transport, Local Sources and Climate Change Impacts

3.19.A.T-01 Local Sources vs Long-Range Environmental Transport of Contaminants to the Arctic – State of Knowledge, Conclusions and Recommendations

Cynthia A. de Wit[1]*, Derek C.G. Muir[2], Roland Kallenborn[3] and Katrin Vorkamp[4], (1)Department of Environmental Science, Stockholm University, Sweden, (2)Environment and Climate Change Canada, Aquatic Contaminants Research Division, Canada, (3)Faculty of Chemistry, Biotechnology and Food Sciences, Norwegian University of Life Sciences, Norway, (4)Department of Environmental Science, Aarhus University, Denmark*

Persistent organic pollutants (POPs) have predominantly reached the Arctic via atmospheric long-range environmental transport (LRET) from more southerly latitudes. Riverine and oceanic LRET have played a role for some more water-soluble POPs. New chemicals of emerging Arctic concern (CEACs) may also undergo LRET, but as many are consumer and industrial chemicals, they may also have local sources in the Arctic. LRET to remote monitoring sites in the Arctic is one criterion for listing chemicals on the Stockholm Convention for POPs. It is thus important to determine if Arctic measurements reflect local sources of POPs and CEACs or LRET. An assessment of local sources versus LRET of POPs and CEACs in the Arctic was carried out by members of the Arctic Monitoring and Assessment Programme (AMAP) POPs expert group and is being published as reviews and case studies in a special issue of Environmental Science: Advances. Results show that an expanding range of CEACs are present in the Arctic. The atmosphere is still the predominant pathway for LRET, but many CEACs are more water-soluble, thus riverine and oceanic LRET are becoming more important as pathways. Numerous local sources of POPs and CEACs to air and aquatic systems were identified, mainly linked to public, industrial and military (active and former) infrastructure, including Arctic settlements. Important local sources are municipal, industrial and military solid waste sites, untreated sewage and wastewater, open burning of solid waste, airports, active industrial and active and inactive military sites. Wildfires within the Arctic are now major emission sources of some POPs compared to LRET. LRET is still the main source of POPs and CEACs to the Arctic, but local sources may become more important considering projected Arctic climate change scenarios. Melting glaciers, ice and snow due to climate change are releasing previously deposited POPs and CEACs that have undergone LRET. Climate change will increase wildfires, permafrost thaw and extreme weather, leading to future uncontrolled releases of POPs and CEACs from thousands of waste sites. Climate change will increase human economic activities in the Arctic including fisheries, tourism, and shipping potentially leading to increasing local CEAC emissions. Most CEACs with local emissions in the Arctic likely fall outside the Stockholm Convention, and other regulatory instruments do not typically include Arctic vulnerability in chemical risk assessments.

3.19.A.T-02 Arctic Amphipods as Bioindicators of Plastic Pollution: Identification and Simultaneous Quantification of Small Microplastics and Microlitter (< 100 µm)

Giulia Vitale[1]*, Gabriella Caruso*[2]*, Valentina Iannilli*[3]*, Massimiliano Vard*[4]*, Beatrice Rosso*[4]*, Carlo Barbante*[5] *and Fabiana Corami*[4]*, (1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Venezia, Italy, (2)Insitute of Polar Sciences of the National Research Council, Italy, (3)ENEA, Research Centre, Italy, (4)Institute of Polar Sciences, National Research Council (ISP-CNR), Italy, (5)Ca' Foscari University of Venice, Italy*

The study aimed to identify and simultaneously quantify the body burden in Arctic Amphipods (Amphipoda, Crustacea) of small microplastics, plastic additives and other microlitter components, focusing on the particles below 100 µm. These are the sizes that can be easily ingested by the organisms, hence entering the trophic web and reaching its upper layers; indeed, these are also the particles sizes that can be easily long-range transported. As part of the Microtracer project (Small MICROplastics (<100 µm) bioindicaToRs in the changing ArctiC EnviRonment), during the summer of 2022, different genera of amphipods were collected at different sites of the Kongsfjorden, the Svalbard Archipelago. Organisms were pseudo-digested to extract microplastics and microliter components, which were then analyzed via Micro-FTIR for characterization and quantification. Preliminary results showed no differences in the abundance of microplastics and microliter components between the sampled sites or genera collected. The most abundant polymers and components were Polypropylene (PP) and Poly-N-Methylacrylamide (PnMA). Markers of tire wear and road particles were frequently detected, along with vulcanizing agents, specifically used in tires. According to the size distribution of microplastics and other microlitter, most particles were smaller than 100 µm. An exception is the site close to the village, where most of the particles exceed the 80-100 µm. This site might be a local source of particles. Analyzing the aspect ratio (AR), the shape of MPs and MLCs were mainly spheroidal or cylindrical. Smaller shapes and dimensions are the most common, however, due to the limits of sampling and analytical methods, these smaller particles are often overlooked. These findings highlight that amphipods can be employed as bioindicators of plastic pollution and that further studies on smaller microplastics and microlitter components are needed.

Disclaimer/Disclosure: The sampling campaign was partially funded by The Research Council of Norway, with an Arctic Field Grant (AFG, RisID: 11842, 2021-2022), in collaboration with the Norwegian Polar Insitute (NPI; Tromsø). The MICROTRACER project (PRA, Programma di Ricerche in Artico, RidID: 11919, 2022-2024), contributed to the sampling and the carry-on activities of the project. Finally, the Insitute of Polar Science of the National Research Council (CNR-ISP) in Italy provided accommodation in Ny-Alesund at the Base Dirigibile Italia, and all the laboratory equipment in Svalbard. The CNR-ISP with the Ca′ Foscari University also provided all the necessary laboratory equipment in Venice.

3.19.A.T-03 Non-Target Screening of Chemicals of Emerging Concern in Marine Mammals in the Nordic Environment

Linyan Zhu[1]*, Svante Rehnstam*[2]*, Lutz Ahrens*[2]*, Mikael Harju*[3]*, Pawel Rostkowski*[3]*, Jens Sondergaard*[4] *and Katrin Vorkamp*[1]*, (1)Aarhus University, Department of Environmental Science, Denmark, (2)Swedish University of Agricultural Sciences (SLU), Department of Aquatic Sciences and Assessment, Sweden, (3)NILU, Norway, (4)Department of Ecoscience, Aarhus University, Denmark*

An increasing of chemicals of emerging concern (CECs) such as pharmaceuticals, personal care products, industrial chemicals, pesticides, and per- and polyfluoroalkyl substances (PFAS) are detected in aquatic ecosystems, posing significant risks to marine organisms and ecosystems. In the Nordic environment, marine mammals like harbor porpoises (*Phocoena phocoena*) and ringed seals (*Pusa hispida*) can accumulate CECs through trophic transfer. This study employs non-target screening (NTS) using high-resolution mass spectrometry (HRMS) to investigate the presence and distribution of CECs in livers of 19 individuals of harbor porpoises and ringed seals from Greenland and the Baltic Sea. All samples were extracted twice, using optimized methods for GC and LC analysis, respectively. The samples were then analyzed using gas chromatography (GC) and liquid chromatography (LC) with HRMS, to expand the chemical domain. The GC- and LC-HRMS data analysis was conducted using two different workflows on

Compound Discoverer 3.3 with both open-source and in-house libraries. A total of 108 compounds from diverse chemical classes were identified, indicating substantial exposure of these animals to a mixture of pollutants. The majority of the tentatively identified contaminants were pharmaceuticals, personal care products, pesticides, plasticizers, PFAS, and industrial additives. The detected compounds will undergo further evaluation for persistence, bioaccumulation, mobility, and toxicity through experimental or predictive approaches. Comparative analysis of chemical patterns across different species and locations will provide insights into spatial and ecological variability. The findings highlight the urgent need to prioritize identified CECs with persistent, bioaccumulative, mobile, and toxic properties for regulatory risk assessment and improved chemical management strategies in the Nordic region. This study demonstrates the utility of NTS in uncovering chemical pollution profiles and their implications for ecosystem health and conservation in marine environments.

3.19.A.T-04 Contaminant Incorporation in Sea Ice: Understanding the Roles of Sea Ice Formation and Contaminant Properties

Alice Pradel[1], Florian Odic[2], Rudolf Hufenus[3], Martin Schneebeli[4] and ***Denise M. Mitrano[2]****, (1)Department of Environmental Systems Science, ETH Zurich, Switzerland, (2)ETH Zurich, Switzerland, (3)EMPA - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (4)SLF, Switzerland*

Despite being remote, polar seawater is widely contaminated by anthropogenic contaminants. Besides re-distributing materials during the formation, drift, and melting of sea ice, this could also put the polar food web at high risk of exposure since the porosity of sea ice, generated by brine channels, is an important habitat for microalgae. To understand how contaminants of different size (dissolved, colloidal, particulate) and composition (natural, incidental, plastic) interact, we developed a novel laboratory experimental set-up which mimics sea ice growth either as frazil or columnar ice. The morphology of both types of ice (assessed by ?-computed tomography) and its salinity were similar to that of young natural ice. Using this set-up we quantified a model dissolved species (Rose Bengal), two colloids (nanoplastic and nanosoot) and four particulate species (microplastics with two different sizes and densities) within the bulk ice (in the case of the frazil ice study) or ice and brine (separately for the columnar ice study) and underlying liquid separately. We anticipated the extent of particle incorporation into sea ice would be dictated by contaminants size and, in the case of particles, their density. During frazil ice formation, rising ice crystals may scavenge particles as they rise. This was only evidenced for microplastics, where they were 3 times enriched in bulk ice compared to underlying seawater. Nanoplastics were depleted from the bulk ice in the same proportion as sea salts. In columnar ice experiments, salts and dissolved contaminants were equally enriched in the brine channels and depleted from ice. Nanoplastics and nanosoot were also depleted from the ice, but had lower enrichment in the brine, perhaps due to their aggregation state. Microplastics followed divergent transport pathways depending on their density. High-density plastics were depleted in both brine and ice whereas low-density plastics were slightly depleted from brine and enriched in ice. Collectively, depending on both ice formation pathway and contaminant physicochemical properties, divergent incorporation could be seen. Frazil ice is responsible for the enrichment of high-density particulate contaminants in ice, whereas columnar ice is not. Both frazil and columnar ice, colloidal species are depleted from the bulk ice. This work elucidates which type of contaminants organisms may be exposed to and the fate processes which distribute them throughout the environment.

3.19.A.T-05 Investigating Climate Change Impacts on PCB-153 Exposure in Arctic Food Webs Using the Nested Exposure Model

Ingjerd S. Krogseth[1]*, Heli Routti[2], Knut Breivik[1], Sabine Eckhardt[1], Igor Eulaers[3], Jorn Dietze[4], Gregor Decristoforo[4], Mikael Harju[1], Jon Aars[2] and Frank Wania[5], (1)NILU, Norway, (2)Norwegian Polar Institute, Norway, (3)Norwegian Polar Institute, Norway, (4)UiT Arctic University of Norway, Norway, (5)University of Toronto Scarborough, Canada*

Global climate change is drastically changing the Arctic environment and its ecosystems. At the same time, Arctic wildlife is still exposed to high concentrations of persistent organic pollutants (POPs). A mechanistic understanding of how global POP emissions and co-occurring climate change impacts wildlife is vital to enable scientifically sound mitigation strategies. Here, we further develop and evaluate the Nested Exposure Model (NEM), a global dynamic and spatially resolved environmental fate and bioaccumulation model. NEM is applied to estimate the impact of combined changes in global contaminant emissions and climate parameters on PCB-153 exposure in the Arctic environment and ecosystems, including polar bears (Ursus maritimus). NEM has previously been evaluated for selected key species in Norwegian Arctic food webs, including fish, ringed seal (*Pusa hispida*) and seabirds. Here, three new species are added to NEM; lichen (C*ladina rangiferina*), reindeer (*Rangifer tarandus*), and polar bear. The polar bear is parameterised based on literature and field data from Svalbard. NEM is run based on global emissions for PCB-153 from 1930 until 2025, estimating PCB-153 concentrations in biota in the European Arctic areas. Model estimates are compared to existing PCB-153 measurement data, supplemented with new measurements in samples of subcutaneous fat from Svalbard reindeer (n = 16). NEM estimates PCB-153 concentrations in lichen, male reindeer, and female reindeer that are a factor of 0.3, 2.3 and 6.9, respectively, compared to the measured concentrations. Estimated concentrations in individual female polar bears from 1991 to 2020 (n = 460) are a factor of 0.2 21.8 (median 1.8) compared to measured concentrations, and the temporal trend is well reproduced. The overall model bias for individual predictions of PCB-153 in female polar bears is also 1.8. This suggests that NEM performs well in reproducing concentrations in lichen, reindeer and polar bears on Svalbard, when run based on global emissions. More detailed results with a particular focus on polar bears, including exploration of selected model scenarios based on a changing climate, will be presented. NEM has potential to be expanded to other contaminants, species, and ecosystems of interest, making it a useful tool for both scientific and regulatory communities interested in understanding and protecting ecosystem and human health from legacy and emerging organic contaminants.

Disclaimer/Disclosure: Funding was provided from the Research Council of Norway (287114, 343110), the Fram Centre research programmes CLEAN and SUDARCO and Fram Centre incentive funding (82024). We thank Åshild Pedersen and Vebjørn Veiberg for collection of reindeer samples.

3.19.B Legacy and Emerging Organic Contaminants in the Global Ocean and Polar Regions: Long-Range Transport, Local Sources and Climate Change Impacts

3.19.B.T-01 Emerging and Legacy Per- and Polyfluoroalkyl Substances in the Global Ocean and Polar Regions

Zhiyong Xie, *Helmholtz-Zentrum Hereon, Germany*

Per- and polyfluoroalkyl substances (PFASs) have been extensively studied across various environmental compartments in the global ocean. Current research reveals that PFASs are ubiquitous, earning their reputation as "forever chemicals" even in the remote polar environments. Long-range environmental transport via atmospheric circulation and oceanic currents are key pathways through which PFASs are globally distributed. In seawater and snow, perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS), and short-chain perfluorinated alkyl acids (C4 C6 PFAAs) are the predominant compounds, while perfluoroundecanoic acid (PFUnDA), perfluorononanoic acid (PFNA) and PFOS dominate in polar biota. Emerging PFASs, such as hexafluoropropylene oxide dimer acid (HFPO-DA) and fluorotelomer sulfonates (6:2 and 8:2 FTS), have also been detected, despite their relatively recent use as replacements for legacy PFASs. Spatial distributions suggest declining PFAS concentrations with increasing distance from continental sources, indicating ongoing discharge and transport processes. Neutral PFASs favor atmospheric transport and can transform into ionic forms through photochemical and biodegradation processes, which can be an important source of ionic PFASs in the remote ocean and polar regions. Elevated PFAS concentrations in Arctic and Antarctic coastal areas highlight the role of glacier melt and sea ice retreat as secondary sources. Given the impacts of climate change, future research should integrate observations and models to better understand PFAS biogeochemical cycles in polar regions.

3.19.B.T-02 Role of Marine Bacteria on the Interactions Between Perfluoroalkyl Substances and Bioplastics

Clara Serrano Lorigados[1], *Naiara Berrojalbiz*[1], *Jessica Patrone*[1], *Nuria Trilla*[1], *Maria Paula Carrillo*[1], *Jon Iriarte*[2], *Arianna Bautista*[3], *Maria Fernandez-Altimira*[1], *Marinella Farre*[4], *Marta Llorca-Casamayor*[1], *Maria Vila-Costa*[1] *and Jordi Dachs*[1], *(1)IDAEA-CSIC, Spain, (2)Environmental Chemistry, IDAEA-CSIC,Spain, (3)IDAEA-CSIC, Spain, (4)IDAEA-CSIC, Barcelona, Spain*

Recent studies on persistent organic pollutants (POPs) have revealed the presence of per- and polyfluoroalkyl substances (PFAS) in Southern Ocean environments. While the role of the marine biological pump in degrading some POPs is well-documented, PFAS are notably persistent in the environment. However, recent evidence suggests that marine bacteria may facilitate PFOS biodegradation, potentially through desulfurization, as indicated by transcriptomic analyses of bacterial communities in PFOS-spiked waters. Additionally, the increasing presence of bio-based biodegradable plastics (e.g., PLA) in marine environments raises concerns, as their degradation rates are significantly slower under marine and polar conditions compared to compost environments, complicating their environmental impact. To elucidate PFAS biodegradation mechanisms, the reproducibility of proposed pathways and factors influencing the process must be studied. This includes co-metabolic strategies in marine bacteria under sulfur-enriched conditions, such as those in Port Foster Bay (Deception Island, Antarctica). The role of PLA bag fragments in PFAS adsorption/desorption, their leaching of plastic additives, and their potential as carbon sources for biofilm-forming bacteria are also critical considerations. These factors may significantly affect bacterial communities involved in PFAS degradation and their functional mechanisms. An experiment was conducted during the Spanish Antarctic Campaign (February 2024) using seawater collected from Port Foster Bay at 40 m depth. Diatoms, abundant in Antarctic waters, were filtered out for half of the treatments. Seawater with and without diatoms was spiked with a sulfonated PFAS mixture under abiotic and biotic conditions, with and without PLA bag fragments. Incubations were maintained under natural sunlight and temperature in sterile, ultra-clean PP bottles for 8 days. Sampling at various time points included analyses of PFAS chemical degradation, chlorophyll-a levels, nutrient availability, bacterial abundance, community composition, and transcriptomic profiles. This study aims to deepen understanding of PFAS interactions with Antarctic bacteria, highlighting how environmental factors, such as phytoplankton presence and their by-products, along with other pollutants, influence the degradation of these persistent "forever chemicals" known for their bioaccumulation and toxicity.

3.19.B.T-03 Emerging Organic Compounds Occurrence in the "Touristic" Antarctic Peninsula

Belen Gonzalez-Gaya[1]*, Amaia Callejo-Rubio*[2]*, Aizpea Lejardi-Rigou*[2]*, Juan Francisco Ayala Cabrera*[1]*, Maitane Olivares*[1]*, Ailette Prieto*[1]*, Olatz Zuloaga*[1] *and Johan Etourneau*[3]*, (1)Plentzia Marine Station, University of the Basque Country, Spain, (2)University of the Basque Country, Spain, (3)EPHE/PSL University & EPOC CNRS - University of Bordeaux, France*

The ecosystems of the polar regions are facing actual changes stemming from both natural phenomena and human activities. Antarctica is now impacted not only by persistent pollutants generated in inhabited continents arriving via long range transport, but also by local sources including scientific bases and an increasing touristic pressure. Indeed, in the last years, daily use chemicals including non-persistent ones such as pharmaceuticals, personal care products or similar polar Contaminants of Emerging Concern (CECs) have been measured in the Antarctic Peninsula surroundings. The aim of this study was to develop and implement an advanced, wide-ranging analytical method by means of solid-phase extraction (SPE) followed by analysis with high-resolution mass spectrometry (LC-HRMS, qOrbitrap). This methodology was designed to detect and quantify a variety of organic pollutants in snow and water samples collected in November 2023 from the coastal Antarctic Peninsula. The families of compounds analysed in this study include endogenous hormones, pesticides, industrial chemicals, lifestyle products, and pharmaceuticals. Briefly, clean and penguin colonies snow, surface and subsurface seawater and on-board residual water from a touristic boat were gathered in November 2023 in the coastal Antarctic Peninsula. Between 200 mL and 2 L of water or melted snow were filtered onto GF/F glass filters on board before its extraction with HLB Oasis cartridges using a slightly modified, in-house-validated protocol. Cartridges were shipped to the University of the Basque Country frozen, eluted and concentrated prior injection. The instrumental analysis was performed on a Thermo Scientific Dionex UltiMate 3000 UHPLC coupled to a Thermo Scientific Q Exactive Focus quadrupole-Orbitrap equipped with a heated ESI source (Thermo, CA, USA). The injection of the extracts was performed in positive and negative ionization modes in full scan data-dependent MS2 discovery acquisition. A selection of around 300 compounds, including many different CECs families was used for a target analysis.

Disclaimer/Disclosure: JFAC acknowledges the European Union (EU) for his Marie Curie postdoctoral fellowship. BGG acknowledges IkerBasque Foundation for her tenure track position. Le Ponant is thanked for their support to scientific development in Antarctic waters.

3.19.B.T-04 High-Resolution Record of Global Background Persistent Organic Pollutants from Antarctic Marine Sediments

Jun-Tae Kim*, Korea Institute of Science and Technology, "Korea, Republic of"*

Introduction:

The global spread of persistent organic pollutants (POPs) serves as a key marker of human impact in the Anthropocene. Antarctic marine sediments, particularly diatom ooze with high sedimentation rates, offer unique opportunities to reconstruct historical pollution trends. However, the potential of these sediments

as archives of atmospheric deposition remains largely unexplored.
Materials and Methods: A 67.5 cm marine sediment core was collected from the Antarctic Peninsula's continental shelf at 730m depth. The core chronology was established using 210Pb dating. Multiple pollutant classes including PCBs, PBDEs, OCPs, PAHs, and OPAHs were analyzed using GC-HRMS and GC-MS/MS. Geochemical proxies (TC, TN, TOC) were measured to characterize organic matter content and origin. The observed deposition patterns were compared with MPI-MCTM modeling predictions.
Results and Discussion: The core provided a continuous 68-year record with a high sedimentation rate (0.99 cm/yr) and no stratigraphic disturbance. Geochemical analyses revealed high organic content (TOC: 0.926-2.07%) with consistent marine origin (OC/TN: 6.84-8.58). Temporal trends in POPs concentrations matched global emission patterns, with peak levels observed in the mid-1990s for most compounds. Notable findings included recent rebounds in DDTs, BDE 209, and HCHs concentrations post-2010, potentially linked to glacial melting and increasing primary production.
Conclusions: This study presents the highest-resolution record of atmospheric pollutant deposition in the Antarctic Ocean during the Anthropocene. The diatom ooze successfully preserved global emission signals, demonstrating the Southern Ocean's significant role as a sink for anthropogenic pollutants. The observed recent rebounds in certain POPs highlight the potential impacts of climate change on pollutant cycling in polar regions.

3.19.P-We261 Investigating Microplastic Transport in Western North American Snow

Aleksandra Karapetrova[1]*, Win Cowger*[2]*, Sonya Maple*[3]*, Audrey Jeanne Braun*[1]*, Andrew Gray*[1] *and Jay Gan*[1]*, (1)University of California Riverside, United States, (2)Moore Institute for Plastic Pollution Research, United States, (3)California Department of FIsh and Wildlife, United States*

The atmosphere is one of the least studied environmental compartments for microplastic (MP) transport likely because of the relatively small size of airborne MPs and the challenges in identifying them. MPs from within and below clouds can deposit into alpine terrestrial environments in snowfall via atmospheric scavenging. To measure the extent of MP atmospheric pollution, 11 sites across western coastal North America were sampled and analyzed for MP presence in fresh snowfall, months-old summer surface snow, and stratified deposits in snow pits. Following this study, fresh snowfall at 7 sites in the California Sierra Nevada mountain range were regularly sampled to determine the deposition rate of MPs in the region. MPs were detected and characterized using an improved method integrating linear array µ-Fourier Transform Spectroscopy (µFTIR) and batch spectral analysis using the open-source platform Open Specy. This method enables high-throughput detection and analysis of MPs > 50 µm Feret diameter. The recovery rates of MPs from sample filtration to data analysis were an average of 98% for 250-300 µm MPs and 76% for 70-90 µm MPs. The low field and laboratory contamination rates (? 1 polyamide fragment per blank) were very low. The concentrations of MPs in the fresh snowfall of remote sites and sites proximal to MP sources ranged from 5.1-150.8 p/L and 104.5-325 p/L of meltwater, respectively. Summer surface snow that was several months old had MP concentrations ranging from 57.5-539 p/L of meltwater, and snow sampled at different depths within a snowpack had concentrations ranging from 35-914 p/L. All particles identified as MPs were fragments, and most (~ 90%) were under 200 µm. The most common polymer types found were polyamide, polyethylene terephthalate, polystyrene, polyolefin, and polyvinylester polymers. These are the first field observations of MP in the alpine snow in the Cascade Range, Sierra Nevada Mountains, and arctic tundra snow on the Seward Peninsula, USA. An atmospheric model of MPs based on GEOS-Chem was used to understand potential sources of MPs in the California Sierra Nevada mountain range. Our results also demonstrate the value of a streamlined method that may be used for measuring MPs in the environment, contributing to a better understanding of long-range MP transport, and the global extent of MP pollution.

3.19.P-We271 Microplastics Distribution and Occurrence in Greenlandic Fjords

Tristan Zimmermann[1]*, Lars Michael Hildebrandt*[2]*, Cornelius Vetter*[3]*, Claudia Elena Schmidt*[3]*, Daniel Profrock*[1] *and Helmuth Thomas*[3]*, (1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (3)Helmholtz-Zentrum Hereon, Germany*

The northeastern coast of Greenland (Tunu) is hardly, if at all, inhabited and reveals near pristine characteristics. As sea ice still covers the fjords and ocean for most of the year, the population and vessel densities are close to zero. Nevertheless, microplastics (MPs, 1 5,000 µm) and nanoplastics (< 1 µm) are to be found even in places without nearby pollution sources. To date, there is only a limited number of studies on micro- and nanoplastics (MNPs) in the Arctic and numerous questions regarding their transport, distribution, fate, and final consequences for this unique environment remain unanswered.
Within this context microplastic sampling was conducted at eight locations within the fjords of East Greenland and the Denmark Strait with the research vessel Maria S. Merian in August 2022 (cruise

MSM110, Ecological tipping cascades in the Arctic seas (ECOTIP)), using the Geesthacht Inert MP Fractionator. Four fractions were taken per sampling station: one hydrocyclone and three filter cartridges with a 300 µm, 100 µm and 10 µm mesh size. 2.5 to 5.2 m3 of ocean water were filtered per sample to process a representative water volume. Transflection-mode infrared spectroscopic measurements were conducted using an Agilent 8700 Laser Direct Infrared (LDIR) Chemical Imaging System.
Measured MP number concentrations ranged between 12 ± 4 L 1 (1 SD, n = 4) at the mouth of the Scoresby Sound and 1.0 ± 0.8 L 1 (1 SD, n = 3) in the Dove Bay. Twelve polymer types were identified in total. PET is by far the most abundant polymer type in all 18 samples with an overall average share of 96 ± 3% (1 SD, n = 18). Polylactic acid (PLA) is the second most frequent polymer type with an average share of 1.6 ± 0.5% (1 SD, n = 18).
The fjords of East Greenland and the Denmark Strait are notable hotspots for MP pollution. On average, PET constituted 96% of the total MP abundance, while PLA constituted 1.6%. The level of PLA detected is believed to be the highest ever recorded in marine samples, which raises questions regarding its source and transport. The results revealed no discernible trends between MP concentration, polymer composition, or size distribution and glacial meltwater inputs. Therefore, it is assumed that oceanic currents and sea ice transport exert a substantial influence on the distribution of MPs. The collection of replicate samples proved to be important in demonstrating the temporally varying patchiness of MP distributions.

3.19.P-We278 Unraveling the Effects of Microfibers Across Treatment Stages via a Critical Prey Species, in the Context of Climate Change

Lauren Miki Kashiwabara[1], Patrick Reece[2], Clarissa Raguso[3], Lisa Hildebrand[2], Leigh Torres[2] and ***Susanne M. Brander**[2], (1)Department of Fisheries, Wildlife, and Conservation Sciences, Oregon State University, Corvalis, United States, (2)Oregon State University, United States, (3)University of Milan, Oregon State University, Italy*

Mysid shrimp are an important prey item in marine and freshwater food webs globally, including those containing key predators such as gray whales and salmonids. Gray whales require millions of zooplankton daily, primarily mysids, and are threatened by worsening climate conditions such as ocean acidification. Additionally, whales can consume over 20 million microparticles (primarily microfibers) daily from mysid prey. Microfibers exert chemical and physical toxicity, but knowledge is sparse regarding how much each contributes to organismal stress. Therefore, our goals were to further estimate impacts to coastal food webs and to better understand the contribution of chemical vs. physical effects from microfibers, in addition to understanding impacts in the context of climate change on these critical prey species. We quantified responses to polyester microfibers across treatment stages (griege/naïve, ozonated, chemically modified) and weathering states, including low pH exposure, on native and surrogate mysids. Briefly, microfibers were produced from textiles across treatment stages provided by an anonymous clothing manufacturer. Mysids were exposed to 5 (*A. bahia*, purchased) or 10 microfibers (*H. sculpta*, native field collected) / mL for 7 days or 48 hours, respectively. Following exposures, *A. bahia* underwent a sublethal low pH challenge. Behavioral toxicity was measured in both species. Results demonstrate that growth was reduced in *A. bahia*, and behavioural responses are predominately hypoactive, being most sensitive to chemical treatment or weathering, and potentially exacerbated at a lower pH. Behavioural impacts are more pronounced in native *H. sculpta*. These effects have broad implications for individual, population and ecosystem health. Current studies investigate the same fabric treatments in cotton in both species, including RNA seq analysis, and seek to better understand microfiber occurrence in relevant coastal areas. To our knowledge, this is one of the first studies utilizing textile microfibers across known treatment stages in both native and surrogate (model) species and could directly inform more sustainable textile production in the future.

Disclaimer/Disclosure: The research was funded by Oregon Sea Grant and the National Science Foundation.

3.19.P Legacy and Emerging Organic Contaminants in the Global Ocean and Polar Regions: Long-Range Transport, Local Sources and Climate Change Impacts

3.19.P-We259 Tissue Distribution of Chlorinated Paraffins in Finless Porpoises (*Neophocaena phocaenoides*): Risk Assessment via Physiologically Based Toxicokinetic (PBTK) Model

***Yetong Shao**, Yuefei Ruan and Qi Wang, City University of Hong Kong, Hong Kong (Greater China)*

Chlorinated paraffins (CPs) are high-production chemical mixtures that accumulate significantly in marine animals. With the phasing-out of short-chain CPs (SCCPs) since 2024 in China, environmental levels of medium-chain (MCCPs) and long-chain CPs (LCCPs) are expected to rise, leading to potentially increasing exposure risk to marine predators. However, the tissue distribution of CPs, particularly MCCPs and LCCPs, remains understudied. This study simulated the toxicokinetics and tissue distribution of SCCPs, MCCPs, and LCCPs in finless porpoises (*Neophocaena phocaenoides*) using a physiologically based toxicokinetic (PBTK) model. The model was optimized through calibration and validation with bioaccumulation data of CPs in different tissues (liver, kidney, brain, muscle, and blubber) of stranded finless porpoises sampled in Hong Kong waters. Results showed that lipid-normalized concentrations of CPs increased with age across all tissues, due to low clearance rates. The liver had the highest concentrations, followed by muscle and blubber. Although blubber is often used in environmental monitoring, it contains lower CP levels compared to liver and muscle, suggesting potential underestimation of bioaccumulation when using blubber alone. As such, this study enhances understanding of CP bioaccumulation across different tissues over time, aiding in assessing the health impacts and ecological risk of CPs on finless porpoises.

3.19.P-We260 Antarctica Sampling and Logistic Hurdles for Cyclic Volatile Methylsiloxanes (cVMS)

Jeremy Durham[1], Debra Ann McNett[1], Mark Irvine[2], Isabel Sauermilch[3], ***Rita M. Seston****[4], Reinhard Gerhards[5], Robert Bialik[6], Pernilla Nizzetto[7], Dragomir Mateev[8] and Evgen Dykyi[9], (1)Dow Chemical Company, United States, (2)ERM - Environmental Resource Management, United Kingdom, (3)ERM - Environmental Resource Management, Germany, (4)Hyla Consulting LLC, United States, (5)Gerhard Consulting, Germany, (6)Poland Antarctic Institute, Poland, (7)NILU, Norway, (8)Bulgaria Antarctic Institute, Bulgaria, (9)Ukraine Antarctic Institute, Ukraine*

Environmental monitoring of cyclic volatile methylsiloxanes (cVMS) occurred during the austral summer of Antarctica 2023-2024, with additional air samples occurring throughout the following year in select locations. The sampling locations included Polish Henryk Arctowski station, Bulgarian St. Kliment Ohridski station, Ukrainian Vernadsky station and the Norwegian Troll station.
The objective of the project is to determine the potential presence of cVMS in air, surface media, and aquatic biota in Antarctica. The study design included the sampling and analysis of air, terrestrial surface media (i.e., soil and vegetation), aquatic biota, and sediments to obtain accurate cVMS concentrations with a thorough understanding of the influence of local sources and potential bias from collection and analytical procedures. State-of-the-art sampling, quality control procedures and analytical methods were developed and used to minimize the artifacts due to sample contamination or loss and to evaluate the long-range environmental transport (LRET) and back deposition potential of cVMS in remote regions. While Antarctica is often considered to be a remote region in the context of environmental pollution resulting from anthropogenic activities, the presence of research stations and increasing pressure from tourism were considered as potential local sources in the study design.
Environmental monitoring in Antarctica and remote locations brings about many sampling and logistical challenges. This presentation will highlight the importance of a detailed and in-depth study plan and standard operating procedures (SOPs) with the focus of this presentation on 1) preparation of materials, 2) sampling and 3) sample logistics.
1) Preparation of materials includes collection documents, pre-cleaned sampling equipment and storage containers and development of sampling kits (equipment containers and quality control samples)
2) Sampling includes the detailed SOPs, documentation of sampling activities and utilization of quality control samples.
3) Sample logistics include the packing and tracking of samples via different routes and carriers and working through customs to ensure sample integrity throughout shipment to laboratory.

3.19.P-We261 Investigating Microplastic Transport in Western North American Snow

Aleksandra Karapetrova*[1], Win Cowger[2], Sonya Maple[3], Audrey Jeanne Braun[1], Andrew Gray[1] and Jay Gan[1], (1)University of California Riverside, United States, (2)Moore Institute for Plastic Pollution Research, United States, (3)California Department of Fish and Wildlife, United States*

The atmosphere is one of the least studied environmental compartments for microplastic (MP) transport likely because of the relatively small size of airborne MPs and the challenges in identifying them. MPs from within and below clouds can deposit into alpine terrestrial environments in snowfall via atmospheric scavenging. To measure the extent of MP atmospheric pollution, 11 sites across western coastal North

America were sampled and analyzed for MP presence in fresh snowfall, months-old summer surface snow, and stratified deposits in snow pits. Following this study, fresh snowfall at 7 sites in the California Sierra Nevada mountain range were regularly sampled to determine the deposition rate of MPs in the region. MPs were detected and characterized using an improved method integrating linear array µ-Fourier Transform Spectroscopy (µFTIR) and batch spectral analysis using the open-source platform Open Specy. This method enables high-throughput detection and analysis of MPs > 50 µm Feret diameter. The recovery rates of MPs from sample filtration to data analysis were an average of 98% for 250-300 µm MPs and 76% for 70-90 µm MPs. The low field and laboratory contamination rates (? 1 polyamide fragment per blank) were very low. The concentrations of MPs in the fresh snowfall of remote sites and sites proximal to MP sources ranged from 5.1-150.8 p/L and 104.5-325 p/L of meltwater, respectively. Summer surface snow that was several months old had MP concentrations ranging from 57.5-539 p/L of meltwater, and snow sampled at different depths within a snowpack had concentrations ranging from 35-914 p/L. All particles identified as MPs were fragments, and most (~ 90%) were under 200 µm. The most common polymer types found were polyamide, polyethylene terephthalate, polystyrene, polyolefin, and polyvinylester polymers. These are the first field observations of MP in the alpine snow in the Cascade Range, Sierra Nevada Mountains, and arctic tundra snow on the Seward Peninsula, USA. An atmospheric model of MPs based on GEOS-Chem was used to understand potential sources of MPs in the California Sierra Nevada mountain range. Our results also demonstrate the value of a streamlined method that may be used for measuring MPs in the environment, contributing to a better understanding of long-range MP transport, and the global extent of MP pollution.

3.19.P-We262 Patterns in Mercury Biomagnification in Boreal and Subarctic Lake Food Webs – Similarities and Differences Across Climate and Productivity Gradients
Alexander Piro[1]*, Natalia Kozak*[2]*, Ossi Keva*[1]*, Emmi S. Eerola*[1]*, Katja Kulo*[3]*, Timo Ruokonen*[3]*, Jan Weckstrom*[1]*, Tommi Malinen*[4]*, Mikko Kiljunen*[5]*, Sami Taipale*[6] *and Kimmo Kalevi Kahilainen*[1]*,*
(1)University of Helsinki, Finland, (2)Inland Norway University of Applied Sciences, Norway, (3)Natural Resources Institute Finland (Luke), Finland, (4)KVVY, Finland, (5)University of Jyvaskyla, Finland, (6)Department of Biological and Environmental Science, University of Jyväskylä,Finland
Climate change and intensive land use are significant and increasing pressures on northern lake environments, thus transforming the composition and interactions of aquatic ecosystems. These changes will likely influence mercury (Hg) dynamics in these systems. Increasing temperatures and an extended warm season enabling increased agriculture and forestry activities jointly drive the leaching of nutrients and toxic Hg from catchments into water bodies and potentially influencing biomagnification of Hg up through aquatic food webs to unknown extents across complex landscape gradients. How this process occurs along an extended climate-productivity gradient paired with catchment metrics has not been thoroughly explored. We sampled lake food webs from primary producers to top predators across a landscape gradient in 19 subarctic and 16 boreal lakes in Finland. We tested the joint effects of climate, productivity, and catchment metrics in a principal component analysis (PCA) on total Hg (THg) biomagnification in food webs across both regions by assessing the trophic magnification slope (TMS) and mercury baseline (baseline THg) through the regression of log10 transformed THg (log10THg) against trophic levels (TL). We then used principal components comprised of climate, productivity, and catchment variables jointly in stepwise general linear regression models to assess TMS and baseline THg. We found differing regional importance regarding influences on THg biomagnification. Subarctic lake THg biomagnification variables, TMS and baseline THg, demonstrated pronounced importance with a negative trend regarding lake productivity classification along a climate-productivity gradient (PC1), while the boreal TMS required all relevant principal components (PC1, PC2, PC3) for modelling and still achieved lesser predictive capacity compared to subarctic lakes. Principal components were not significant for the modelling of boreal baseline THg. A confluence of more diverse food webs with a higher exposure to intensive land use over a longer period in the boreal compared to the subarctic is the likely reason for the lower predictive power observed in boreal TMS and baseline THg. Ongoing climate warming and northward intensification of land use suggest that pristine subarctic lakes will likely trend towards the higher impact status seen in the boreal lakes in the future.

We thank all individuals who assisted in the field and laboratory work involved in this work.

3.19.P-We263 Enantioselective Accumulation and Trophodynamics of p-Phenylenediamines Antioxidants and Their Quinones in the Mangrove Ecosystem

Yuxin Sun*, South China Normal University, China (Mainland)*

p-Phenylenediamines (PPDs) and their quinones (PPDQs) are contaminants of emerging concern. However, limited information exists on their occurrence and fate in the aquatic environment, which are particularly unknown in the mangrove wetlands. Herein, the distribution, bioaccumulation, trophodynamics and chiral signatures of PPDs and PPDQs were explored in Qi ao Island Mangrove Nature Reserve of China. Concentrations of ?PPDs and ?PPDQs in mangrove biota ranged from not detected (nd) to 352 and nd to 49.4 ng/g lipid weight, respectively. Terrestrial birds had higher concentrations of ?PPDs than mangrove aquatic biota. The enantiomeric compositions of N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD) and its quinone (6PPDQ) were evaluated in the field for the first time. A significant enrichment of (+)-6PPD was observed in crab and fish, and a preferential enrichment of (-)-6PPD was found in birds. Nonracemic signatures were also found for 6PPDQ in mangrove biota, with the preference accumulation of (+)-6PPDQ. IPPD, DPPD, DTPD and DPPDQ exhibited significant trophic magnification in the mangrove food web, while no clear trophodynamics trend was found for other target PPDs and PPDQs. Further investigation is necessary to explore the factors affecting the trophodynamics of PPDs and PPDQs and the mechanisms underlying the enantioselective bioaccumulation of 6PPD and 6PPDQ.

3.19.P-We264 Do Local Sources of Pollution Influence the Exposure of Ringed Seals (*Pusa hispida*) Analyzed in Arctic Contaminants Monitoring Programs?

Magali Houde[1], Nadia Facciola[2], Heli Routti[3], Katrin Vorkamp[4], Jens Sondergaard[5] and ***Derek C.G. Muir****[2], (1)Environment and Climate Change Canada (ECCC), Gatineau, Canada, (2)Environment and Climate Change Canada (ECCC), Canada, (3)Norwegian Polar Institute, Norway, (4)Department of Environmental Science, Aarhus University, Denmark, (5)Aarhus University, Denmark*

The monitoring of contaminants in Arctic wildlife is mainly designed for long-range transported chemicals and supports international initiatives to mitigate global threats from chemical pollution. As human activities increase in the Arctic, the question of potential impact of local pollution on wildlife exposure has emerged. In this study, we examined the current monitoring practices and the state of knowledge of pollutants in Arctic ringed seals (*Pusa hispida*) from Canada, Greenland, Norway, Russia, and Alaska and tested the potential influence of local pollution sources from different locations in Canada (2008-2022). Multivariate constrained ordination was applied to examine the effects of ringed seal biological metrics (age, sex, girth, dietary proxies), settlement population density, and potential local contaminant sources (infrastructures, industries) on contaminant concentrations [polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), per- and polyfluoroalkyl substances (PFAS), polybrominated diphenyl ethers (PBDEs), trace elements] in seals. Results indicated that biological data, location, and local source variables explained 13% (PBDEs), 38% (OCPs), 42% (trace elements), 45% (PFAS), and 68% (PCBs) of the contamination variation in seals through time. Variation partitioning showed that local source variables (e.g., infrastructure, industries) explained less than 2% of variation for PFAS, OCPs, PBDEs and trace element compared to 17.2% for PCBs. Results suggest that effects of local contaminant sources are tightly linked to study site characteristics as well as seal biology. Local sources should be identified and assessed close to communities to ensure efficient mitigation measures.

3.19.P-We265 Recording the Baseline Before the Change: First Steps Towards an Integrated Chemical and Biological Pollution and Effects Assessment Off Dronning Maud Land Antarctica

Gesine Witt*[1], Matthias Brenner[2], Moritz Kielmann[1] and Sarah Zwicker[3], (1)HAW Hamburg, Germany, (2)Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, (3)Leibniz Centre for Tropical Marine Research (ZMT), Germany*

With rising global surface temperatures, an increasing number of volatile pollutants emitted in lower latitudes of the southern hemisphere will evaporate and undergo an, in turn, prolonged atmospheric long-range transport. Thus, more persistent organic pollutants (POPs) will eventually deposit in the southern cold-trap - the Antarctic. At the same time, a warming ocean will accelerate the re-release of ice-sealed contaminants into the Southern Ocean. Consequently, an increase in bioavailable anthropogenic pollution is a foreseeable perspective for Antarctica and its biota. However, in Dronning Maud land, this intensification of pollution stress and its biological implications will proceed somewhat unnoticed due to a

lack of holistic, baseline investigations of pollutants and their impact.
Therefore, in this project, we will perform an integrated pollution and risk assessment for Dronning Maud land and its biota, based on a three-month sampling campaign of the sea-ice of Atka Bay. Using innovative passive sampling techniques, we will investigate the current status of POP pollution in different environmental matrixes ranging from sea ice to (deceased) penguin tissue.
Starting at the onset of the melt season and extending into austral summer, we will follow up on the release of pollutants from the ice into the seawater and their putative uptake into ice alga and further into kill feeding on them. By determining pollutant body burdens, we will assess pollutants bioaccumulation and further biomagnification in Antarctic key species. Furthermore, in evaluating this in a recurring sample collection, we will learn about the seasonality of POP pollution.
As a significant counterpart to chemical analytics, we will complement the screening for POPs with a biological impact assessment. For this, we will investigate the biomarker response in krill to employing cellular and subcellular biomarkers of detoxification, oxidative stress, and regeneration. Again, the seasonal, stationary, sampling approach will enhance our knowledge of the variability of these physiological and potentially pathological responses. This will facilitate the interpretation of future sampling campaigns and forecast biomarker behavior. Involving other research stations in developing this concept, we aim to expand the current boundaries of pollution research and contribute to establishing future comprehensive and coordinated pollution and effect assessments in Antarctica.

Disclaimer/Disclosure: The project is funded by the German Research Foundation (DFG) as part of the DFG priority programme 1158 Antarctic Research, project number WI1410/13-1.

3.19.P-We266 PLASTFLOW - How Much Plastic Flows Into the Sea? Quantifying Plastic Fluxes and Identifying Plastic Hotspots in the Scheldt Estuary in Belgium

Nelle Siele Meyers[1]*, Ana I. Catarino*[2]*, Jana Asselman*[3]*, Ronny Blust*[4]*, Raewyn M. Town*[5]*, Hanne Diels*[6]*, Erik Toorman*[7]*, Nithin Achutha Shettigar*[7]*, Boudewijn Decrop*[8]*, Theofano Koutrouveli*[8]*, Els Knaeps*[9]*, Lisa Inès Devriese*[10]*, Silke De Buyser*[2]*, Jelle Rondelez*[2]*, Marie Robberecht*[2]*, Charlotte Dhondt*[2] *and Claudia Meneses*[2]*, (1)Ocean and Human Health, Flanders Marine Institute (VLIZ), Oostende, Belgium, (2)Flanders Marine Institute (VLIZ), Belgium, (3)Ghent University, Belgium, (4)University of Antwerp, Belgium, (5)University of Antwerpen, Belgium, (6)Unversity of Antwerpen, Belgium, (7)KU Leuven, Belgium, (8)IMDC, Belgium, (9)Flemish Institute for Technological Research (VITO), Belgium, (10)Ocean & Human Health, Flanders Marine Institute (VLIZ), Belgium*

Within the PLASTFLOW project, we aim to update the assessment of litter levels and plastic fluxes in the Scheldt estuary, Belgium, focusing on changes since the 2020-2021 baseline study. Through follow-up measurements during 2024-2025, the project focuses on quantifying seasonal variations, refining computational models of plastic fluxes, and providing clear insights into the amount of plastic flowing into the sea for policy development.
Sampling occurs at six locations along the Scheldt River, covering water and sediment across various depths to account for the behaviours and fluxes of different polymer types and densities. Surface water is sampled using net-based methods, while pollution in the water column is assessed with suspension and bedload samplers. Sediment is collected from the riverbed using a Van Veen grab, and riverbank samples are taken via quadrant-based approaches along transects, complemented by drone analysis. The combinations of these innovative methods provide a representative snapshot of macro-, meso-, and microlitter distribution.
During the planned campaigns within PLASTFLOW, three types of follow-up measurements are being acquired, each time during spring, summer, autumn, and winter: tidal cycle measurements, to assess and quantify the tidal movement of plastic particles along the Scheldt River; spot sampling measurements; and hotspot measurements, to assess long-term trends in microplastic deposition and identify key environmental parameters of plastic retention and accumulation.
Initial results point out Antwerp as a hotspot for microplastics in both water and sediment (286-615 plastics/m^3), pellets (2822-6611 pellets/m^3), mesoplastics (56-1238 plastics/m^3), and macroplastics (23-181 plastics/m^3). While areas further upstream appear to be hotspots for microplastics as well (151-778 plastics/m^3 at Wintam and 275 plastics/m^3 at Temse), meso- and macroplastic as well as pellet abundance on the riverbanks in both these areas was low (0-90 pellets/m^3, 1-20 mesoplastics/m^3, and 2-7 macroplastics/m^3).
All acquired samples will be used to produce computational models that will be applied to determine the

transport of plastic particles along the Scheldt estuary, and to validate those models. By integrating these results into computational models, the project will enhance predictions of plastic fluxes and accumulation, supporting updates to monitoring frameworks and aligning with the EU Green Deal's Zero Pollution Action Plan.

Disclaimer/Disclosure: This study was conducted within the scope of the Cmartlife project LIFE19 IPE/BE/000008, action D2 Monitoring the plastic flux. The Cmartlife project has received funding from the LIFE Programme of the European Union. More info about the project on: https://vlaco.be/kenniscentrum/onderzoeksprojecten/cmartlife

3.19.P-We267 Factors Influencing Regulated Pollutants in the Air of Admiralty Bay, Antarctic Peninsula

***Amanda Câmara de Souza**[1], Tatiane Combi[2], Cesar de Castro Martins[1] and Rafael Andre Lourenco[1], (1)Oceanographic Institute, University of São Paulo, Brazil, Brazil, (2)Center for Marine Studies, Federal University of Parana, Brazil*

Antarctic is an important sink for pollutants due to its low sea surface temperatures, long periods without solar radiation, and well-defined seasonality, enhancing pollutant deposition and limiting degradation. However, climate change challenges this role, as rising temperatures accelerate re-volatilization of persistent organic pollutants (POPs) and polycyclic aromatic hydrocarbons (PAHs) from soil and snow. This study aimed to investigate POPs and PAHs in the atmosphere of Admiralty Bay, Antarctic Peninsula, using semi-permeable membrane devices (SPMD) to understand the factors influencing their presence in the air. The sampling devices were deployed at two locations in the austral summer of 2023, spring of 2023, and summer of 2024. Identification and quantification of target analytes were performed using an Agilent Model 7890B gas chromatograph coupled to an Agilent Model 7010B triple quadrupole TQMS operating in multiple reaction monitoring mode. The detection of high concentrations of low-chlorinated PCBs and HCB being the most prevalent pollutant - both restricted under the Stockholm Convention - suggests that long-range atmospheric transport (LRAT) is the main pathway for POPs. Trajectory models indicate that air masses often originate from the Southern Ocean, South America, and the Antarctic Peninsula and act as potential sources of contamination. Higher PAH concentrations near local activities indicate an influence from research stations and tourism emissions. The predominance of HCBs over PAHs may indicate a significant role in degradation processes. Higher levels of contaminants during the austral summer and at coastal sites may indicate potential re-volatilization from water, soil, and snow reservoirs. In summary, the distribution of POPs and PAHs in Admiralty Bay results from multiple factors, including LRAT, local emissions, physicochemical properties, secondary sources, meteorological conditions, and air mass dynamics. This study demonstrates the feasibility of using SPMDs in Antarctica, providing a practical and efficient method for continuous monitoring in remote and challenging conditions. It also contributes to understanding pollutant dynamics in the Antarctic environment, highlighting the need for global emission controls and continuous monitoring of this vulnerable region.

Disclaimer/Disclosure: The work was supported by the Antarctic Brazilian Program (PROANTAR), Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq, 442692/2018-8; 440884/2023-3). A.C. Souza would like to thank Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP; grant no. 2020/15701-8 and grant no. 2024/05324-3). Finally, this work is part of the CARBMET project (The multiple faces of organic CARBon and METals in the Antarctica ecosystem) sponsored by CNPq, CAPES and Brazilian Ministry of Science, Technology, and Innovation.

3.19.P-We268 Emerging Per- and Polyfluoroalkyl Substances (PFAS) Induced Intestinal Barrier Dysfunction in Marine Medaka (*Oryzias melastigma*)

***Naiyu XIE**, Yuefei Ruan and Qi Wang, City University of Hong Kong, Hong Kong (Greater China)*

Perfluoroethylcyclohexane sulfonate (PFECHS) and 6:2 chlorinated polyfluoroalkyl ether sulfonate (6:2 Cl-PFESA) are emerging per- and polyfluoroalkyl substances (PFAS) and are considered as alternatives to perfluorooctane sulfonate due to their similarity in chemical structure and physicochemical properties. However, their adverse effects on marine organisms are not fully understood, particularly concerning intestinal health. In this study, newly fertilized marine medaka (*Oryzias melastigma*) was exposed to 6:2 Cl-PFESA and PFECHS at environmentally relevant concentrations (nominal: 0.1, 0.3, and 1.0??g/L) for 90 days to investigate their potential digestive toxicity. Results showed that 6:2 Cl-PFESA exhibited a higher bioaccumulation potential compared to PFECHS, and both emerging PFAS preferred to accumulate in the liver rather than the intestines. Physiological analysis demonstrated that PFECHS exposure disrupted the digestive system, as evidenced by increased activities of digestive enzyme (e.g., disaccharidase, alkaline protease, and neutral protease). Microbiome sequencing revealed that significant alterations in intestinal microbial community structure were observed in PFECHS-exposed medaka, with decreased relative abundance of beneficial bacteria (e.g., Bacteroides and Pseudomonas) and an increased proportion of Alkalimarinus and pathogenic bacteria Vibrio in the PFECHS-exposed group. Co-occurrence network analysis indicated a reduction in species interactions and network complexity after treatment with PFECHS. Correlation analysis revealed a close association between pathogenic bacteria and digestive enzymes. Our research emphasizes the potential risks of emerging PFAS and provides insights to evaluate the relationship between gut microbiota and intestinal barrier function, highlighting the necessity to establish risk assessment and management strategies for new pollutants.

3.19.P-We269 Pharmaceuticals and Other Compounds of Emerging Concern in the Wastewater Effluent of Cruise Ships in the Arctic

Veronica van der Schyff[1], Marek Stiborek[1], Zdenek Simek[1], Branislav Vrana[1], Verena Meraldi[2], Andrew Luke King[3] and ***Lisa Melymuk***[4]*, (1)RECETOX, Masaryk University, Czech Republic, (2)Hurtigruten Expeditions, United Kingdom, (3)Norwegian Institute for Water Research (NIVA), Norway, (4)Masaryk University, Brno, Czech Republic*

The cruise ship industry is the fastest-growing industry in the tourism sector. The size, passenger capacity, and number of amenities on modern cruise ships make them comparable to terrestrial settlements. As such, they can inflict similar pressures on the surrounding environment as urban areas, such as noise, air, and water pollution. Due to improvements in ship design and technology, as well as receding polar ice, cruising in polar regions has seen an increase of 118% between 2018 and 2022.

This study investigates the chemical composition of wastewater from three expedition cruise ships operating in the North Atlantic and Arctic waters, focusing on pharmaceuticals, personal care products, and industrial chemicals. Wastewater was collected from the final holding tank prior to discharge, containing treated black-and grey water. Over 150 distinct compounds were identified or present with a high probability at Schymanski level 1 and 2. Analysis was done using high-performance liquid chromatography-electrospray ionization quadrupole time-of-flight mass spectrometry (HPLC-ESI-QTOF). Twenty seven compounds were identified with high probability in all three ships, which warrant priority attention in future studies. For all ships, pharmaceuticals dominated the chemical profile (43-58% of identified compounds), followed by industrial chemicals (21-30%), and natural compounds (12-15%). The compound group of the highest concern is pharmaceuticals due to their potential for biological activity at low concentrations, even after wastewater treatment. The pharmaceuticals present were primarily cardiovascular medications. Additionally, multiple antibiotics were detected, raising concerns that cruise ship wastewater effluent could contribute to the spread of antibiotic-resistant bacteria.

Other ships, like naval vessels and cargo ships, are expected to have distinctly different chemical profiles, with industrial chemicals dominating cargo ship wastewater, while passenger-heavy ships such as ferries may have higher concentrations of pharmaceuticals and personal care products. Investigating wastewater discharge across shipping industries, particularly in sensitive habitats such as polar regions and coral reefs, is crucial to understanding the broader impact of shipping on global pollution levels.

3.19.P-We270 Nontarget Analysis of Arctic Sediments: An Empirical Indicator of Persistent Chemicals Overlooked by Regulation

Xiaodi Shi[1]*, Liisa Jantunen[2], Jane Kirk[2], Amila O. De Silva[3], Orjan Gustafsson[4], Anna Sobek[5] and Jonathan P. Benskin[6], (1)Stockholm University, Stockholm, Sweden, (2)Environment and Climate Change Canada (ECCC), Canada, (3)Environment and Climate Change Canada (ECCC), Gatineau, Canada, (4)Stockholm University, Sweden, (5)Environmental Science, Stockholm University, Sweden, (6)Department of Environmental Science (ACES), Stockholm University, Sweden*

Arctic sediments function as a receptor for global anthropogenic chemicals. As a consequence, detection of chemicals in remote Arctic sediments offers empirical evidence of their persistence, long-range transport (LRT) potential, and, indirectly, high production volumes. In other words, detection of chemicals in remote Arctic sediments is useful for assessing the persistence criteria for regulation. The overarching aim of this project is to apply state-of-the-art mass spectrometric tools on high Arctic sediments to identify persistent contaminants of global concern, and then apply statistical and modeling approaches to further understand their emission sources and LRT. Three high Arctic lake sediment cores and 81 circum-Arctic shelf surface sediments were obtained from archives at Stockholm University and Environment and Climate Change Canada to assess the prevalence, temporal and spatial variability of contaminants, along

with dominant LRT pathways.
Samples were characterized using a newly developed gas chromatography-atmospheric pressure chemical ionization-ion mobility-high resolution mass spectrometry method, for simultaneous target, suspect, and non-target analyses of a wide range of hydrophobic organic chemicals. In addition to known substances (including polycyclic aromatic hydrocarbons, polychlorinated biphenyls, organochlorine pesticides, and organophosphate esters), we annotated 78 substances at Confidence Level 2/3 according to the Schymanski scale. Of these substances, 81% were reported in Arctic sediments for the first time, while 86% were not part of the Arctic Monitoring and Assessment Programme's list of chemicals of emerging Arctic concern, including a novel fluorotelomer methylsulfone. Taken together, this work offers new knowledge on emission sources and global transport of persistent chemicals of global concern while providing scientific guidance on analytical approaches to help improve chemical management and policy.

3.19.P-We271 Microplastics Distribution and Occurrence in Greenlandic Fjords

Tristan Zimmermann[1], *Lars Michael Hildebrandt*[2], *Cornelius Vetter*[3], *Claudia Elena Schmidt*[3], *Daniel Profrock*[1] *and Helmuth Thomas*[3], *(1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (3)Helmholtz-Zentrum Hereon, Germany*

The northeastern coast of Greenland (Tunu) is hardly, if at all, inhabited and reveals near pristine characteristics. As sea ice still covers the fjords and ocean for most of the year, the population and vessel densities are close to zero. Nevertheless, microplastics (MPs, 1 5,000 µm) and nanoplastics (< 1 µm) are to be found even in places without nearby pollution sources. To date, there is only a limited number of studies on micro- and nanoplastics (MNPs) in the Arctic and numerous questions regarding their transport, distribution, fate, and final consequences forin this unique environment remain unanswered.

Within this context microplastic sampling was conducted at eight locations within the fjords of East Greenland and the Denmark Strait with the research vessel Maria S. Merian in August 2022 (cruise MSM110, Ecological tipping cascades in the Arctic seas (ECOTIP)), using the Geesthacht Inert MP Fractionator . Four fractions were taken per sampling statione: one hydrocyclone and three filter cartridges with a 300 µm, 100 µm and 10 µm mesh size. 2.5 to 5.2 m3 of ocean water were filtered per sample to process a representative water volume. Transflection-mode infrared spectroscopic measurements were conducted using an Agilent 8700 Laser Direct Infrared (LDIR) Chemical Imaging System.

Measured MP number concentrations ranged between 12 ± 4 L 1 (1 SD, n = 4) at the mouth of the Scoresby Sound and 1.0 ± 0.8 L 1 (1 SD, n = 3) in the Dove Bay. Twelve polymer types were identified in total. PET is by far the most abundant polymer type in all 18 samples with an overall average share of 96 ± 3% (1 SD, n = 18). Polylactic acid (PLA) is the second most frequent polymer type with an average share of 1.6 ± 0.5% (1 SD, n = 18).

The fjords of East Greenland and the Denmark Strait are notable hotspots for MP pollution. On average, PET constituted 96% of the total MP abundance, while PLA constituted 1.6%. The level of PLA detected is believed to be the highest ever recorded in marine samples, which raises questions regarding its source and transport. The results revealed no discernible trends between MP concentration, polymer composition, or size distribution and glacial meltwater inputs. Therefore, it is assumed that oceanic currents and sea ice transport exert a substantial influence on the distribution of MPs. The collection of replicate samples proved to be important in demonstrating the temporally varying patchiness of MP distributions.

3.19.P-We272 Global Monitoring of Microplastic Pollution Exceeding 20 Microns: A Study Using Commercial Tanker Ships in the Atlantic, Pacific, and Indian Oceans

Yutaka Kameda, *Chiba Institute of Technology, Japan*

Microplastics (MPs) in the marine environment remain a global concern, as degraded and fragmented MPs pose a heightened risk to marine organisms. While many studies have investigated MPs in oceans worldwide, the diversity in sampling and analytical methodologies has hindered the ability to compare results and fully understand their distribution.
In collaboration with NYK Line, we conducted a global survey of MPs using commercial tanker ships. Seawater was collected from fire hydrants aboard vessels and filtered using 10 µm mesh plankton nets, following a standardized methodology based on Kameda et al.'s approach. This enabled the collection of samples from 198 sites at depths ranging from 5 to 10 meters below the surface. Extracted MPs were

filtered onto PTFE membranes, and micro-FTIR imaging technology combined with identification software YCALOS that we developed was used to accurately identify and quantify MPs larger than 20 µm across the entire membrane surface.
MP concentrations ranged from 23.7 to 4660.0 particles/m^3 (n=100), with 15 types of polymers detected, including ABS, alkyd resin, polyacrylate-styrene, epoxy resin, polyamide, PE, PET, PMMA, polyphenylene sulfide, PP, polystyrene, polyurethane, polyvinyl acetate, polyvinyl chloride, and styrene-butadiene rubber.
Using kriging interpolation, contour maps were created to reveal the distribution patterns of each polymer. MPs concentrations were found to be generally higher in the Northern Hemisphere compared to the Southern Hemisphere. In the Atlantic Ocean, a significant outflow of MPs was observed near the Amazon River estuary. Moreover, distinct differences in distribution were noted among various polymer types. These findings provide critical insights into the global distribution and degradation of MPs in the marine environment, enhancing our understanding of marine plastic pollution. The results offer valuable data that can inform strategies for mitigation and foster a more comprehensive understanding of the impacts of MPs on marine ecosystems.

3.19.P-We273 PFAS Presence in Antarctic Drinking Waters

Belen Gonzalez-Gaya[1]*, Juan Francisco Ayala Cabrera*[1]*, Ivan Dorado*[2]*, Yolanda Segura*[2]*, Luis Moreno*[3]*, Adrian Silva*[4] *and Yolanda Valcarcel Rivera*[2]*, (1)Plentzia Marine Station, University of the Basque Country, Spain, (2)University Rey Juan Carlos, Spain, (3)Geological and Mining Institute of Spain (IGME-CSIC), Spain, (4)Argentine Antarctic Institute, Argentina*
Per- and polyfluoroalkyl substances (PFAS) are highly persistent substances, known as the forever chemicals. According to scientific results, several deleterious health consequences can be attributed to PFOA and PFOS including hepatotoxicity, growth disturbance, or neurobehavioral, immune and reproductive toxicity. At the moment, drinking water is considered as one of the main exposure routes of PFAS for humans and can be particularly relevant in isolated locations where poor water treatment systems are implemented or long storing periods for drinking water are required.
The aim of the work has been to determine the presence of PFAS in the drinking water consumed at various scientific bases located in the northern Antarctic Peninsula (Vashel Bay, South Orkney Islands, Dundee Island). This is the first study to analyze the presence of PFAS in water for human use in Antarctica.
Briefly, a validated protocol using HLB cartridges was applied to extract PFAS. The analysis was done using high-throughput cutting-edge methodologies based on HRMS (Q Exactive Focus quadrupole-Orbitrap, Thermo-Fisher Scientific) combining ionization sources such as heated electrospray (HESI) and atmospheric pressure chemical ionization (APCI) to sort out the complexity on the analysis of PFAS by extending the analyte coverage of the LC-HRMS methodologies.
Targeted analysis included 42 substances from different families including new emerging PFAS such as ADONA or HFPO-DA (GenX). Preliminary results show that 14 individual PFAS were detected in the drinking water from the bases, including PFBA, PFOA, PFBS, PFOS, FOSA, 6:2 FTCA or 4:2 FOTH. The preliminary results indicate safe levels of PFAS according to EU Drinking Water Directive (2020), according to a limit of 0.5 µg/l for individual regulated PFASs. However, considering the sum of the whole PFAS detected, the established limits are surpassed.
Suspect screening is being conducted using Compound Discoverer 3.3.2.31 (ThermoFisher Scientific) software with a PFAS specifically designed workflow. This analysis aims to detect the max number of fluorinated substances, to uncover the occurrence of other PFAS in drinking water. A system of surveillance and control of the presence of these substances in Antarctic bases should be implemented to protect researchers and itinerant population as well as reduce their environmental presence.

Disclaimer/Disclosure: URJC Program for Promotion and Development of Research and Innovation is thanked for funding. JFAC acknowledges the European Union (EU) for his Marie Curie postdoctoral fellowship. BGG acknowledges IkerBasque Foundation for her tenure track position.

3.19.P-We274 Cross-Cutting Studies of Per- and Polyfluorinated Alkyl Substances (PFAS) in Arctic Wildlife and Humans

Khaled Abass[1]*, Eva Cecilie Bonefeld-Jorgensen*[2]*, Rossana Bossi*[3]*, Rune Dietz*[4]*, Steve Ferguson*[5]*, Kim J. Fernie*[6]*, Philippe Grandjean*[7]*, Dorte Herzke*[8]*, Magali Houde*[9]*, Melanie Lemiere*[10]*, Robert J. Letcher*[11]*,* ***Derek C.G. Muir***[12]*, Amila O. De Silva*[9]*, Sonja Ostertag*[13]*, Amy Rand*[14]*, Jens Sondergaard*[4]*, Christian*

Sonne[15], Elsie Sunderland[16], Katrin Vorkamp[3], Simon Wilson[17] and Pal Weihe[18], (1)University of Oulu, Finland, (2)University of Aarhus, Denmark, (3)Department of Environmental Science, Aarhus University, Denmark, (4)Aarhus University, Denmark, (5)Fisheries and Ocean Canada, Canada, (6)Environment and Climate Change Canada (ECCC), Burlington, ON, Canada, (7)University of Rhode Island, United States, (8)NILU, Norway, (9)Environment and Climate Change Canada (ECCC), Gatineau, Canada, (10)Universite Laval, Canada, (11)National Wildlife Research Centre, Environment and Climate Change Canada (ECCC), Gatineau, QC, Canada, (12)Environment and Climate Change Canada (ECCC), Canada, (13)University of Waterloo, Canada, (14)Chemistry, Carleton University, Canada, (15)Bioscience, Aarhus University, Denmark, (16)Harvard University, United States, (17)AMAP, Norway, (18)Faroese Health Authority, Faroe Islands
The Arctic Monitoring and Assessment Program initiated a cross-cutting activity to integrate knowledge across the Arctic region on the presence and impacts of per- and polyfluoroalkyl substances (PFAS). Several PFAS undergo long-range transport via atmospheric (volatile polyfluorinated compounds) and oceanic pathways (perfluorinated alkyl acids, PFAAs), causing widespread contamination of the Arctic. Beyond targeting a few well-known PFAS, applying sum parameters, suspect and non-targeted screening are promising approaches to elucidate predominant sources, transport, and pathways of PFAS in the Arctic environment, wildlife, and humans, and establish their time-trends. Across species, concentrations were dominated by perfluorooctanesulfonic acid (PFOS), followed by perfluorononanoic acid (PFNA); highest concentrations were present in mammalian livers and bird eggs. Time trends were similar for East Greenland ringed seals (*Pusa hispida*) and polar bears (*Ursus maritimus*). In polar bears, PFOS concentrations increased from the 1980s to 2006, with a secondary peak in 2014-2021, while PFNA increased regularly in the Canadian and Greenlandic ringed seals and polar bear livers. Human time trends vary regionally (though lacking for the Russian Arctic), and to the extent local Arctic human populations rely on traditional wildlife diets, such as marine mammals. In accordance to the highest level of PFAS found in East Greenland marine mammals, the human population at the East coast elicited the highest PFAS concentration. Arctic human cohort studies implied that several PFAAs are immunotoxic, carcinogenic or contribute to carcinogenicity, and affect the reproductive, endocrine and cardiometabolic systems. Physiological, endocrine, and reproductive effects linked to PFAS exposure were largely similar among humans, polar bears, and Arctic seabirds. For most polar bear subpopulations across the Arctic, modeled serum concentrations exceeded PFOS levels in human populations, several of which already exceeded the established immunotoxic thresholds for the most severe risk category. Data are typically limited to the western Arctic region and populations. Monitoring of legacy and novel PFAS across the entire Arctic region, combined with proactive community engagement and international restrictions on PFAS production remain critical to mitigate PFAS exposure and its health impacts in the Arctic.

3.19.P-We275 Developing a Risk Assessment Framework for Mineral Based Ocean Alkalinity Enhancement

***Kristi Kay Weighman**[1], Emilia Jankowska[2] and Grace Andrews[1], (1)Hourglass Climate, United States, (2)Hourglass Climate, Poland*
Climate change presents an unprecedented challenge, demanding rapid, scalable solutions to address rising greenhouse gas levels and temperatures. Among various approaches, ocean alkalinity enhancement (OAE) has emerged as a promising carbon dioxide removal (CDR) strategy. In addition to boosting the ocean s capacity to absorb and store CO?, OAE mitigates ocean acidification, offering relief to stressed marine ecosystems. However, scaling OAE requires a robust environmental risk assessment (ERA) framework to evaluate potential impacts, such as those of alkalinity feedstocks on marine life. This framework should integrate lab studies, field experiments, and modeling to adapt to diverse implementation scenarios. Hourglass is developing a predictive tool for evaluating the ecotoxicological impacts of OAE to support responsible project design, permitting, and scaling of this CDR solution for climate mitigation. This ERA focuses on the dissolution products of mineral alkalinity feedstocks like olivine, particularly the bioavailability and toxicity of nickel the primary trace metal found in olivine. By combining fate and transport modeling, biotic ligand modeling (BLM), and toxicokinetic-toxicodynamic (TKTD) modeling, the ERA simulates nickel exposure scenarios based on olivine application data, predicting effects on marine species and populations.
In particular, Hourglass is using The General Unified Threshold model of Survival (GUTS) to simulate nickel exposure scenarios based on field data, contributing to the development of a comprehensive ERA framework. GUTS, recognized by the European Food Safety Authority in 2018 for assessing pesticide risks to aquatic organisms, is a natural choice for TKTD modeling in olivine applications. By simulating

survival across varied exposure scenarios, GUTS helps establish safe concentration thresholds and exposure durations. Its open-source, user-friendly design will help support wide-spread adoption by the emerging CDR industry.

3.19.P-We276 Climate Change and Permafrost Thaw Impact on Drinking Water Quality in Greenland

Ida Huusmann Knofler, *Lisbeth Truelstrup Hansen and Pernille Erland Jensen, Technical University of Denmark, Denmark*

Permafrost underlies 22% of the Northern Hemisphere's exposed land surface and is thawing at an alarming rate as a direct consequence of climate change. Permafrost thaw may potentially release stored organic matter and contaminants into the environment. Contaminants, including heavy metals, persistent organic pollutants and infectious agents locked in permafrost, may present a risk for both human and animal health. This project aims to understand the impact of permafrost thaw to water quality and thus health in Greenland. To evaluate the impact on drinking water quality in Greenland different sites spanning the west coast have been selected. Since most of the Greenlandic communities are supplied with water sourced from lakes, the sampling focus is evolving around this. To get a first evaluation of the recent historic pollution in water lakes in Greenland, 50 cm sediment cores have been collected from the drinking water lakes in Sisimiut (in the sporadic permafrost zone) and Ilulissat (in the continuous permafrost zone), and divided into 4.5 cm increments, which will be dated via the 210Pb dating method. The dated cores will be analyzed for their content of nutrients (phosphorous and nitrogen) and organic matter, organic local and long distance transported contaminants (polychlorinated biphenyls and fuel products including polycyclic aromatic hydrocarbons), local organic contaminants (fuel products), heavy metals and radionuclides. Alongside the chemical assessment, presence of cyanobacteria and fecal contaminants will also be evaluated by dPCR analysis on extracted DNA. The results will provide a solid offset for our further investigations to create an understanding of how historic and current contaminant emissions combined with climate change related temperature increases affect the quality of freshwaters in an area with permanently frozen ground.

3.19.P-We277 Pollution of Microplastics in the Pearl River Estuary of China: From the Perspective of Multiple Environmental Media

Xinhong Wang, *Xiamen University, China (Mainland)*

The estuarine hydrological changes lead to the dramatic changes of pollutants in estuary. A comprehensive understanding of the changing characteristics of estuarine pollutants is essential for environmental management. This study investigated the abundance and concentration, seasonal variations of microplastics in groundwater, water column, and sediments in the Pearl River estuary using FITR and py-GC/MS. The results found that the average abundance of microplastics in groundwater was 2694 p/m^3 with an average concentration of 150.47 mg/m^3. In the water column, the average abundance was 243.86 p/m^3 with an average concentration of 0.52 mg/m^3 in winter, and 112.27 p/m3 with an average concentration of 0.21 mg/m^3 in summer. In sediment, the average abundance was 117.78 n/kg with an average concentration of 4.24 mg/kg. Microplastics exhibited spatial and temporal variability in their pollution characteristics across different environmental media. The level of PVC contamination in the water column was underestimated, and a large amount of PP and PE was deposited in the sediments. FITR-corrected py-GC/MS was used to determine the loadings and contributions of microplastics. The Pearl River estuary transported a total of 1605.3 t of microplastics during the dry season, Surface runoff contributed the largest amount, accounting for 67.52% of the total. Besides, it was important to consider the contribution of groundwater and sediments. This work provided a comprehensive analysis of the environmental fate of microplastics in various environmental media, quantified their concentration, and enhanced our understanding of microplastic fluxes to the sea in estuaries.

3.19.P-We278 Unraveling the Effects of Microfibers Across Treatment stages via a critical prey species, in the context of climate change

Lauren Miki Kashiwabara[1], Patrick Reece[2], Clarissa Raguso[3], Lisa Hildebrand[2], Leigh Torres[2] and ***Susanne M Brander, (she, her, hers)***[2]*, (1)Department of Fisheries, Wildlife, and Conservation Sciences, Oregon State University, Corvalis, United States, (2)Oregon State University, United States, (3)University of Milan, Oregon State University, Italy*

Mysid shrimp are an important prey item in marine and freshwater food webs globally, including those

containing key predators such as gray whales and salmonids. Gray whales require millions of zooplankton daily, primarily mysids, and are threatened by worsening climate conditions such as ocean acidification. Additionally, whales can consume of over 20 million microparticles (primarily microfibers) daily from mysid prey. Microfibers exert chemical and physical toxicity, but knowledge is sparse regarding how much each contributes to organismal stress. Therefore, our goals were to further estimate impacts to coastal food webs and to better understand the contribution of chemical vs. physical effects from microfibers, in addition to understanding impacts in the context of climate change on these critical prey species. We quantified responses to polyester microfibers across treatment stages (griege/naïve, ozonated, chemically modified) and weathering states, including low pH exposure, on native and surrogate mysids. Briefly, microfibers were produced from textiles across treatment stages provided by an anonymous clothing manufacturer. Mysids were exposed to 5 (A. bahia, purchased) or 10 microfibers (H. sculpta, native field collected) / mL for 7 days or 48 hours, respectively. Following exposures, A. bahia underwent a sublethal low pH challenge. Behavioral toxicity was measured in both species. Results demonstrate that growth was reduced in A. bahia, and behavioural responses are predominately hypoactive, being most sensitive to chemical treatment or weathering, and potentially exacerbated at a lower pH. Behavioural impacts are more pronounced in native H. sculpta. These effects have broad implications for individual, population and ecosystem health. Current studies investigate the same fabric treatments in cotton in both species, including RNA seq analysis, and seek to better understand microfiber occurrence in relevant coastal areas. To our knowledge, this is one of the first studies utilizing textile microfibers across known treatment stages in both native and surrogate (model) species and could directly inform more sustainable textile production in the future.

3.19.P-We279 Per- and Polyfluoroalkyl Substances (PFAS) in Sub-Antarctic Seabirds: Evidence for Long-Range Transport and Bioaccumulation of Emerging Contaminants

Imogen Bailes[1]*, Jonathan Barber*[2]*, Sara Losada*[2]*, Richard Phillips*[3]*, Lloyd Peck*[3]*, Christopher Green*[4] *and Andrew Sweetman*[5]*, (1)Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom, (2)Cefas, United Kingdom, (3)British Antarctic Survey (BAS), United Kingdom, (4)DEFRA, United Kingdom, (5)Lancaster University, United Kingdom*

Poly- and perfluoroalkyl substances (PFAS) are a large group of chemicals that are characterised by a hydrophilic moiety (e.g., SO3- or COO-) and a hydrophobic perfluorocarbon chain that varies in length. PFAS display unique properties due to combined oil and water repellence, extreme stability, and hence are used in a wide range of industrial processes and consumer products. These chemicals can be problematic in the environment due to their potential to undergo long-range transport, persistence and toxicity. Some longer-chain PFAS have already been listed in the Annexes of the Stockholm Convention and included in other international regulations, but replacements have started to emerge. Furthermore, the European Chemicals Agency (ECHA) is seeking to ban the use and production of PFAS (defined as chemicals containing CF2) completely in Europe. As such, it is important to document current levels of both legacy and emerging PFAS in the environment prior to this proposed ban so that any resulting decline in concentrations can be assessed accurately. Here, we employ an ultra-performance liquid chromatography coupled to a high-resolution mass spectrometer (Orbitrap) to analyse a range of both legacy and emerging PFAS including 11 PFCAs (C4-C14), 9 PFSAs (C4-C10), 3 FASAs, 3 PFPiAs and 6 fluorotelomer acids, among others. We have analysed the liver tissues of 78 seabirds, from 13 different species sampled from South Georgia between 2018 and 2022. The data show varying spatial and temporal trends between different species and we draw comparisons between trophic levels by employing stable isotope analysis. Trends in these data reveal various pathways e.g., atmospheric and hydrospheric, for PFAS into the Southern Ocean before bioaccumulating through food chains. Our research addresses the need to understand exposure levels in wildlife to PFAS compounds in areas close to and remote from sources.

3.19.P-We280 Occurrence of Chemicals of Emerging Concern in Antarctic Soil

Wenying Mi[1]*, Yujue Yang*[2]*, Nengfei Wang*[3]*, Anette Kuster*[4]*, Jan Koschorreck*[4]*, Xiangzhou Meng*[5] *and* ***Zhiyong Xie***[6]*, (1)MINJIE Institute of Environmental Science and Health Research, Germany, (2)Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, China (Mainland), (3)Linyi University, China (Mainland), (4)German Environment Agency (UBA), Germany, (5)Tongji University, China (Mainland), (6)Helmholtz-Zentrum Hereon, Germany*

Chemicals of emerging concern (CECs), including pharmaceuticals, personal care products, and industrial chemicals, are increasingly detected in remote environments due to anthropogenic activities. This study investigates the occurrence and distribution of CECs, e.g. phthalate esters, organophosphate esters, UV filters and musk fragrances in Antarctic soils. Soil samples were collected near the Chinese Zhongshan Station, located on the Larsemann Hills of east Antarctica. This region experiences a warming trend, is relatively humid, and has a sub-Antarctic maritime climate. The vegetation in this area is very sparse. Samples were collected in 2008, 2014, and 2019 from five locations, including below-peak soil, intertidal soil, and sediment. After Soxhlet extraction, samples were analyzed using an Agilent gas chromatograph coupled to a triple quadrupole mass spectrometer (LC-MS/MS). Results revealed the presence of a range of contaminants, including synthetic musk, plasticizes and flame retardants, with concentrations varying from different locations. These findings indicate both long-range transport and localized sources of pollution. The persistence of these chemicals raises concerns about their potential ecological impacts on Antarctic flora and fauna, which are adapted to the Antarctic environment. This study underscores the need for improved waste management practices at research stations and highlights the importance of monitoring CECs in fragile ecosystems to mitigate their long-term environmental consequences.

3.19.P-We281 Local Sources Versus Long-Range Transport of POPs and CEACs in the Arctic: Future Developments Related to Climate Change

Derek C.G. Muir[1]*, Maria Gunnarsdottir*[2]*, Krystyna Koziol*[3]*, Frank von Hippel*[4]*, Danuta Szuminska*[3]*, Nicoletta Ademollo*[5]*, Simonetta Corsolini*[6]*, Amila O. De Silva*[7]*, Geir Wing Gabrielsen*[8]*, Roland Kallenborn*[9]*, Zaneta Polkowska*[10]*, Eva Kruemmel*[11] *and Katrin Vorkamp*[12]*, (1)School of Environmental Sciences, University of Guelph, Canada, (2)University of Iceland, Iceland, (3)Kazimierz Wielki University, Poland, (4)University of Arizona, United States, (5)National Research Council, Italy, (6)University of Siena, Italy, (7)Environment and Climate Change Canada (ECCC), Gatineau, Canada, (8)Norwegian Polar Institute, Norway, (9)Norwegian University of Life Sciences, Norway, (10)Gdansk University of Technology, Poland, (11)Inuit Circumpolar Council, Canada, (12)Aarhus University, Dominica*

Local sources of persistent organic pollutants (POPs) and Chemicals of Emerging Arctic Concern (CEACs) from use in communities, shipping, and industrial activity contribute to Arctic contamination as does long-range environmental transport. Increased human activity in the Arctic as the climate warms may enhance the significance of local sources. Furthermore, climate change may lead to secondary sources from existing reservoirs of POPs and CEACs in the Arctic. This review examines the emerging evidence for releases from these secondary sources of formerly deposited POPs and CEACs as the Arctic climate warms and the potential for future releases with increased infrastructure development and economic activity. Arctic permafrost degradation represents an important source of natural and anthropogenic polycyclic aromatic hydrocarbons (PAHs), and indications of POP releases related to permafrost thaw, from previous deposition as well as waste sites. Deposition of POPs and some CEACs to Arctic glaciers is relatively well studied while fewer studies explore the impacts of remobilization. Expansion of economic development may increase emissions or create new sources of CEACs in the Arctic. The predicted northward expansion of agriculture, aquaculture, and ship traffic could bring increased emissions of CEACs to northern waters, including pesticides not previously used in the Arctic. Increased industrial chemical use, such as fire-fighting foams, flame retardants, and lubricant and plastic additives, is likely to occur following the expansion of infrastructure such as airports, seaports, mining, and oil and gas development. While PAHs are relatively well-studied, there is an urgent need for environmental measurements and modelling of emissions of CEACs associated with the expansion of economic activity in the Arctic as well as to predict the future release of legacy POPs from secondary sources, particularly from permafrost.

3.19.P-We282 Identifying Bioaccumulative Emerging Per- and Polyfluoroalkyl Substances in a Coastal Food Web

Yuefei Ruan[1]*, Qi Wang*[1]*, Kenneth M.Y. Leung*[1] *and Paul K.S. Lam*[2]*, (1)City University of Hong Kong, Hong Kong (Greater China), (2)Hong Kong Metropolitan University, Hong Kong (Greater China)*

The trophodynamics of many emerging per- and polyfluoroalkyl substances (PFASs) in aquatic food webs remain poorly understood. Here, coastal seawater and marine organism samples were collected from the northern South China Sea to investigate the trophic biomagnification potential of legacy and emerging PFASs. Significant trophic magnification was observed for 22 PFASs, where the trophic magnification

factors of cis- and trans-perfluoroethylcyclohexane sulfonate (PFECHS) isomers were reported for the first time. Perfluorohexanoic acid was trophic-magnified, possibly attributed to the PFAS precursor degradation.
Our study is extended to lab-based validation. The toxicokinetics of emerging PFASs have rarely been reported. Here, tissue-specific uptake and depuration kinetics of PFECHS and 6:2 and 8:2 chlorinated polyfluoroalkyl ether sulfonates were studied in marine medaka (*Oryzias melastigma*). Evident bioconcentration was found for these three PFASs in the exposed fish, which showed longer residence times in eyes than in other tissues; trans-PFECHS showed higher bioconcentration potential than cis-PFECHS, and PFECHS exposure resulted in significant alterations in multiple proteins associated with eye function in medaka.

However, any opinions, findings, conclusions, or recommendations expressed in this publication do not reflect the views of the Hong Kong SAR Government or the ITC.

3.20 Chemical Fate in the Soil-Plant-System and Related Impacts and Risks

3.20.T-01 Uptake of Tire-Derived Compounds by Lettuce Grown in Soils

Anya Sherman[1]*, Luzian Hammerle*[1]*, Evyatar Ben-Mordechay*[2]*, Thorsten Huffer*[1]*, Benny Chefetz*[2] *and Thilo Hofmann*[1]*, (1)University of Vienna, Centre for Microbiology and Environmental Systems Science, Department of Environmental Geosciences EDGE, Austria, (2)Department of Soil and Water Sciences, Institute of Environmental Sciences, Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel*

Tire wear particles and associated organic compounds (tire-derived compounds, TDCs) enter agricultural environments via irrigation with treated wastewater and application of biosolids. In recently published work, multiple TDCs were detected in commercial leafy vegetables, at concentrations up to 665 ng/g dry weight, confirming that TDCs are present in the agricultural environment and accumulate in edible plants. Lettuce uptake and translocation of five TDCs, namely benzothiazole, 1,3-diphenylguanidine (DPG), hexamethoxymehtylmelamine (HMMM), N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD), and 6PPD-quinone was previously studied hydroponically. In hydroponic experiments, compounds are assumed to be completely bioaccessible for plant uptake, whereas in soil systems mainly the fraction of compounds dissolved in soil pore water is bioaccessible. In this study, we investigated the uptake of the same TDCs by lettuce plants grown in three soils, where TDCs were continuously introduced to the soil-plant system via spiked irrigation water over twenty-six days. TDCs were detected in lettuce grown in all three soil types (1.1 94.4 ng/g), but at very different concentrations than in hydroponic studies. These differences could be attributed to the bioaccessibility of TDCs in soils. Sampling of soil at different depths revealed that vertical mobility was low, and that all TDCs were predominantly retained in the root zones of plants. However, bioaccessibility was reduced by the formation of non-extractable residues in soils, especially for HMMM and 6PPD, which reduced their accumulation in lettuce plants. Bioconcentration factors, calculated as the ratio of TDCs measured in lettuce leaves to the extractable fraction of TDCs in soil, were in agreement with results from our hydroponic study, confirming that lettuce uptake and translocation processes were consistent between the two systems. Accumulation of all studied TDCs (including both neutral and cationic species) was greatest in lettuce grown in soil with a high sand and low clay content, and lowest in lettuce grown in soil with a low sand and high clay content. Together with previously published work, these novel results demonstrate that both plant uptake and translocation, as well as bioaccessibility in soil determine the accumulation of tire-derived compounds in leafy vegetables, which introduces these contaminants of emerging concern into the food supply.

3.20.T-02 Do Persistent and Mobile Chemicals Impact Agricultural Wastewater Reuse? – Accumulation in Arugula

Alina H. Seelig[1]*, Veikko Junghans*[2]*, Thorsten Reemtsma*[1] *and* ***Daniel Zahn***[1]*, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Humbold University Berlin, Germany*

With increasing water stress agricultural wastewater reuse is becoming increasingly relevant worldwide, which leads to higher demands on wastewater quality to minimize detrimental effects of human and environmental exposure with contaminants. Persistent and mobile (PM) chemicals are difficult to remove from wastewater, many of them passing even advanced wastewater treatment without significant concentration reduction. Consequently, these PM chemicals seem highly relevant for wastewater reuse, yet little is known on their up-take by plants. This study investigates the uptake by and distribution in arugula (Eruca sativa var. Speedy) for 65 PM chemicals in pot experiments with spiked water. Water uptake of the plants was controlled to calculate the maximum theoretical uptake (TMU; amount of irrigation water taken up * concentration in irrigation water). Uptake into edible parts of arugula exceeded 10% of the TMU for 18 PM chemicals and reached up to 64% of the TMU for perfluoropropionic acid. The median plant uptake into edible parts was 2.8 times higher for PM chemicals studied herein compared to 50 less polar anthropogenic chemicals from literature ($p = 0.05$) while the median translocation factor describing the distribution between roots and the edible parts of the plant was six times higher for the PM chemicals tested compared to 98 chemicals from literature studies ($p = 0.005$). These results are in contrast to established models for plant uptake often predicting a reduced uptake for very polar chemicals. In irrigation experiments with reclaimed wastewater 25 PM chemicals were detected in arugula leaves with concentrations of up to 115 ng/g fresh weight. A risk assessment based on the toxicological threshold of concern showed that no critical exposure can be reached with normal consumption levels. However, for more than half of the PM chemicals with a TMU > 10% experimental toxicity data is missing and additional exposure pathways (e.g. drinking water) may contribute significantly to the total human exposure with PM chemicals. Consequently, PM chemicals should be evaluated critically in the context of agricultural wastewater reuse as they seem to combine a low potential for removal during water treatment with an increased potential for plant uptake.

Disclaimer/Disclosure: The authors thank the German Federal Ministry of Education and Research (BMBF, Bonn, Germany) for funding the project Point-of-Use Re-Use: Dezentrale landwirtschaftliche Wiederverwendung von häuslichem Abwasser zur Verringerung von Nutzungskonkurrenzen PU2R (FKZ: 02WV1564G).

3.20.T-03 Passive Sampling in Soil

Abdullah Shahid[1], *Alexandra Kate Richardson*[2], *Christopher Sweeney*[3], *Helene Fain*[4] *and Leon Barron*[5], *(1)Environmental Research Group, Imperial College London, South Kensington, United Kingdom, (2)Imperial College London, South Kensington,, United Kingdom, (3)Syngenta Ltd, Bracknell, Berkshire, United Kingdom, (4)Syngenta, United Kingdom, (5)Environmental Research Group, Imperial College London, United Kingdom*

The viability of using passive sampling for plant protection products in soils is presented. Currently available passive sampling technologies are lacking due to high costs, poor scalability and difficulty of use. A 3D-printed passive sampling device (3D-PSD), previously validated for water analysis, was repurposed for soil deployment. An analytical method was first developed, and its performance was evaluated for the quantitative determination of 18 compounds in passive sampler extracts, soil and leachate with respect to linearity, range, accuracy, precision, limits of detection and limits quantitation. The 3D-PSD was able to capture a total of two-thirds of all compounds spiked in a controlled laboratory test system ranging from compounds more polar in nature, such as sulfamethoxazole, which was not detected in soil but was found in the leachate during simulated rainfall events. To less polar compounds such as Pyraclostrobin were detected both in soil and on disk. Carbamazepine and its transformation product, Carbamazepine-10,11 epoxide, were detected in high concentrations in the leachate, soil and disk samples, due to their presence already being detected in the soil substrate. In the field tests a total of six spiking events were studied. The 3D-PSD detected half of the spiked compounds and one transformation product of an originally spiked parent compound, CGA321113 a Trifloxystrobin derivative. The 3D-PSDs were field tested in garden soil for 21 days. Pet parasiticides such as Imidacloprid and turf antifungals like propiconazole were detected on disk using liquid chromatography-high resolution mass spectrometry and compared against a commercial library of 1219 compounds. This work is so far the first to demonstrate the application of passive sampling for plant protection products to understand their stability and movement in the soil environment.

Disclaimer/Disclosure: This project is co-funded by the Institute for Chemical Biology Doctoral Training programme at Imperial College and industry partners at Syngenta.

3.20.T-04 The Enantiomeric Uptake, Translocation, and Metabolism of Ibuprofen in Rice (*Oryza sativa* L.)

***Pengfei Zhao**, Mengting Jiang, Zhekun Zhang, Huihui Xia, Junhui Zheng, Liqin Zhang and Hua Wang, Huzhou University, China (Mainland)*
The enantiomeric uptake, translocation, and metabolism of ibuprofen (IBP), a commonly used pharmaceutical and personal care product (PPCP), in rice have not been well understood. In this study, we investigated the enantiomer-specific patterns and mechanisms of IBP uptake, translocation, and metabolism using a hydroponic rice model. Our results showed that rice tissues exhibit a stronger uptake capacity for the R-enantiomer (R-IBP) compared to the S-enantiomer (S-IBP), with R-IBP also demonstrating higher translocation from roots to shoots. We identified seven metabolites in rice tissues, suggesting enantiomer-specific metabolic pathways. Transcriptomic analysis revealed that differentially expressed genes (DEGs) were significantly enriched in pathways related to Photosynthesis, Ribosome, Nitrogen metabolism, ABC transporters, MAPK signaling, and Photosynthesis (Kyoto Encyclopedia of Genes and Genomes, KEGG). Molecular docking analysis further indicated that R-IBP exhibited stronger binding affinity to key metabolic enzymes compared to S-IBP, supporting the observed differences in metabolism. This study provides novel insights into the enantiomeric behaviors of ibuprofen in crops, contributing to a deeper understanding of PPCP fate and effects in agricultural systems.

3.20.T-05 Terrestrial Pollution: A Case Study of Fate and Impact of Antibiotics on Soil Microbes
***Oluyemi Ojo**, Environment, University of York, York, United Kingdom*
Pharmaceuticals and personal care products (PPCPs) are perceived as contaminants of emerging concerns due to their inherent ability to induce physiological changes at low doses in non-target species in the environment. Despite the increased use of PPCPs, their environmental ecotoxicological profile is yet to be established. This study is focused on bridging this gap in the terrestrial ecosystem. The overall aim of this research is to investigate the effects of pharmaceuticals and personal care products on terrestrial habitat. A systematic review of previous publications and ecotoxicological databases revealed PPCPs have an inhibitory or lethal effect on the biochemistry, physiology, population, and yield of some plants, soil microbiota, and soil invertebrates. A total of 2678 publications were identified exploring the antimicrobial fate, occurrence, and effects in the soil environment. A total of 857 soil entries were found in the Umweltbundesamt database (UBA 2021). The most highly monitored antimicrobials in soils were tetracycline, oxytetracycline, and chlortetracycline, and the antimicrobials detected at the highest concentrations were enrofloxacin, ciprofloxacin, and chlortetracycline. The highest measured environmental concentration of antimicrobials was found in South America, Asia, and Europe. Effects data were found for 11 of the top 15 antimicrobials monitored. Of these, only 2 had data on all key ecological components of the soil environment (microbes, invertebrates, and plants). Based on the ubiquity of these PPCPs, a risk assessment was carried out using the risk quotient (RQ) approach. Risk characterization of these chemicals indicates that sulfonamides, tetracyclines, and fluoroquinolones are of environmental concern as they have risk quotients greater than 1, i.e., RQ > 1. Furthermore, several knowledge gaps have been identified. This includes toxicity data for chemicals and the degree to which the ecotoxicological effects of PPCPs could disrupt ecosystem service delivery is yet to be well elucidated. The impacts of PPCPs on vital microbial functions at the soil-rhizosphere are also yet to be constrained. Persistence, effects, and adsorption studies were carried out on five target APIs. The results generated have shown the probable toxicological effects of these antibiotics on terrestrial microbes. The results from this study would inform policies on the management of potential threats from PPCPs.

3.20.P Chemical Fate in the Soil-Plant-System and Related Impacts and Risks

3.20.P-We283 Forest Plant Uptake of Metals Inherited from the Great War
***Laure Parodi**[1], Deborah Closset[2] and Stephanie Sayen[3], (1)University of Picardie Jules Verne; University of Reims Champagne-Ardenne, France, (2)University of Picardie Jules Verne, France, (3)Molecular Chemistry Institute of Reims, UMR CNRS 7312, University of Reims Champagne-Ardenne, France*
The highly localised fighting of World War I (WWI) resulted in large amounts of munitions concentrated along the former front line in northern and eastern France. These munitions represent a toxic legacy that is still buried in the ground. Their degradation can now be considered as a source of trace metal contamination throughout this area, and the absorption of these metals by forest plants may induce changes in plant functional traits.
Our research aims at determining the fate of metals in soils and plants on former battlefields, across different environments and in presence of other potential contaminants such as explosives. For this purpose, we surveyed two regions with contrasted vegetation and soil properties (substrate, topography, soil pH and organic matter content). Samples from each matrix (soil, water, plant tissue) were taken into

woodlands affected by the fighting and from unaffected woodlands (controls), and subsequently analysed for a range of trace metal elements.
Higher concentrations in soils and wates were measured for some metals in the red zone (i.e. the area completely destroyed by the conflict) compared to the control zone. Our results enable to validate the hypothesis of a WWI-associated soil contamination by trace metals and highlight their mobility. The analyses of metal contamination in plant tissues allow to compare their uptake from the soils located in the red zone compared to the control zone. These results will contribute to identify the metals with the highest environmental impact, and to relate them to alteration in plants life-history traits measured in our study.

3.20.P-We284 Interactions Between Reclaimed Water Irrigation and Planting Season Revealed by Non-Target HRMS Rice Fingerprinting

*Keng-Jui Lin[1], **Wen-Ling Chen**[1], Feng-Wen Chen[2], Yu-Chien Cho[2] and Shan-Li Wang[1], (1)National Taiwan University, Taiwan (Greater China), (2)Agricultural Engineering Research Center, Taiwan (Greater China)*

Reclaimed water irrigation is a potential resolution to mitigate agricultural water scarcity, especially for rice irrigation. However, the effects of reclaimed water irrigation on rice are not clarified, including its interaction with seasonal variations. Aiming to elucidate the relationship between reclaimed water irrigation, planting season, and the potential physiological effects on rice, this study performed non-target small-molecule fingerprinting in rice using high-resolution mass spectrometry (HRMS).
Rice plants were cultivated in August-December 2023 and March-July 2024. Rice plants were sampled for each irrigation group (reclaimed or river water, each $n = 35$) at the end of each season. Homogenized white rice samples were processed through solvent extraction and cartridge cleanup. The samples were analyzed using a liquid chromatography orbitrap mass spectrometry system. The molecular features with high variabilities (relative standard deviations > 30%) were filtered. The distribution of rice samples was illustrated using orthogonal partial least squares discriminant analysis (OPLS-DA) models. Features with scores of variable importance in projection greater than one, significant differences between groups ($p < 0.01$), and fold changes of relative concentrations greater than two were selected as candidate markers.
The OPLS-DA models that were constructed using 2152 features discriminated between two planting seasons and between two irrigation waters ($R2Y > 0.643$, $Q2 > 0.573$). Seventy-one molecules were selected and identified as markers of planting season. They were mainly endogenous compounds and more abundant in rice planted in 2024 than in 2023. For rice grown in 2023, 102 molecules were selected and identified as markers of irrigation water, while only 26 molecules were for 2024. These markers were primarily endogenous compounds. In the rice grown in 2023, the markers were more abundant in the rice irrigated with reclaimed water than those with river water. However, the rice grown in 2024 revealed an opposite trend.
HRMS non-target analysis was successfully applied to illustrating the small-molecule distributions in rice. The results demonstrated that the small-molecule fingerprints in rice differed by the irrigation water used, which interacted with planting season. Further findings on the effects on rice may provide crop rotation suggestions to improve the implementation of reclaimed water irrigation.

3.20.P-We285 Reactive Transport of Coexisting Organic Pollutants and Nitrate

*Darrell Tang[1], **Nikola Rakonjac**[2] and Soren Thiele-Bruhn[3], (1)University of Oulu, Finland, (2)Wageningen University, Netherlands, (3)Universitat Trier, Germany*

Background: Soil and groundwater contamination is globally widespread. Soil microbes may biodegrade organic contaminants by oxidising them, which requires electron acceptors. In agricultural soils, organic contaminants typically coexist with nitrate, a soil contaminant and electron acceptor. Soils are not well-mixed reactors. Hence, even if organic contaminants, electron acceptors, and microbes are present, their spatial distributions might not overlap, and biodegradation may not occur. To address this, we studied how soil hydrology affects overall contaminant mixing, transport, and biodegradation. We compared models of various complexities to simulate contaminant transport, mixing, and fate for cases where veterinary pharmaceuticals (VP) and nitrate from manure coexist, to identify what models should be prioritized for such research.
Methods: We first modeled 1D soil columns to estimate VP leaching from manured soils, without considering mixing with nitrate. 1D models are fast to compute, and can be applied spatially distributed to obtain broad overviews at regional scales. We then developed leaching models with more complexity (2D space, microbe-growth- and mixing-dependent biodegradation rates, soil heterogeneity, transient fluxes,

etc). However, we omitted contaminant adsorption to limit the overall model complexity. Nevertheless, we recognize the importance of sorption, and sorption interactions on VP transport, and also conducted sorption batch experiments of multiple VPs in manure in soils, to study mixture and nitrate related effects on VP adsorption.
Results: The 1D results underscore the need to consider a combination of factors (e.g., mixing and reaction rates) in assessing VP leaching, which varies by compound. Even with the additional complexities of the 2D model, biodegradation outcomes for various contaminants with various biodegradation parameters are ranked similarly as in the 1D model, except perturbed with random noise. The sorption experiments showed that nitrate influenced VP sorption. Thus, if VP and nitrate coexist in soils as mixtures, which generally occurs under organic manure, then additive, synergistic, or antagonistic interactions on sorption must be expected.
Conclusion: It may be most efficient to use 1D models, but account for additional complexity as a statistical uncertainty by using a range of parameter values. In future studies, we will integrate insights from the VP sorption experiments into reactive transport models.

3.20.P-We286 Composted Biosolids and Biochar as Sources of Wastewater Derived Contaminants for Plant Uptake

Evyatar Ben-Mordechay[1]*, Guy Rozner*[1]*, Vered Mordehay*[1]*, Nadav Ziv*[2]*, Yehoshua Maor*[3] *and Benny Chefetz*[4]*, (1)The Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel, (2)Earth Biochar, Israel, (3)Phytor Lab, Hadassah Medical Center Hebrew University, Israel,(4)The Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel, Agriculture Research Organization - Volcani Institute; Rishon LeZion, Israel*

Climate change, overuse of water resources, and population growth have led to the depletion of freshwater sources. To overcome these challenges, treated wastewater was introduced into the water cycle. However, studies have shown that wastewater treatment plants do not completely remove organic pollutants, such as pharmaceuticals, corrosion inhibitors, PFAS, etc. Therefore, the use of treated wastewater for irrigation or composted sewage sludge (i.e., composted biosolids) as fertilizer exposes the agricultural environment to wastewater-derived contaminants, which may accumulate in plants. Thus, the main objective of this study is to explore cost-effective methods to reduce plant uptake of these contaminants by applying composted biosolids and/or biochar (pyrolyzed biosolids) to the soil. We hypothesized that these amendments would increase the number of sorption sites and enhance the soil's affinity for wastewater-derived organic contaminants, thereby reducing their bioavailability through sorption processes.
The experiment examined the uptake of organic contaminants in alfalfa plants grown over 180 days, with six harvests. The plants were grown in soils mixed with composted biosolids or biochar (or their combination) and irrigated with treated wastewater or fresh water. Our results indicate that while composted biosolids could serve both as a source of contaminants when combined with freshwater irrigation, and as a sink (i.e., sorbent) when combined with treated wastewater irrigation, biochar primarily served as a significant sorbent due to its high surface area and hydrophobic properties. For example, the average concentration of carbamazepine in alfalfa leaves was highest in plants grown in soils irrigated with treated wastewater without application of organic amendment (mean concentration of 15 ng/g). In contrast, plants grown in soils amended with composted biosolids or biochar exhibited a 25% and 80% reduction in carbamazepine concentration in the leaves, respectively. These results were consistent across all five harvests. Our data demonstrate that application of composted biosolids or biochar significantly reduces the plant uptake of organic contaminants, probably due to a decrease in their bioavailability due to sorption processes, thereby reducing human exposure to contaminants of emerging concern.

Disclaimer/Disclosure: This work was financially supported by the Partnership for Research and Innovation in the Mediterranean Area (PRIMA program): "Risk reduction of chemical residues in soils and crops impact due to wastewater used for irrigation” (RESIDUE- PCI2020-111967 research grant award).

3.20.P-We287 Land Application of Biosolids: Bioaccumulation of Emerging Contaminants in Vegetables

Audrey Jeanne Braun*, University of California-Riverside, United States*

Biosolids, the nutrient-rich organic materials resulting from the treatment of sewage sludge, can be land-applied to improve plant health and soil quality in addition to offering benefits over detrimental disposal methods such as landfilling and incineration. However, biosolids contain numerous unregulated organic chemicals (UOCs) leading to concerns that may impede public perception of the benefits gained from land application, potentially hindering the expansion of its beneficial use. Therefore, understanding the broad human and environmental health risks of biosolids-borne UOCs is imperative for the safe use of biosolids in agriculture. In this study, biosolids were land-applied to vegetable crops (sweet corn, cucumber, potato) at agronomically realistic rates for one growing season. Thin-film passive samplers were deployed in the field plots as a biomimetic tool to estimate the bioavailability of biosolids-borne UOCs. Passive samplers, soil samples, and the edible tissues of various vegetables were collected and analyzed for 20 priority UOCs. The concentrations quantified in the samples evaluate the bioavailability, uptake, and presence of the priority UOCs in food crops. In future work, biosolids will be applied to fruit trees at agronomically realistic rates to determine the bioaccumulation of UOCs in the edible portion of the fruits. These completed studies will contribute to holistic human health and ecological risk assessments.

3.20.P-We288 Assessment of the Bioaccumulation, Translocation, and Distribution of Per- and Polyfluoroalkyl Substances in Terrestrial Plants

***Frouke Decat**, Jodie Buytaert, Els Prinsen, Sevgi Oden, Tim Willems, Lieven Bervoets and Thimo Groffen, University of Antwerp, Belgium*

Per- and polyfluoroalkyl substances (PFAS) are synthetic pollutants with persistent and bioaccumulative properties, raising environmental and human health concerns. Terrestrial plants can absorb PFAS through their roots from soil in contaminated areas. However, research on species-specific PFAS accumulation and distribution in plants, especially regarding short-chain emerging PFAS and PFAS mixtures, remains limited.

This research focused on four plant species common sunflower (*Helianthus annuus* L.), barley (*Hordeum vulgare* L.), broad bean (*Vicia faba* L.), and spearmint (*Mentha spicata* L.) to unravel the bioaccumulation, translocation, and distribution patterns of nine environmentally relevant PFAS. In greenhouse experiments, individual plants were exposed to soil spiked with varying concentrations of a PFAS mixture. After 60 days of exposure, plant parts, including roots, leaves, stems, and apices, were harvested and their PFAS content was determined.

During the experiment, aphids infected several plants, especially broad beans exposed to the highest PFAS concentrations, which showed upwardly folded leaves with yellow/brown tips symptoms typical of Bean leaf roll virus (BLRV). An enzyme-linked immunosorbent assay (ELISA) could not confirm the presence of BLRV. Although our study provides initial observations, further research is needed to determine whether PFAS exposure increases plant susceptibility to aphid infestation and to clarify if the observed abnormal phenotypic effects are directly caused by PFAS or if PFAS exposure amplifies the plant s response to aphids or other stressors. These aspects, however, are beyond the scope of the current study.

In further analyses, scheduled for early 2025, the following endpoints will be determined for each species: i) the total PFAS loading of the aboveground biomass and the PFAS loading within each aboveground tissue; ii) the relative and absolute PFAS concentrations of the aboveground biomass and the PFAS concentration of each aboveground tissue separately; iii) the bioaccumulation factors for the aboveground biomass and the bioaccumulation factor of each aboveground tissue separately; and iv) the translocation factors between the roots and the aboveground tissues. We expect our findings to advance the application of phytoremediation for PFAS-contaminated soils and to provide key insights into specific PFAS accumulation sites within plants, which is essential for evaluating potential consumption risks.

3.20.P-We289 Imidacloprid Uptake and Accumulation in Lettuce Plant (*Lactuca sativa* L. var. *longipolia*) and Its Effects on Abundance of Microbial Communities in Cultivated and Non-Cultivated Arid Soil

*Ahmed A. Ahmed[1], Abdulqader Bazeyad[1], Fahad Alotaibi[2], Khaled D. Alotaibi[2], Garry Codling[3] and **Hattan Alharbi**[1], (1)Department of Plant Protection, College of Food and Agriculture Sciences, King Saud University, Saudi Arabia, (2)Department of Soil Science, College of Food and Agriculture Sciences, King Saud University, Saudi Arabia, (3)Centre for Resilience in Environment, Water and Waste (CREWW), Exeter University, United Kingdom* Systemic plant protection products, such as neonicotinoids (NIs), are capable of being translocated throughout a plant. Although NIs are less toxic to mammals, fish, and birds, their impact on microbial and non-target insects is of concern. This study investigates the uptake, translocation, and accumulation of the NI, imidacloprid (IMI), in romaine lettuce (*Lactuca sativa* L. var. *longipolia*). Exposing 15-day-old seedlings to 10 mg/L of IMI, the effects on microbial communities in both cultivated (CS) and non-cultivated soil (NCS) were studied along with IMI translocation within plant tissues. The concentrations of IMI in soil varied temporally and between soil types after initial application, with a decrease from 2.0 and 7.7 mg/kg on the first day of sampling to 0.5

and 2.6 mg/kg on the final sampling day (day 35) for CS and NCS, respectively. The half-life of IMI soil was 10.7 and 72.5 days in CS and NCS, respectively, indicating that IMI degraded more quickly in CS, possibly due to smaller grain size, aeration, microbial degradation, and water flow. The accumulated concentrations of IMI in lettuce tissues ranged from 12.4 ± 0.2 and 18.7± 0.9 mg/kg in CS and NCS, respectively. The highest concentration of IMI was found in the shoots, followed by the roots, whereas the soil showed the lowest IMI residuals at the end of the trial. Soil bacteria and fungi were altered by the application of IMI, with a lower abundance index within the bacterial community, indicating a negative impact on the distribution of bacteria in the soil. The results of this study have important implications, especially for understanding the dynamics of NI uptake and distribution in lettuce in cultivated and non-cultivated Arid Soil. Understanding how these chemicals move within plants, such as lettuce, provides valuable insights that can be applied to agricultural practices, food safety assessments, and regulatory decision-making concerning NIs.

3.20.P-We290 Absorption and Translocation of 14C-Glyphosate in Neotropical Weed *Machaerium hirtum* (Vell.) Stellfeld

Kassio Mendes[1]*, Leila Camintia*[2]*, Rodrigo Sousa*[1]*, Lilian Moreira*[3]*, Melissa Morgado*[4] *and Rodrigo Pimpinato*[1]*, (1)University of São Paulo, Brazil, (2)Santa Catarina State University, Brazil, (3)University of Sao Paulo, Brazil, (4)Federal University of São Carlos (UFSCar), Brazil*

The use of radioactivity in agriculture allows for a range of insights, particularly in understanding the effects of herbicides on weeds. In this context, the present study aimed to determine the absorption and translocation of carbon-14-labeled glyphosate (14C-glyphosate) in neotropical weed *Machaerium hirtum* (Vell.) Stellfeld (Leguminosae-Papilionoideae-Dalbergieae). The study was carried out in a completely randomized design, and the treatments were evaluated 3, 48, and 72 hours after application (HAA), with three replications. The plants had four fully developed true leaves at the time of the 14C-glyphosate application, which was performed on the adaxial surface of the leaf (3,299.82 Bq). Quantitative evaluation was performed via liquid scintillation spectrometry (LSS) by 5 min, on the segments root, stem, treated leaf, leaves below the treated leaf, and leaves above the treated leaf, after combustion in the biological oxidizer by 3 min. Semi-quantitative evaluation was done using autoradiography of each experimental unit with a radioscanner. The data obtained were transformed into percentages of radioactivity in each weed segment to determine absorption and translocation. At 3 HAA, radioactivity was detected in all parts of the weed, with 77.01% of the absorbed total retained in the treated leaf. At 48 HAA, although 94.15% of the applied radioactivity was not absorbed, there was an increase in absorption and translocation of the herbicide, with 5.54, 0.13, 0.08, 0.04, and 0.06% of the radioactivity present in the treated leaf, root, leaves below, leaves above, and stem, respectively. At 72 HAA, greater translocation was observed in weed, reaching 0.37% for the other parts of the plant (except the treated leaf). It was concluded that 14C-glyphosate exhibits a low percentage of absorption and translocation in *M. hirtum* throughout the evaluated period, which can be attributed to the morphological and anatomical characteristics of the neotropical weed.

3.20.P-We291 Roots of Concern: Addressing PFAS Contamination in Vegetation at a Former Military Airbase

John van Tol[1] *and Iris van der Veen*[2]*, (1)Soil & Groundwater, TAUW bv, Netherlands, (2)TAUW bv, Netherlands*

Measuring per- and polyfluoroalkyl substances (PFAS) in vegetation is crucial for understanding the environmental implications of these persistent contaminants. While PFAS uptake by plants presents opportunities for innovative remediation strategies such as phytoremediation, it also poses potential human and ecological risks and challenges during site redevelopment. Activities such as tree removal, mulching, or composting may reintroduce PFAS into the soil, complicating remediation efforts and raising concerns about ecological integrity and human exposure.

Our study focuses on a former military airbase, where an extensive PFAS contamination in soil (contaminated area > 11.000 m2) and groundwater (> 3 million m3) is linked to the historical use of Aqueous Film-Forming Foam (AFFF) in firefighting operations from ~1960 to 2006. The site features a sandy soil and a groundwater depth of 8 to 10 meters, beyond the reach of tree roots. An inventory of PFAS in current onsite vegetation (trees and grass) was conducted at locations with elevated soil concentration, as soil remediation and redevelopment into a residential area is planned. We measured PFAS in four tree species analyzing soil, litter, trunks, and leaves. Most sampled trees were situated in soils with PFAS concentrations exceeding Dutch threshold levels (> 59 µg/kg dry weight) in the upper 2 meters. We also assessed PFAS levels in three grass plots located at contaminated soils. Elevated PFAS concentrations were observed in vegetation corresponding to high soil levels, with leaf concentrations generally higher than those in woody material. Among the studied species, beech trees had the highest PFAS concentrations, while birch trees had the lowest. Short-chain PFAS were more prevalent in vegetation than in soil, likely due to their greater water solubility. The presence of PFAS in vegetation complicates future management of the former military airbase. Leaf litter from contaminated trees can lead to soil recontamination after soil remediation. Current disposal options for organic material with PFAS are limited, raising long-term management concerns. Additionally, grass from heavily contaminated areas may further contribute to soil contamination if not managed properly. To prevent migration of PFAS, mowed grass and other biomass from these heavily contaminated areas should be separated from other non/less contaminated areas and needs to be treated/processed properly in order to remove/contain PFAS.

3.20.P-We292 The Impact of Container Size on the Plant Uptake of Pharmaceuticals from Soil

***Radka Kodesova**[1], Oleksandra Rieznyk[2], Helena Svecova[3], Ales Klement[4], Miroslav Fer[5], Antonin Nikodem[2] and Roman Grabic[3], (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)Czech University of Life Sciences Prague, Czech Republic, (3)University of South Bohemia in České Budějovice, Czech Republic, (4)Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Prague, Czech Republic, (5)Czech University of Life Sciences Prague, Prague, Czech Republic*

Soil can be contaminated with pharmaceuticals, the source of which is, for example, treated wastewater that is used to irrigate plants. A number of studies have already proven that plants have the ability to absorb, accumulate and transform certain compounds. It depends on a number of parameters, for example the distribution of roots and compounds in the soil. The distribution of substances in the soil is determined by their sorption on soil particles, transport with flowing water, and their transformation in the soil environment. Compounds that are more sorbed to the soil are less mobile and remain near the soil surface after irrigation. On the contrary, substances that are sorbed less penetrate to greater depths. Thus, the size of the containers can affect the uptake of compounds by plants. This study therefore focused on comparison of the results obtained for pea plants (*Pisum sativum*, L.), which were grown in containers with a volume of 340-cm3 and in cylinders with a volume of 1185-cm3. The plants were irrigated with a mixture of 6 pharmaceuticals: carbamazepine (CAR), citalopram (CIT), clindamycin (CLI), fexofenadine (FEX), irbesartan (IRB), and sulfamethoxazole (SUL). During both experiments, the concentrations of these pharmaceuticals and some of their metabolites were analyzed both in soil and in plant tissues. The absorption of compounds and their distribution in plant tissues partially corresponded to the assumptions based on the dissociation of substances. While the concentration in the roots corresponded to a certain extent to the concentrations in the soil, CAR and its metabolites were mainly present in the above ground plant parts. The content of substances in plant tissues was greatly influenced by the ability of plants to transform substances. The pods contained more metabolites than the primary substances CAR, CLI and SUL. Bioaccumulation factors found for 340-cm3 pots were mostly greater than those obtained for 1185-cm3 cylinders, except SUL. The values were influenced by the distribution of the roots, the availability of compounds for plants and in some cases (e.g. SUL) probably also the different rate of degradation of substances in the soil.

Disclaimer/Disclosure: The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QL24010384 and QK21020080.

3.20.P-We293 Pesticides in Pollen and Nectar: Initial Residue Concentrations and Their Dependency on Chemical, Application and Plant Characteristics

*Stefan Trapp[1], **Arno Rein**[2] and Peter Fantke[3], (1)Department of Environment and Resource Engineering, Technical University of Denmark, Denmark, (2)Chair of Hydrogeology, TUM School of Engineering and Design, Technical University of Munich, Germany, (3)substitute ApS, Graaspurvevej 55, DK-2400 Copenhagen, Denmark; Department for Evolutionary Ecology and Environmental Toxicology, Goethe University, 60438 Frankfurt am Main, Germany, Denmark*

A severe decline of insect biomass has been observed in Europe in recent years, and honeybees were affected by colony collapse disorder. The application of pesticides was identified as one of the major factors for this development, and guidelines for risk assessment of plant protection products on honeybees, bumble bees and solitary bees were developed aiming at minimizing impacts and risks. We have collected a large data set on pesticide residue levels observed in pollen, nectar and other plant parts potentially exposing pollinators. In total, 1720 data were retrieved from EFSA (European Food Safety Authority)

documents and scientific literature, covering 71 different chemicals and 20 crops. From this data set, initial concentrations for pollen and nectar arising from spray application were selected, measured at the time of application up to one day later. These initial concentrations were referred to the application rate, yielding residue per unit dose (RUD) data sets with 161 events for pollen with 32 different chemicals and 164 events for nectar with 27 different chemicals. Median RUD values were calculated to describe the typical realistic initial applied dose.
Earlier findings from risk assessment of plant protection products on bees can overall be confirmed, where RUD in pollen exceeds RUD in nectar and results show a wide variability. Polar pesticides had higher median RUD values, especially in nectar, but the explained variability of substance properties is generally small (10% or lower). Experimental setup and conditions were found to override substance-specific differences. We identified the following factors that contribute to the observed differences in RUD: spray direction (up/sideward > downward), sampling method of nectar and pollen (from flower > by traps > from bees), experimental setting (greenhouse > field or tunnel) and geometry of flowers (Fabaceae had the highest RUD in nectar).
One goal of this study was to find a prediction method for initial pesticide residues in nectar and pollen after spray application to flowers and plants. We have provided median RUD values for the different conditions. Physicochemical properties of the active ingredients revealed some but no dominant influence on the RUD nectar and pollen. Currently, no conclusions can be drawn on how combinations of the mentioned factors affect RUD variability.

Disclaimer/Disclosure: This work was financially supported by the Characterizing pollinator impacts for life cycle assessment (PollLCA) project funded by Bayer Crop Science.

3.20.P-We294 Insecticide Uptake and Fate in Pepper and Tomato Plants – Experiments and Modeling Considering Different Plant Growth Assumptions

Arno Rein[1]*, Stefan Trapp*[2]*, Peter Fantke*[3]*, Melis Yalcin*[4]*, Nalan Turgut*[4]*, Cansu Ahat*[4]*, Elif Camci*[4] *and Cafer Turgut*[4]*, (1)Chair of Hydrogeology, TUM School of Engineering and Design, Technical University of Munich, Germany, (2)Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (3)substitute ApS, Graaspurvevej 55, DK-2400 Copenhagen, Denmark; Department for Evolutionary Ecology and Environmental Toxicology, Goethe University, 60438 Frankfurt am Main, Germany, Denmark, (4)Faculty of Agriculture, Adnan Menderes University, Turkiye*

Agricultural activities are intensified globally, often accompanied by an increasing use of agrochemicals like pesticides, which can pose significant risks to ecosystems and human health. We have carried out field and greenhouse experiments with pepper and tomato plants and six frequently used insecticides. Those included acetamiprid, indoxacarb, deltamethrin, ?-cyhalothrin, spinosad and chlorantraniliprole, applied via spray as individual compounds to different experimental plots. Observations were interpreted with numerical modeling, in order to identify and quantify relevant fate processes.
The observed dynamics of fruit concentrations could be described overall well by modeling. After application, concentrations decreased in pepper and tomato fruits, where lower degradation and dissipation was observed for tomatoes. Chemical input to individual above-ground compartments (fruit, leaf, stem) and soil, arising from spray, was among the unknowns and therefore required to be estimated. Input to fruits was estimated 1-13% and 1-17% of the total applied amount, and input to stem, leaf and/or soil 0-13% and 0-26% (ranges for pepper and tomato, respectively). Estimated chemical input was revealed to be highly variable across the investigated compounds, with considerable uncertainty due to a partly low sensitivity of stem/leaf/soil input to fruit concentrations. The pathway stem-fruit was relevant for all compounds except ?-cyhalothrin (both for pepper and tomato) and deltamethrin (for tomato). The pathways soil-root-stem-fruit and leaf-stem-fruit (phloem) were only sensitive for acetamiprid and chlorantraniliprole.
Our developed dynamic model approach, implementing the appearance and growth of individual fruits, was after calibration successful in describing insecticide fate in pepper and tomato plants. One focus of our investigation was on dynamic modelling of plant growth and connected xylem and phloem flow, where the dynamic approach revealed superior to the assumption of constant plant mass and transpiration, combined with first-order rate constants for growth dilution. Information on the time-window of experiments within the vegetation period and on the number and appearance of individual fruits is important for adequately describing growth and thus chemical fate within plants. The model can readily be applied for other compounds and plants, if related data on chemical properties and plant characteristics are available.

Disclaimer/Disclosure: This research was supported by Adnan Menderes University Research Fund (Project Numbers ZRF-15039, ZRF-14037, ZRF-15071, ZRF-17046) and by the Bayer AG Crop Science Division (Project PollLCA, Characterizing Pollinator Impacts for Life Cycle Assessment).

3.20.P-We295 Phosphorus Mobility in Oxisols: Implications of Phosphorus Sources for Sustainable Agricultural Systems

***Rodrigo Sousa**, Brazil*

A comprehensive understanding of the interrelationship between soil texture, pH, and phosphorus (P) sources is crucial for the advancement of agricultural practices and the reduction of environmental impacts. The objective of this study was to investigate the influence of soil texture and phosphorus (P) sources on phosphorus mobility in two Oxisols with contrasting clay contents: a sandy loam and a clay soil. The movement of phosphorus derived from organomineral fertilisers and triple superphosphate was assessed using miscible displacement experiments conducted in acrylic soil columns. The experiments were conducted under two pH conditions: 4.8 (natural) and 6.0 (adjusted). Breakthrough curve (BTC) analysis demonstrated that at a natural pH of 4.8, the two-site kinetic model provided an effective description of P dynamics, capturing the complex interactions between phosphorus ions and the soil matrix. In contrast, at pH 6.0, a linear model proved to be a superior representation of the simplified P transport mechanisms. The results demonstrated that clay-rich soils exhibited a greater phosphorus sorption capacity, particularly at lower pH levels, while sandy loam soils demonstrated a higher risk of nutrient leaching due to rapid phosphorus movement. Furthermore, the findings emphasized the importance of selecting appropriate phosphorus sources, as these choices significantly influence mobility and availability. This research provides actionable insights for managing phosphorus in highly weathered tropical soils, aiding the development of agricultural strategies that balance soil fertility and environmental protection.

3.20.P-We296 Seasonal Variation in Uptake of Contaminants of Emerging Concern into Edible Plants: Insights from a Field Study from Australia

***Minna Saaristo**[1], Sijing Li[2], Kara Fry[1], Erinn Richmond[1], Warish Ahmed[2], Laura Carter[3], Mike Williams[2] and Mark P. Taylor[1], (1)EPA Victoria, Australia, (2)CSIRO, Australia, (3)School of Geography, University of Leeds, United Kingdom*

Irrigation of agricultural crops with recycled wastewater is becoming an increasingly important means of ensuring consistent access of water in Australia. There is growing concern that contaminants in recycled water may affect edible crops. Accordingly, the aims of the project were to: 1) Detect and quantify >1000 contaminants of emerging concern in recycled wastewater (class A,C), soil and plant tissues used for crop irrigation; 2) Quantify contaminants in roots, leaves and florets to unravel uptake and distribution within plant tissues under field conditions over two consecutive years; 3) Measure indicators of plant condition (e.g. physiological traits) to assess whether recycled wastewater has an adverse impact on crop health. Plant, soil and water samples were collected from five farms using recycled water and from two reference farms (not using recycled wastewater). Water, soil and plant tissues were screened for trace metals and >1000 organic chemicals (pesticides, PPCPs, EDCs, PFAS and a suite of industrial chemicals) along with nine genes related to antimicrobial resistance (AMR). Targeted, quantitative analysis (LC-MS/MS) was used for organic chemicals, along with suspect screening on high resolution mass spectrometry (HRMS) analysis. A total of 143 samples was collected, of which 41 were plants (roots, shoot, florets), 41 soil, and 55 water samples. Our study shows that of the targeted organic contaminants, >65 were measured in water and 100 in plants, with the majority being pesticides, as well as PPCPs, industrial chemicals, PFAS and phthalates, and typically at low (ng/L) concentrations. The majority of these chemicals, apart from PPCPs and EDCs, were also measured at reference sites, suggesting additional sources of contamination contributed to the residues detected in recycled water. Suspect screening revealed additional contaminants not included in the targeted quantitative suite, with significantly elevated concentrations in wastewater compared to surface water. Most of these contaminants were identified as pesticides and PPCPs. Seasonality differences were detected with lower overall concentrations of contaminants detected in samples collected in 2024 vs 2023. Ongoing analysis of HRMS data will assess whether potentially hazardous chemical residues were taken up in edible plant tissues from wastewater irrigation. Overall, our study shows that wastewater irrigation in these scenarios is unlikely to cause harm to consumers or adjacent environments.

3.20.P-We297 A Monitoring Study to Ascertain a Baseline for Organic Contaminants in UK Agricultural Soils

John Nightingale[1]*, Laura Carter*[2]*, Felicity C.T. Elder*[3] *and Andrea Lorena Garduno Jimenez*[2]*, (1)University of Leeds, Leeds, United Kingdom, (2)University of Leeds, United Kingdom, (3)Defra, United Kingdom*

The application of organic wastes, such as animal manures and biosolids, as soil amendments (animal manures and biosolids) is a common practice within the UK. Such practices are known to improve soil fertility from a nutrient perspective but they are also well known to introduce emerging contaminants into terrestrial ecosystems. This raises significant environmental and human health concerns associated with their translocation to receiving aquatic compartments but also for uptake into arable crop (produce for consumption). The extent of emerging organic contaminants in UK soils is not comprehensively understood. To address this knowledge gap sixteen farms (30 fields) across the UK were sampled in 2022 (<200 field samples). A validated, multi-residue extraction technique (n = 19, 0.1 30 µg/kg) was employed on the soil samples prior to analysis via non-target approaches (HRMS) and targeted approaches (LCMS/MS). The target chemicals included a diverse array of organic contaminants, including human pharmaceuticals (e.g., antibiotics, anticonvulsants, NSAIDs), veterinary medicines, personal care products, herbicides, pesticides, and biocides. Our findings reveal the presence of several organic contaminants across the sampled farms, including carbamazepine (0.03-44.49 µg/kg dw), clotrimazole (0.2-274 µg/kg dw), oxytetracycline (12.25-29.24 µg/kg dw), enrofloxacin (0.15-9.58 µg/kg dw), and diazinon (2.96-7.19 µg/kg dw), while metformin and ofloxacin were identified to be <LOQ. Notably, non-target screening identified over 300 additional organic contaminants in soil extracts (pharmaceuticals>plasticizers>research chemicals>fungicides>veterinary medicines). The data indicate higher levels of contamination in soils treated with biosolids compared to those receiving conventional animal manures. These results highlight the significant impact of utilizing biosolids and underscore the nascent stage of our understanding regarding the risks associated with these practices. Given the projected increase in biosolid use as part of sustainability goals, there is an urgent need for more comprehensive risk evaluations to better assess the long-term implications of persistent chemical contaminants in soils and their potential effects on the food chain.

3.20.P-We298 Understanding Movement of Dimethylsilanediol (DMSD) in Soil: In situ Transformation and Transport Behaviors

Jaeshin Kim*, David Adrian and Marc-Andre Courtemanche, The Dow Chemical Company, United States*

As polydimethylsiloxanes (PDMS) and volatile methylsiloxanes (VMS) are widely used, understanding the fate and distribution of their degradation products in the environment is essential for assessing their overall fate and exposure to humans and ecosystems. During their production and uses, PDMS and VMS may enter wastewater treatment plants and then partition to sludge. If biosolids are applied to agricultural soil as fertilizer, PDMS and VMS may be deposited in the topsoil and begin to degrade. Degradation products form at varying rates depending on soil conditions. Dimethylsilanediol (DMSD), a major degradation product of xxx, undergoes various fate processes, including volatilization, phytovolatilization, degradation (biotic and abiotic), soil runoff, and vertical migration. Understanding the fate and transport of DMSD in soil is needed for evaluating the ultimate fate of VMS. Recent experimental studies on the fate of DMSD in bare soil and plant-soil systems have significantly advanced our understanding of the vertical movement of DMSD in soil. In this study, we developed mathematical models and optimized the parameters with experimental data to better understand i) upward transport of DMSD to topsoil along with pore water during dry periods, ii) volatilization into the air at the soil surface, and iii) phytovolatilization via plant transpiration. Our model predicted DMSD concentrations and movements that were in good agreement with measured data when DMSD was directly spiked in topsoil. Additionally, we applied the model across various scenarios to examine how key parameters influence the transport of water and DMSD in both bare soil and plant-soil systems. Sensitivity analyses show that soil type, KOC and KOA are key factors governing hydraulic conductivity, DMSD versus water transport and rate of DMSD transfer to air. Furthermore, we improved the model by incorporating in situ formation of DMSD from its precursors with no direct addition of DMSD and tested different environmental variables to investigate the transport of DMSD in soil columns. The model predicts that DMSD would be effectively removed from the topsoil layer, with negligible downward movement to deeper soil layers. DMSD accumulation is not expected even after multiple soil amendments by land application of wastewater biosolids. This research enhances our scientific understanding of the dynamic transport of DMSD and water, both in the presence and absence of plants.

3.20.P-We299 Immobilization and Geochemical Fractionation of Metalloids in Contaminated Soils Amended with Waste-Based Sorbents

Veronika Spirova[1]*, Tomas Farago*[1]*, Martina Vitkova*[2]*, Szimona Zarzsevszkij*[2] *and Lubomir Jurkovic*[1]*, (1)Comenius University in Bratislava, Faculty of Natural Sciences, Department of Geochemistry, Slovakia, (2)Czech University of Life Sciences Prague, Faculty of Environmental Sciences, Department of Environmental Geosciences, Czech Republic*

Immobilization of metalloids in soils by sorbents is one of the means how to reduce their bioavailability. Metalloids sorb to mineral and organic particles through various mechanisms that influence their geochemical lability. The knowledge about immobilization potential of sorbents together with geochemical fractionation of arsenic (As) and antimony (Sb) is therefore essential in the process of risk assessment. In this work, immobilization of As and Sb in contaminated soils from mining site located near town Pezinok, in Western Slovakia by waste-based amendments was investigated. Exhausted coffee and black tea waste, compost, hard wood and sewage sludge biochar, iron scrap, non-stabilized iron sludge and iron sludge neutralized with calcium hydroxide were mixed with contaminated soils and incubated at laboratory conditions. The efficiency of amendments was evaluated by the comparison of As and Sb concentrations in demineralized water extracts. The geochemical fractionation of metalloids in amended soils was assessed using sequential extraction procedure. Ammonium sulphate, ammonium phosphate, oxalate buffer with oxalic acid and oxalate buffer with ascorbic acid were used to extract non-specifically sorbed fraction, specifically sorbed fraction, fractions bound to amorphous and crystallized Fe/Al oxyhydroxides, respectively. The results showed that iron scrap and non-stabilized iron sludge were the most effective immobilizing amendments and reduced the concentration of metalloids in demineralized water and ammonium sulphate extracts when compared with non-amended soils. Organic based amendments and neutralized iron sludge showed either no effect on metalloids mobility or, on the contrary, they increased the concentration of As and Sb in the most bioavailable fractions. The lowest concentrations of metalloids in specifically bound fractions were found in iron scrap amended soils. The results of sequential extraction also showed that As was more prone to displacement from soil sorption complex by phosphate than Sb. Amorphous Fe/Al oxyhydroxides were the main scavengers of As, while Sb was immobilized by both amorphous and crystallized phases of Fe/Al oxyhydroxides. In conclusion, Fe-based waste soil amendments were able to immobilize metalloids in contaminated soils and reduced bioavailable fractions of As and Sb in the extracts. Further research is needed to verify the efficiency of the sorbents in large scale and field conditions.

Disclaimer/Disclosure: This research was supported by the European Union under the Horizon Europe project (RIA), project number 101112723 - Achieving remediation and governing restoration of contaminated soils now (ARAGORN). The expressed opinions and views are those of the authors and do not necessarily reflect the requirements of the European Union. The European Union is not responsible for them.

3.20.P-We300 Wide-Scope Screening of Over 2000 Micropollutants and Transformation Products in Agricultural Soils under Long-Term Reclaimed Water Irrigation

Vasiliki G. Beretsou[1]*, Iakovos C. Iakovides*[1]*, Georgios Gkotsis*[2]*, Maria-Christina Nika*[2]*, Anastasis Christou*[3]*, Costas Michael*[4]*, Nikolaos S. Thomaidis*[2] *and* ***Despo Fatta-Kassinos***[1]*, (1)Department of Civil and Environmental Engineering and Nireas-International Water Research Center, School of Engineering, University of Cyprus, Cyprus, (2)Laboratory of Analytical Chemistry, Department of Chemistry, National and Kapodistrian University of Athens, Greece, (3)Agricultural Research Institute, Ministry of Agriculture, Rural Development and Natural Resources, Cyprus, (4)Nireas-International Water Research Center, School of Engineering, University of Cyprus, Cyprus*

Considering the large number of micropollutants commonly found in reclaimed water and their various physicochemical properties, it is necessary to apply wide-scope analytical methodologies to provide a thorough evaluation and, therefore, a better understanding of their fate in soil when reclaimed water is used for irrigation. In this study, we analyzed the occurrence of >2000 micropollutants, including transformation products (TPs), in agricultural soils collected in July 2020 from reclaimed water-irrigated fields with different irrigation histories (i.e., increasing irrigation periods from 0.5 to 10 years). The sampled fields, located in the suburbs of Nicosia in Cyprus, were cultivated with alfalfa and were irrigated with reclaimed water from a membrane bioreactor (MBR) treatment facility. To the authors' knowledge, this is one of the very first studies where the occurrence of such a large number of micropollutants belonging to various chemical classes (i.e., pesticides, pharmaceuticals, drugs of abuse, industrial chemicals, TPs, etc.) with different physicochemical properties is investigated in long-term reclaimed water-irrigated fields. A generic sample preparation method using solid-liquid extraction followed by solid-phase extraction was applied. The extracts were analyzed by ultra-high performance liquid chromatography coupled with a quadrupole time-of-flight mass spectrometer. Target analysis was performed with the use of an in-house developed database of 2466 micropollutants, including TPs. In total, 32 compounds were detected in the soil samples belonging mostly to pharmaceuticals, TPs of pharmaceuticals, and pesticides. Specifically, our analysis revealed the presence of 28 pharmaceuticals and TPs of pharmaceuticals, along with three pesticides and caffeine in the soil samples. Among these, 10 compounds, namely caffeine, carbamazepine, clarithromycin, climbazole, fenbendazole, flumazenil, lamotrigine, telmisartan, tramadol, and venlafaxine, exhibited a frequency of appearance exceeding 70%. It should be also highlighted that 3 TPs of 2 corresponding parent compounds (i.e., omeprazole and venlafaxine) were also detected in the soil samples. The results indicate that attention should be paid to agricultural soils irrigated with reclaimed water not only from the point of view of the physicochemical characteristics of reclaimed water but also from the point of view of the concentration levels of micropollutants and their potential accumulation.

3.20.P-We301 Establishing Ecosystem Stress Baselines Using Drone-Based Multispectral Imaging: Vegetation Indices and Seasonal Dynamics in Plant Communities

Dong Geun Song *and Sang Don Kim, School of Environment and Energy Engineering, Gwangju Institute of Science and Technology (GIST), "Korea, Republic of"*

Effective diagnosis of ecosystem stress in terrestrial ecosystems requires reliable baseline data that reflect natural variability in vegetation health. This study aims to establish diagnostic thresholds for vegetation stress in Korean vegetation communities by analyzing baseline vegetation indices and seasonal dynamics using drone-based multispectral imaging. A key challenge is the lack of sufficient baseline data under normal conditions for identifying and comparing ecological damage, as well as distinguishing natural variability from stress-induced changes in vegetation indices such as the Normalized Difference Vegetation Index (NDVI), Normalized Difference Red Edge Index (NDRE), and Green Normalized Difference Vegetation Index (GNDVI). To address these challenges, baseline data were collected from coniferous and broadleaf vegetation communities under normal conditions using drone-based multispectral imaging. From these data, mean values and standard deviations were calculated, and 95% confidence intervals were established as potential diagnostic thresholds. Seasonal variability in vegetation indices was also examined to determine natural patterns, which can provide a framework for evaluating potential stressors, such as chemical exposure. Comparative analysis revealed distinct seasonal dynamics and baseline differences between coniferous and broadleaf communities, influenced by leaf presence or absence. General trends in vegetation indices were consistent across years, indicating that these indices can effectively capture seasonal changes and provide meaningful insights into vegetation health. The findings suggest potential for developing specialized diagnostic models tailored to different vegetation types, advancing ecosystem stress detection and monitoring. The integration of high-resolution drone-based multispectral imaging and reliable baseline data enhances the ability to monitor large areas with greater accuracy compared to traditional satellite imagery or manual inspections. This research lays the foundation for ecotoxicological diagnostic tools and strengthens environmental monitoring applications by integrating drone-based imaging with established baselines.

3.20.P-We302 PFAS Mixtures in Irrigation Ponds: Effects on Soybean (*Glycine max*) Reproductive Phenotype

Eguono Wayne Omagamre *and Joseph Pitula, University of Maryland Eastern Shore, United States*

As climate change intensifies droughts, irrigation ponds are becoming essential for agricultural water supply. However, these ponds may be vulnerable to contamination by per- and polyfluoroalkyl substances (PFAS) through runoff from biosolid-amended fields. Understanding how runoff influences PFAS levels in ponds and their impacts on crops is critical for sustainable agriculture. This study examined PFAS contamination in an agricultural system with biosolid application. Samples from irrigation ponds, runoff ditches, and soil were analyzed, revealing 12 PFAS compounds in runoff ditches. Perfluorooctanoic acid

(PFOA) and perfluorobutane sulfonate (PFBS) were most abundant (60 ± 4 ppt and 78 ± 11 ppt, respectively). Short-chain PFAS totaled 211.4 ppt, exceeding long-chain PFAS at 90.2 ppt. Irrigation pond water contained similar PFAS, but at six times lower concentrations (48.86 ppt). Soil exhibited the highest total PFAS levels (6247 ppt), dominated by long-chain PFAS (5644 ppt). A growth chamber experiment evaluated the effects of PFAS mixtures (25, 250, 2500, and 25000 ppt) on soybean plants over 150 days. Plant height, chlorophyll content, pod and bean production, biochemical responses, and PFAS accumulation were measured. PFAS uptake followed a chain-length-dependent mechanism: short-chain PFAS (PFBA, PFPeA, PFBS, PFHxA) were detected in beans at 250 ppt, while long-chain PFAS (PFHpA, PFHpS) appeared only at 25000 ppt alongside short-chain PFAS. High PFAS concentrations reduced shoot height during early growth, though recovery occurred by Day 50. Chlorophyll content increased at Day 15, reappearing in the highest treatments by Day 50. Bean production and nutritional quality were modulated by PFAS exposure, with the 25000 ppt group producing three times as many beans (14 per plant) as the control (4 per plant, $p < 0.01$). Water availability improved soybean resilience under PFAS stress, supporting recovery and enhanced reproduction. Biochemical analyses indicated oxidative stress, with elevated ROS, SOD, and CAT levels at high PFAS concentrations. Root transcriptomics revealed upregulation of water uptake pathways and aquaporin genes, alongside downregulation of biosynthetic pathways, likely reallocating resources to reproduction. These findings highlight the risks of PFAS in irrigation systems and their chain-length-dependent accumulation in edible tissues.

3.20.P-We303 Does PFAS Pollution Result in Smaller Beans? A Case Study on PFAS Accumulation and Growth Hormone Levels in Broad Beans

Demi Rotthier*, Sevgi Oden, Tim Willems, Kris Vissenberg, Thimo Groffen and Els Prinsen, University of Antwerp, Belgium*

Per- and polyfluoroalkyl substances (PFAS) are widely used, resulting in substantial accumulation and pollution by these forever chemicals. Terrestrial plants are able to take up PFAS through their roots, and previous research suggested an association between PFAS accumulation in plants and their phytohormone levels.

In this study we focused on broad bean plants (*Vicia faba* L) and compared PFAS bioaccumulation, translocation, and distribution patterns with phytohormone levels in various plant parts. The targeted hormones included aminocyclopropane-1-carboxylic acid, cytokinins, indole-3-acetic acid, gibberellins, jasmonic acid, and abscisic acid, along with the amino acid methionine, which is essential for ethylene biosynthesis.

An environmentally relevant PFAS mixture, containing the ten most dominant PFAS present in private gardens near a PFAS hotspot, was used in this study. These compounds with varying chain length and functional groups were chosen to identify potential distribution differences within the plant due to the characteristics of these individual compounds. In a greenhouse set-up, individual plants were grown on soil spiked with three different concentrations of this PFAS mixture alongside a control group. The bean plants were separated into two harvest groups whereby plants were harvested when the plants entered the flowering stage (40 days of exposure), whereas other plants were harvested after pod and seed development (70 days of exposure). Upper leaves (above the flowers), middle leaves (flower zone), lower leaves (below the flowers), flowers, apex, middle stem, lower stem, roots, beans and pods of *V. faba* were collected separately and flash frozen in liquid nitrogen.

After solvent extraction and solid phase extraction, PFAS and phytohormones were quantified using UPLC-MS/MS. Image analysis of each individual plant was conducted using Image J to identify differences in growth. The results will identify bioaccumulation, translocation and distribution patterns of the 10 PFAS compounds added to the broad bean plant. Comparing the PFAS-related results and size of the different plant parts to the hormone levels in each plant part, will allow us to understand how PFAS affects plant growth and which mechanisms are involved.

In addition, this study will identify PFAS accumulation sites within this species, which is crucial for assessing potential human consumption risks.

Disclaimer/Disclosure: The authors gratefully acknowledge the support of the Research Fund of the University of Antwerp (BIOTOX-TERRA).

3.20.P-We304 Bioaccumulation of Legacy and Novel Per- and Polyfluoroalkyl Substances (PFAS) in Food Plants

***Rebecca E. Yates**[1], Zhaoyang Liu[2] and Jay Gan[1], (1)University of California, Riverside, Department of Environmental Sciences, United States, (2)State Environmental Protection Key Laboratory of Soil Health and Green Remediation, College of Resources and Environment, Huazhong Agricultural University, China (Mainland)*
Per- and polyfluoroalkyl substances (PFAS), known as forever chemicals, are a class of fluorinated organic compounds commonly used in industrial and consumer products worldwide. After decades of use, PFAS are ubiquitous in environmental matrices, including in ground and surface water, wastewater, soil, sediment, and biota. The persistence, bioaccumulative potential, and toxicity of legacy PFAS have led to global restrictions of some compounds such as perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), prompting the use of novel alternatives. The environmental fate and exposure risks of such alternatives are not fully understood, though some studies suggest toxicities comparable to their legacy counterparts. Industrial and domestic emissions are the main contributors to environmental PFAS contamination, while practices such as irrigation with reclaimed water and biosolids application may further introduce PFAS to agricultural systems, and thus, the food chain. Crop accumulation and subsequent human consumption is a significant pathway of dietary exposure to PFAS. Therefore, the behavior of PFAS, and especially the novel alternatives, in food plants requires urgent attention. One class of novel alternatives is ether-PFAS, which contain one or more oxygen atoms in the carbon backbone. The goal of this study was to investigate the extent of plant biotransformation of ether-PFAS and characterize the transformation products for the first time. To achieve this, three representative ether-PFAS compounds were selected: hexafluoropropylene oxide dimer acid (HFPO-DA or GenX), 4,8-dioxa-3H-perfluorononanoic acid (ADONA), and 6:2 chlorinated polyfluorinated ether sulfonic acid (6:2 Cl-PFESA). The parent compounds were spiked individually into *Arabidopsis thaliana* (thale cress) cell cultures, which were sampled after 0, 3, 6, 12, 24, 48, and 96 h of incubation. Parent compound concentrations were determined for each sampling time using UPLC-MS/MS, and statistically significant differences in concentrations between compounds and sampling times were evaluated using one-way ANOVA and Tukey s HSD ($p < 0.05$). A non-targeted screening and profiling of the biotransformation products was conducted using HPLC QTOF-MS, with product identities confirmed against authentic standards. Overall, this study provides novel insight into the behavior and fate of ether-PFAS in plants, which is essential for future ecosystem and human health risk assessments.

3.21 Understanding the Complexity of Tire Particles and Associated Chemicals: Environmental Monitoring, Toxicological Effects and Strategies for Mitigation

3.21.T-01 Leaching of Organic Compounds from Tire Particles Under Conditions Simulating the Deep Sea

***Natascha Schmidt**[1], Aurelio Foscari[2], Marc Garel[3], Christian Tamburini[3], Bettina Seiwert[2], Dorte Herzke[1], Thorsten Reemtsma[2] and Richard Sempere[3], (1)NILU, Norway, (2)UFZ, Germany, (3)MIO, France*
Tires can contain high amounts additive chemicals, which can leach out and enter the (aquatic) environment, with potential toxic consequences. Little is known on the impact of high hydrostatic pressure on anthropogenic particles and leaching of chemicals. Therefore, our objective was to investigate the leaching of organic compounds from tire particles in natural seawater under atmospheric pressure vs. high hydrostatic pressure conditions. The test material consisted of (i) cryo-milled tire thread (CMTT), (ii) virgin crumb rubber (VCR) from an artificial soccer field and (iii) weathered crumb rubber (WCR) which consisted of VCR that had been immersed in the sea for 12-18 months prior to the experiments. Seawater was collected at the surface and at 2000 m depth, filtered (0.7 ?m GF/F) and filled into glass bottles containing the test material. The samples were then subjected to atmospheric pressure and high hydrostatic pressure (200 bar) conditions, respectively. A subset of abiotic samples was made for both pressure conditions by adding $HgCl2$ (final conc. 10 mg L-1). Samples were taken after 6 h, 24 h, 7 days and 14 days, filtered and analyzed for DOC, nutrients, prokaryotic abundance and organic compounds. High hydrostatic pressure was shown to influence bacterial growth, particle agglomeration and chemical leaching of tire particles. CMTT leached higher amounts of chemicals, while WCR released phosphate from its former biofilm into the dissolved water phase, thereby further boosting bacterial growth. Leaching of target analytes was generally higher under high hydrostatic pressure conditions and under biotic conditions, with opposite trends concerning the latter for chemicals prone to biotransformation processes. Interestingly, even after ?12 months in the environment WCR still released a variety of organic compounds, suggesting a long-term potential of tire particles to release additive compounds into the marine environment.

3.21.T-02 Stability Assessment of Tire-Derived Chemicals for Quantitative Air Monitoring with Passive Samplers and Filters

Raimon M. Prats[1]*, Alexander Kasperkiewicz*[1]*, Amandeep Saini*[2]*, Chubashini Shunthirasingham*[1] *and Tom Harner*[2]*, (1)Environment and Climate Change Canada (ECCC), Canada, (2)Environment and Climate Change Canada (ECCC), Gatineau, Canada* Tire-derived chemicals (TDCs) are a diverse group of organic pollutants found in the complex chemical mixture that makes up vehicle tires. Many of these compounds (e.g., phenylenediamines like 6PPD, benzothiazoles and benzotriazoles) serve as rubber additives, acting as vulcanization agents, antioxidants, or UV-stabilizers. This broad group of environmental contaminants has recently gained prominence due to reports of acute toxicity and their potential to generate atmospheric transformation products that present additional environmental and health risks.

Recent studies have shown that TDCs are ubiquitous in urban air globally and demonstrated that passive air sampling (PAS) techniques can effectively track and monitor TDCs and derived products in air across major cities worldwide. However, studies are often constrained to qualitative or semi-quantitative characterizations of TDCs due to the uncertainty posed by their rapid degradation.

Thus, there is a need for a comprehensive assessment of TDC stability in collected samples and solvent extracts to reduce uncertainties and enable a more confident and quantitative approach to TDC analysis. We present preliminary findings from a degradation study encompassing over 50 native TDCs, TDC derivatives, and other chemical groups. The stability of these compounds was evaluated in various organic solvents, in processed and stored sample extracts, and under sampler storage conditions for polyurethane foam (PUF) PAS and glass fibre filter air samples.

Results indicate that most TDCs dissolved in solvents remain stable for a few days after spiking, with methanol showing the lowest analytical variability. However, some compounds, like 77PD in methanol, experienced steep declines, dropping to 7% of their initial levels, while IPPD showed moderate decreases after three days. Storage temperature had no noticeable effect on stability. In contrast, significant reductions in relative concentrations were observed for several TDCs in stored sampler extracts for 50 days, with declines ranging from 15% to 50% for many compounds and up to 80% for chemicals like 6PPD and CPPD.

These findings highlight the need for optimized protocols to minimize degradation or account for its magnitude, particularly in long-term stored sampler extracts that may experience more significant declines in concentrations for certain compounds.

Disclaimer/Disclosure: Authors thank the Chemicals Management Plan (Government of Canada).

3.21.T-03 Tyre Particles: Who Dares Win. A Comparison Study Evaluating the Sensitivity of Two Marine Invertebrates to Whole Tyre Particle Toxicity

Charlotte Ashley Woodhouse[1]*, Penelope Lindeque*[2]*, Tamara Susan Galloway*[3] *and Matthew Cole*[2]*, (1)Plymouth Marine Laboratory, University of Exeter, United Kingdom, (2)Plymouth Marine Laboratory, United Kingdom, (3)Biosciences, University of Exeter, United Kingdom*

Tyre particles are an anthropogenic pollutant of high environmental concern. Estuaries have been identified as potential sink for these particles owing to the influx of particulates from upstream sources, highway drainage and overlying bridges. To date, research has primarily focused on understanding the effects of tyre particles on freshwater organisms, however, it is important that we have toxicological research to understand how these particles affect biota across affected habitats. In this study, two estuarine invertebrates (*Corophium volutator* and *Marinogammarus marinus*) were selected to assess the ecotoxicological effects of tyre particles; 20, 40, 60, 80, 100, 120 g/kg (dw) sediment, with the addition of a control containing 0 g/kg (dw) sediment and a positive control, 3,5-Dichlorophenol (3,5-DCP). It is hypothesised that with increasing concentration of tyre particles, there will be an increased risk to biota, with increased mortality and negative impacts on indicators of health. *C. volutator* were taken from laboratory stocks and *M. marinus* were collected from a clean field site and acclimated for 7 days in holding aquaria. Cohorts of four individuals (for each species) were added to a 1 L beaker containing estuarine sediments enriched with tyre particles for a duration of 10 days. During the exposure, mortality, burial data (*C. volutator*) and growth (*M. marinus*) were recorded at regular intervals. Preliminary results show that tyre particles enhanced mortality in both species, with the potential to negatively affect food webs leading to cascading effects. Further, *C. volutator* demonstrated diminished burial behaviour when exposed to tyre particles, making these individuals more prone to predation. The outcomes of this study will elucidate the risk tyre particles pose to biota in benthic estuarine and coastal environments.

3.21.T-04 Realistic Stress Scenarios for the Ecotoxicity Evaluation of Tire Wear Particles

Marcus Lukas[1]*, Robin-Macmahon Bahre*[2]*, Rebecca Kochmann*[3] *and Ulrike Braun*[1]*, (1)German*

Environment Agency (UBA), Germany, (2)Leibniz University Hannover, Germany, (3)German Environment Agency (UBA), Dessau-Rosslau, Germany
Tire wear particles (TWP) are increasingly recognized as a major source of microplastic pollution in air, water, and soil, with risks posed by both the physical particles and their chemical constituents. Tire treads are complex mixtures of natural and synthetic rubbers, fillers, and additives, which differ between passenger car and truck tires. Ecotoxicological studies have linked TWP to oxidative stress, inflammation, and genotoxic effects in organisms. However, some ecotoxicological studies report no effects for TWP. In this study, we systematically investigated TWP leaching over almost three months under conditions simulating mechanical stress, light, and temperature variations. Using TWP from passenger cars and trucks, the ecotoxicological impact was assessed with algae growth tests, complemented by analytical methods to characterize TWP and their leachates.
TWP were generated using tire buffing process and stressed in microcosms containing demineralized water and artificial sediment for 75 days. Experimental conditions included different TWP treatments (e.g., with/without antioxidants, pre-aged), concentrations (120 mg/l, 600 mg/l), light exposure, temperatures and mechanical abrasion. Aqueous samples, filtered at four intervals, were ecotoxicologically assessed using an algae growth inhibition test. TWP surface changes were analyzed via SEM and EDS and particle composition via Pyr-GC/MS and TGA, alongside leachate chemical analysis.
Blank samples promoted slight algae growth, probably due to nutrient leaching from artificial sediment. Filtered samples from tested TWP generally promoted algae growth, varying by conditions and TWP settings. Truck TWP leachates caused lower growth promotion than passenger car TWP, indicating growth promoting leachates from these TWP. In turn, truck TWP exhibited reduced zinc content after weathering, possibly contributing to lower growth promotion. Comparison of antioxidant impacts showed differing effects by passenger car and truck TWP.
Chemical analysis revealed weathering-induced changes, including decreased surface carbon and increased oxygen, silicon, and aluminum signals, indicating surface oxidation or silica/alumina agglomeration.
Overall, stressed TWP did not inhibit algae growth but nutrient supply from sediment and degradation products likely promoted growth or reduced inhibition to baseline levels. This study highlights the role of chemical composition in TWP degradation and leaching.

3.21.P-Th278 Human Exposure Assessment to Tire-Related Chemicals through Urine and Silicone Wristbands: Method Development

*Nicola Montemurro, **Francesca De Angelis**, Merce Gari and Antonia Merola, IDAEA-CSIC, Spain*
Tire-road wear particles (TRWPs) are generated through tire-road friction and are a significant source of non-exhaust emissions. Their accumulation in the environment raises concerns about human health due to the toxicity of Tire-Related Chemicals (TRCs), which include additives and their transformation products. Human exposure to TRCs occurs primarily through inhalation, ingestion, and dermal contact. This study aims to develop and validate methods for quantifying TRCs in urine and silicone band passive samplers. Urine, commonly used in exposome research, and silicone bands, which mimic dermal exposure, offer insights into skin exposure and internal concentrations.
Sample preparation protocols were optimized for recovery and reduced matrix effects. For silicone bands, the solvent volume, number of extractions, and reconstitution volumes were refined, with a final protocol requiring two 15-minute extractions with methanol-ethyl acetate (1:1 v/v) and reconstitution in methanol-water (1:1 v/v). Urine samples were hydrolyzed with ?-glucuronidase to process metabolites, and ?-gone® filtration and liquid-liquid extraction (LLE) methods were compared. While ?-gone provided cleaner samples, its dilution limited detection sensitivity. LLE, with 10-fold concentration and internal calibration, allowed the detection of low-sensitivity compounds despite matrix challenges.
Silicone band extraction yielded quantitative recovery for most compounds after two extractions, validated at three concentration levels. For urine samples, LLE enabled the quantification of low-sensitivity compounds despite matrix effects. Preliminary findings on healthy volunteers detected benzothiazoles benzotriazoles, and cyclic amines in both matrices, with more compounds identified in urine.
These validated methods provide a framework for assessing human exposure to TRCs, identifying biomarkers of TRWPs, and evaluating health risks. By comparing innovative silicone bands with traditional urine sampling, this study enhances understanding of the environmental and human health impacts of tire-related chemicals.

3.21.P-Th283 Monitoring of Tire-Derived Compounds in Commercial Leafy Vegetables and Associated Dietary Exposure

Anya Sherman[1], *Luzian Hammerle*[1], *Evyatar Ben-Mordechay*[2], *Benny Chefetz*[2], *Thorsten Huffer*[1] *and Thilo Hofmann*[1], *(1)University of Vienna, Centre for Microbiology and Environmental Systems Science, Department of Environmental Geosciences EDGE, Austria, (2)Department of Soil and Water Sciences, Institute of Environmental Sciences, Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel*

The toxicity of tire particles has been linked to leachable organic additives and associated transformation products (tire-derived compounds). Tire particles and tire-derived compounds are introduced to the agricultural environment via atmospheric deposition, irrigation with treated wastewater, and biosolids (treated sewage sludge) application as fertilizer. In the agricultural environment, tire-derived compounds may be taken up by edible plants, leading to human exposure. Sixteen tire-derived compounds were measured in twenty-eight commercial leafy vegetable samples grown in Switzerland, France, Spain, and Israel. In commercial leafy vegetables, six tire-derived compounds were detected: benzothiazole (maximum concentration 238 ng/g dry weight), 2-hydroxybenzothiazole (maximum concentration 665 ng/g dry weight), 1,3-diphenylguanidine (maximum concentration 2.1 ng/g dry weight), N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD, maximum concentration 0.4 ng/g dry weight), N-isopropyl-N-phenyl-4-phenylenediamine (IPPD, maximum concentration 0.1 ng/g dry weight), and N-phenyl-N-cyclohexyl-p-phenylenediamine (CPPD, maximum concentration 0.3 ng/g dry weight). At least one compound was present in 71% of samples analyzed. Statistical analyses did not reveal correlation between known growth conditions and tire-derived compound concentrations in the leafy vegetables. Based on measured concentrations and dietary survey data, the estimated daily intake due to leafy vegetable consumption of these tire-derived compounds under a mean and maximum concentration scenario was calculated. The estimated daily intake for 1,3-diphenylguanidine ranged from 0.05 ng/person/day in the mean scenario to 4.0 ng/person/day in the maximum scenario; benzothiazole ranged from 12 to 1,296 ng/person/day; 6PPD ranged from 0.06 to 2.6 ng/person/day; IPPD ranged from 0.04 to 1.1 ng/person/day; CPPD ranged from 0.05 to 2.6 ng/person/day. The estimated daily intake via leafy vegetable consumption was generally lower than or comparable to exposure via other known sources, although leafy vegetables represent only a fraction of total dietary exposure. Future studies should elucidate pathways of tire-derived compounds from road to field, assess the exposure to transformation products, and investigate the biological effects associated with this exposure.

3.21.P-Th295 A Broad Approach to Understand How 6PPD-q, Combined with Phenanthrene, Affects Thermal Tolerance,Hematology, and Omics in Three Salmonid Species

Andreas N.M. Eriksson[1], *Jaden Griffiths*[1], *Lexie Dyck*[1], *Katherine Anderson-Bain*[1], *Justin Dubiel*[1], *Rayen Morales Urrutia*[1], *Sodiq Aremu Olawoore*[1], *Luis Terrazas Salgado*[1], *Markus Brinkmann*[2] *and Steve Wiseman*[1], *(1)University of Lethbridge, Canada, (2)University of Saskatchewan, Canada*

Because of climate change, urbanization, and hydrological manipulation of water flows, water temperatures in urban environments are increasing, which has implications for freshwater fish that inhabit cooler streams and rivers. An additional stressor that fish in urban settings must cope with is stormwater, a complex chemical mixture, including many chemicals that originate from car tires, including antioxidants and their transformation products, such as 6PPD and 6PPD-quinone, and polycyclic aromatic hydrocarbons (PAHs), such as phenanthrene. Recently, 6PPD-quinone was identified as the cause of urban-runoff mortality syndrome of Coho salmon (*Oncorhynchus kisutch*) in the Pacific Northwest. Since the discovery of 6PPD-q, environmental and toxicological understanding of 6PPD-q has progressed fast and 6PPD-q is now detected ubiquitously in urban aquatic systems, while the mechanism of acute lethality has been linked to disruption of mitochondrial functions. However, we know very little about how other contaminants in stormwater runoff influence the toxicity of 6PPD-quinone. In addition, the effects of 6PPD-q alone, and in combination with other stormwater related chemicals, on thermal tolerance in fish is not known. To fill this knowledge gap, we investigated how exposure to a road-runoff surrogate-mixture of 6PPD-quinone (0.5 µg l-1) and phenanthrene (5 µg l-1) influenced the thermal avoidance behaviour of three salmonid species: brown (*Salmo trutta*), bull (*Salvelinus confluentus*), and rainbow trout (*Oncorhynchus mykiss*). Additionally, we investigated body burden, xenometabolome, gill and liver transcriptomes, and plasma-related parameters. Bull trout exposed to the individual components and the

mixture presented thermal avoidance behaviour at significantly lower temperatures (mean range: 17.7 to 19.1°C) compared to control (20.7 ± 0.4°C). No such difference was observed among brown trout. Interestingly, a 5.7 and 7.3 percentage unit reduction in hematocrit was observed among 6PPD-q and mixture exposed brown trout, respectively. No reduction in hematocrit was observed among bull trout, although their blood was observed to be more viscous than control, suggesting altered hematology. Assays with rainbow trout are in progress. Comparative and species-specific molecular processes and biomarkers are to be investigated.

3.21.P Understanding the Complexity of Tire Particles and Associated Chemicals: Environmental Monitoring, Toxicological Effects and Strategies for Mitigation

3.21.P-Th266 Spatial and Temporal Distribution of Tire Particles and Related Additives in Freshwater Ecosystems: Insights from a Swiss Pilot Study

Thibault Masset[1]*, Pauline Ruffiot*[1]*, Shan Yao*[1]*, Timothee Steiner*[2]*, Laurent Thurnheer*[2]*, Jean-Luc Loizeau*[3]*, Rebecca Beauvais*[4]*, Benoit Ferrari*[4] *and Florian Breider*[1]*, (1)EPFL, Switzerland, (2)Summit Foundation, Switzerland, (3)UNIGE, Switzerland, (4)Ecotox Centre, Switzerland*

Tire and road wear particles (TRWP) are produced during abrasion of tires on road pavement. 61% of all microplastics entering Lake Geneva (Switzerland) are estimated to originate from tire wear. Field measurements suggest that levels of TRWPs decrease between their emission source and the aquatic environment with concentrations of 0.5 1.2 g kg-1 in river sediment and 0.5 5 mg L-1 in river water. Many chemicals are intensively used as vulcanization agents, antioxidants and antiozonants; they can represent several percent of the tire rubber mass. The distribution and fate of TRWPs and associated chemicals in the aquatic environment are still poorly understood. Moreover, the potential toxic impacts of these tire-associated chemicals for aquatic biota vary widely suggesting specific species sensitivity.
This study aimed (i) to assess the presence and distribution of tire-related additives in water and sediment from alpine/perialpine lakes and urban streams in Switzerland (ii) to retrace tire-related additives contamination history in sediment cores from Lake Geneva and (iii) to identify the input sources of tire-related additives. Water and sediment from Swiss lakes (n = 17), sediment from streams in the Lake Geneva catchment (n = 60), suspended particulate matter (n = 4) and sediment cores from Lake Geneva (n = 2) were collected. Sediment and water were extracted and analysed by UPLC-MS/MS for 15 additives and by Py-GC/MS for TRWP. Our results showed that several additives were present in most perialpine lakes with a predominance of DPG, 6PPD-Q, aniline and benzothiazoles in the ng L-1 range. The presence of roads in the close catchment of the lakes was positively correlated with concentrations of tire-related additives. However, traces of tire-related additives were detected in high altitude remote lakes highlighting the possibility of atmospheric deposition of TRWPs or gaseous tire-related additives. The concentrations of tire-related additives in sediment cores showed negative correlation with depth. Two main mechanisms likely play a role: a higher road traffic in the catchment of the sampling point in recent years together with a potential degradation of tire-related additives in the most ancient sediment layers. Our results provide important data for a better understanding of tire-related additives fate in freshwater ecosystems and could be used for future risk assessment and mitigation studies.

3.21.P-Th267 From Tires to Tributaries: Suspect Screening of Rubber-Based Contaminants in the Tagus River (Spain)

Juan Escobar Arnanz*, Silvia Royano, Irene Navarro, Adrian De La Torre and María Ángeles Martinez, CIEMAT, Spain*

Products derived from plastic and rubber such as tires or other elastomeric products often contain a wide variety of organic additives such as antioxidants, antiozonants, heat protectors or vulcanizing agents. These substances can be released into the environment through processes such as the erosion and leaching of rubber products either during their use or after disposal. Then, pollutants could be mobilized by rainfall and runoff processes to the aquatic environment where they could pose a risk to these ecosystems. The present study performs an environmental screening to investigate the presence of rubber-derived contaminants in surface water samples (n = 89) from the Tagus River basin (Spain). Samples were collected over three consecutive years (2020, 2021, 2022) along the river's entire course at thirteen locations encompassing both urban and rural areas. Surface water samples were processed using a solid phase extraction methodology and analyzed by liquid chromatography coupled to high-resolution mass spectrometry (UHPLC-QTOF HRMS) with ESI+ and data independent acquisition mode.

A suspect screening workflow was designed for data processing, including a suspect list that contains 145 rubber additives of different chemical nature, incorporating impurities and transformation products. More than 25 compounds were detected and identified at different confidence levels according to Schymanski's scale. Among these, cyclic and bicyclic amines, melamines, benzothiazoles or benzotriazoles were reported in the analyzed samples. Some of them such as hexa(methoxymethyl)melamine (HMMM), bentzothiazole-2-sulfonic acid, benzotriazole and 5-methyl-1H-benzotriazole, were ubiquitous along the Tagus River basin with detection frequencies exceeding 70%. The presence of HMMM was also associated with other widely distributed structural-related impurities co-occurring in minor intensity in the analyzed samples.
These approaches provide valuable preliminary results for evaluating the environmental distribution of persistent anthropogenic pollutants in the aquatic compartment, facilitating the prioritization of specific compounds in future research. Notably, the suspect list developed in this study confirms that rubber-derived compounds are currently present in the Tagus River surface water.

Disclaimer/Disclosure: The present study is part of the project PID2019-105990RB-I00 funded by MICIU/AEI/10.13039/501100011033.

3.21.P-Th268 Seasonal Variation of Tire and Road Wear Particles in Urban Particulate Matter

Tatu Martinmaki[1], *Sanna Saarikoski*[2], *Hilkka Timonen*[2] *and Markus Sillanpaa*[1], *(1)Finnish Environment Institute (Syke), Finland, (2)Finnish Meteorological Institute, Finland*

Tire and road wear particles (TRWP) are known to contribute significantly to urban airborne particulate matter (PM). Besides the synthetic or naturally derived polymeric material, these micro- and nanosized particles are known to contain a variety of potentially hazardous chemicals, causing a risk for both the environment and public health.

TRWP have been reported in every environmental compartment, but quantitative data on airborne TRWP are scarce. Absorption properties and microscopic size of TRWP have proven to be a challenge for microspectroscopic techniques traditionally used in environmental microplastics studies. The aim of this study was to utilize novel thermoanalytical methodology for quantification of TRWP in health relevant PM size fractions: particulate matter smaller than 10 µm and 2.5 µm (PM10 and PM2.5, respectively). PM samples were collected with active aerosol samplers. Sampling took place at two sites in Helsinki, Finland, during winter springtime. Sampling sites represent the exposure for TRWP in urban or urban background environments. Airborne tire wear rubbers were quantified by pyrolysis-gas chromatography-mass spectrometry.
Seasonal variation of tire wear rubber derived TRWP mass concentrations in urban PM10 and PM2.5 is discussed. Development and application of robust and straightforward methods for PM monitoring are needed due to the change in non-exhaust particulate matter emissions caused by transition from internal combustion engine to electric vehicles.

Disclaimer/Disclosure: The authors thank Research Council of Finland for funding the project Abundance, characteristics and significance of nano- and microplastics in urban air (ACINMUA) (funding decisions 354844 and 354845).

3.21.P-Th269 Tire and Road Wear Particles in Urban Rivers and Coastal Marine Environments

Andrew Gray[1], *Clare Murphy-Hagan*[2], *Samiksha Singh*[2], *Hannah Hapich*[2] *and Meredith Evans Seeley*[3], *(1)University of California, Riverside, United States, (2)University of California Riverside, United States, (3)Virginia Institute of Marine Science, Gloucester Point, United States*

Tire and road wear particles (TRWP) are a class of microplastic pollutants of increasing concern, particularly within and adjacent to urban areas because of high emission rates and the toxicity of some tire additives. Although TRWP has been documented in urban waterways, much remains to be learned about their concentration and transport dynamics through watersheds and coastal marine systems. Here we present an overview of TRWP found in several rivers and coastal marine environments in Southern California, USA during our group's water column and sediment sampling activities over the past 4 years. River sampling was conducted during dry weather (no runoff) and stormflow conditions using techniques designed to collect samples representative of concentrations across the depth and width of the flow. Coastal marine water column samples were collected at surface, mid-water, and near bottom depths under summer (little-to-no runoff) and winter (recent stormflow) conditions. Sediment samples were collected through a range of grab and coring techniques. Our river results indicate large concentrations and fluxes of

TRWP relative to many other microplastics found in the same samples, with stormflow dominating transport. TRWP was also a dominant class of microplastics across marine environments, with the highest concentrations in benthic estuarine sediment. However, TRWP was also found throughout the marine water column, even at locations > 40 km offshore during the dry season. This work will serve as a foundation for future TRWP monitoring and further investigation into the impact of these particles and their associated constituents on aquatic systems.

3.21.P-Th270 Identification of Chemical Hazards in Tire Tread with HPTLC-Based Effect-Directed Analysis

Alan J Bergmann[1]*, Thibault Masset*[2]*, Florian Breider*[2]*, Anna Toso*[3]*, Sara Isabel Bastos Gonçalves*[3]*, Kristin Schirmer*[3]*, Benoit Ferrari*[4] *and Etienne Vermeirssen*[5]*, (1)Ecotox Centre, Switzerland, (2)Central Environmental Laboratory, IIE, ENAC, EPFL Ecole Polytechnique Federale de Lausanne, Switzerland, (3)Department Environmental Toxicology, Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (4)Swiss Centre for Applied Ecotoxicology - EPFL ENAC IIE, Switzerland, (5)Swiss Centre for Applied Ecotoxicology, Switzerland*

Tire particles can leach a complex mixture of chemicals to the environment including yet unknown substances. Toxicity of these mixtures is often not explained by target chemical analysis. We aim to detect toxic chemicals in tire tread using in vitro bioassays coupled with chromatography, and ultimately identify those chemicals through effect-directed analysis (EDA).
We extracted chemicals from cryogenically milled tire tread (CMTT) obtained from new tires. We applied estrogen (ER) and aryl hydrocarbon receptor (AhR) bioassays in 96-well and high-performance thin-layer chromatography (HPTLC) plates to detect bioactive chemicals. We compared the unknown chemicals to known tire-associated chemicals, and we collected targeted fractions of active chemicals for chemical analysis. Fractions collected from HPTLC for chemical analysis were retested to confirm toxicity was not lost or subject to transformation. We analyzed the fractions with suspect screening and non-targeted LC-HRMS/MS.
CMTT extracts as whole mixtures in 96-well plates and after separation with HPTLC caused strong agonism of ER and AhR. We observed at least two or four HPTLC-bioassay bands were responsible for ER or AhR, respectively. Although HPTLC bands possibly contain multiple bioactive chemicals, the low number of bands indicates that a minority of chemicals in tire tread are driving ER and AhR activation. Early results showed that among common tire-associated chemicals tested in parallel, N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD) was estrogenic. Collection of the unknown CMTT toxicants into discrete fractions was successful as shown by confirming with the HPTLC-ER and -AhR bioassays. Experiments with HPTLC-bioassays and LC-HRMS/MS showed that the estrogenicity was linked to a 6PPD transformation product: 4-hydroxydiphenylamine. Additional unknown ER and AhR active chemicals are under investigation.
Our work reports on progress of identifying toxicants in tire tread with HPTLC-based EDA. Our strategy uses model tire particles, iterative (HPTLC-) bioassays, fractionation, and chemical analysis to prioritize specific-acting toxicants. The use of CMTT at high concentrations supports our goals of toxicant identification by allowing us to work with a concentrated sample of chemicals linked directly to tires. After identification of these chemical hazards, we can begin to evaluate risk through studies targeting environmentally relevant toxicity and exposure scenarios.

Disclaimer/Disclosure: The work presented here, including the production, handling, distribution and information related to the CMTT and TRWP, was funded by the World Business Council for Sustainable Developments (WBCSD) Tire Industry Project (TIP). TIP is a global CEO-led initiative undertaken by leading tire manufacturing companies. TIP drives research on potential human health and environmental impacts of tires throughout their lifecycle. The study design, execution, interpretation, and manuscript preparation were conducted solely by the authors.

3.21.P-Th271 Degradation Rates and Ageing Effects of UV on Tyre and Road Wear Particles

Luke Parker[1]*, van Os Marloes*[2]*, Merel Nooijens*[2]*, Alex van Renesse van Duivenbode*[2]*, Peter Tromp Sr*[1]*, Elena Hoppener*[1]*, Kalouda Grigoriadi*[2] *and Arjen Boersma*[1]*, (1)TNO, Netherlands, (2)TNO, Netherlands*

Tyre and road wear particles (TRWPs) are suggested to be the largest source of microplastics in the environment with annual global emissions estimated to be between 800-3300 kt. As the most TRWPs are estimated to end up in roadside soils, understanding environmental fate of TRWPs in this compartment is of great importance. An important variable is how fast TRWPs degrade and what effect this may have on the physicochemical properties of the TRWPs.
The aim of this research is to characterise the effect of UV-degradation on TRWPs and calculate the abiotic degradation rate for TRWPs. To achieve this, samples were aged following an accelerated UV-ageing procedure. Four types of materials were used to investigate the impact of various tyre properties: cryomilled tyre tread from premium car tyres, cryomilled end-of-life truck tyres, particles generated from premium car tyres on a road simulator and particles generated from budget car tyres on a road simulator. All materials were fractionated to 50-200 ?m to represent the particles that deposit in roadside soils. The rubber content was analysed at various ageing times using thermogravimetric analysis, changes in tyre additives were investigated using direct thermal desorption gas chromatography mass spectrometry and particle size and morphology were characterised using static light scattering and electron microscopy. For all samples, abiotic degradation was observed to proceed through a first order decay. Cryomilled tyre rubber was seen to degrade faster than road simulator samples, potentially due to a shielding effect of the encrusted road wear particles. When corrected for the accelerated ageing, environmental degradation rates were estimated to be between 0.01-0.03 day-1. Particle size analysis showed that particles became smaller with longer ageing times and a fraction of small particles <10 ?m was formed, suggesting that both surface degradation and fragmentation play important roles. This was confirmed with electron microscopy where it was also observed that after ageing particles had a much smoother morphology.
We believe this work can aid fate modelling studies by providing input data on both degradation rate and changes in particle size. This will help with understanding the scale of the problem, and developing suitable mitigation strategies.

Disclaimer/Disclosure: This work is part of the Low Emission and lOw Noise Tyres (LEON-T) project which has received funding from the European Union s Horizon 2020 research and innovation programme under the grant agreement No 955387.

3.21.P-Th272 Unveiling the Impact of UV-Driven Advanced Oxidation: A Comprehensive Study on the Physical and Chemical Transformation of Tire-Derived Microplastics in Aquatic Environments
Dilraj Surendran, Tokyo Metropolitan University, Japan
Tire-derived microplastics have emerged as a pressing environmental issue, with their persistence and complex chemical makeup posing potential risks in aquatic ecosystems. This study explores how UV radiation alters two prevalent forms of tire-derived microplastics micro rubber chips and crumb rubber, widely used in artificial playgrounds. Samples were exposed to low energy mercury UV light for durations of 1, 3, and 5 days, allowing us to examine both physical degradation and chemical transformations. Our results revealed marked differences in the breakdown of these materials: micro rubber chips and crumb rubber exhibited maximum weight losses of 0.85% and 0.61%, respectively, following five days of UV exposure. The carbonyl index increased to 0.4 for tire chips and 0.5 for crumb rubber, signifying substantial chemical changes over time. Furthermore, total organic carbon (TOC) levels in the leachates escalated, reaching 6.2 ppm for micro rubber chips and 4.5 ppm for crumb rubber, highlighting a steady release of organic compounds as UV exposure continued. These findings illuminate the transformative effects of UV exposure on tire-derived microplastics, emphasizing that UV-driven fragmentation and chemical leaching contribute to the complexity of microplastic pollution in water bodies. This work calls for further research into the identification and behavior of specific leached chemicals through GCMS analysis and heavy metal analysis with the goal of informing effective mitigation strategies. Our study underscores the urgent need for comprehensive measures to address the degradation and containment of tire-derived microplastics, ultimately safeguarding aquatic ecosystems from their far-reaching impacts.

3.21.P-Th273 Influence of Riverine Salt Gradients on the Adsorption of Trace Elements by Tire and Road Wear Particles: Experimental Approach
Angus Rocha Vogel[1]*, Yannik Kolberg*[2] *and Wolf von Tumpling*[2]*, (1)Central Laboratory for Water Analytics and Chemometrics, Helmholtz Centre for Environmental Research (UFZ), Leipzig, Germany, (2)Helmholtz Center for Environmental Research (UFZ), Germany*
Over the past decade, ecotoxicological concerns arose regarding tire wear particles (TWP) and their potential leachates in aquatic environments. As up to 20,000 t/a TWP are estimated to enter German surface waters, TWP have a non-negligible anthropogenic influence.

Despite this, the role of TWP as potential carriers of contaminants, such as trace elements, remains understudied. In our research, we observed the adsorption of heavy metals like Cr, Ni, Zn, Cd, and Pb onto tire and road wear particles (TRWP) in low-salinity surface water samples. This adsorption could deteriorate the chemical water quality of suspended matter, as classified by the German Working Group of the Federal States on Water Issues.
It is known that all major rivers discharging into the sea experience a salt gradient influencing the adsorption behavior of trace elements onto particles. Therefore, the aim of this study was to investigate how varying salt concentrations in surface waters affect the binding behavior of trace elements on TRWP.

The basic experiment we established for the adsorption of heavy metals onto TRWP is the following: A filtered (0.2 µm) river water sample (Freiberger Mulde, Saxony) was prepared. NaCl was added to obtain the required salt concentration (six samples ranging from 0.15 g/L (Freiberger Mulde) to 15.2 g/L Cl- (tidal Elbe, North Sea)) representing river conditions in the Elbe catchment area. TRWP were added at a concentration of 16.7 mg/L. The samples were shaken for 24 h. After filtration and drying in a desiccator, the particles were digested using HNO3 and HCl (3:1) and the element content quantified using ICP-MS/MS.
Among the priority elements (Cr, Ni, Cu, Zn, As, Cd, Pb), only the adsorption of Cd and Zn showed a significant dependency on the salt concentration. As Cl- concentration (and thus conductivity) increased, the adsorption capacity of Cd and Zn onto TRWP decreased. This is likely due to the formation of negatively charged chloride complexes [MCl?]²?, which do not readily bind to the negatively charged TRWP surface. While cations may form ionic interactions with TRWP, chloride complexes do not. These findings help predict the binding properties of trace elements onto TRWP in environmentally relevant contexts, e.g., such as large rivers systems like the Elbe or in water retention projects like sponge cities. This knowledge can help assess the potential risks posed by trace elements adsorbed onto TRWP.

Disclaimer/Disclosure: This work is funded by the German Federal Environmental Foundation (DBU) granting Angus Rocha Vogel a scholarship for his dissertation project (20022/052-34/2).

3.21.P-Th274 Elastomers or Zinc? A Comparison Between Elemental and Organic Analysis for the Detection and Quantification of TWPs

***Kieran Evans**[1], Neil Ward[2], Marc-Krystelle Mafina[3] and Maya Al-Sid-Cheikh[1], (1)University of Edinburgh, United Kingdom, (2)University of Surrey, United Kingdom, (3)PerkinElmer, United Kingdom*
Particles produced from tyre wear contribute significantly to the overall plastic pollution of the environment. While a number of different techniques have been utilized in an attempt to provide evidence for the occurrence and fate of tyre wear particles (TWPs) in the environment, dataare still relatively scarce when compared to other areas such as microplastics. Thermogravimetric analysis coupled with gas chromatography-mass spectrometry (TGA-GC/MS) provides a method whereby TWPs can be quantified in a number of different environmental matrices with little to no sample preparation. This work will, for the first time, compare the tyre elastomer concentrations found using TGA-GC/MS, with the concentrations of a known elemental tyre wear marker, zinc, in stormwater drainage sediments, and roadside surface soils. ZnO is added as an activator in the vulcanisation stages and comprises approximately 1 to 2% of the tyre tread mass. Quantification of zinc has been used as a method by which to quantify the presence of TWPs. However, in matrices such as sediments where rain and river water are also factors, leaching of zinc may prove problematic for accurate and reliable quantification of TWPs using this element as a marker. In this work, we explore the correlation between zinc levels and the concentrations of styrene-butadiene rubber (SBR) and polyisoprene (PI) found in a number in sediments collected from a drainage facility near the A34 in Newbury (UK) which prevents chemical contaminants from entering an SSSI (site of special scientific interest) river system (Lambourn River), to better understand the efficacy of each marker for the quantification of TWPs. Here, we show that the correlation between elastomer content and zinc concentration is far greater during summer months (R-squared values of 0.99 and 0.93 against SBR and PI respectively) compared to winter months (R-squared values of 0.20 and 0.10) against SBR and PI respectively of Furthermore, we explore the transportation of TWPs throughout a roadside drainage facility, evaluating its efficiency in preventing tyre-derived pollutants from being further distributed into the wider environment.

3.21.P-Th275 Influence of Repeated Leaching of Cryogenically Milled Tyre Tread (CMTT) and Tyre and Road Wear Particles (TRWP) on the Dissolved Concentration of Tyre Derived Chemicals

***Harriet Byrne**, Daniel Zahn, Bettina Seiwert and Thorsten Reemtsma, Helmholtz Center for Environmental Research (UFZ), Germany*

Tyre and road wear particles (TRWP) contain ca. 10% organic compounds added to improve tyre properties. These organic compounds and their transformation products are known to leach out once TRWP are deposited in the environment. This leaching may depend on a wide variety of factors, some intrinsic to the tyre and others environmental, but neither is well understood. Typically, leaching studies are done with cryogenically milled tyre tread (CMTT) particles in a solution and aliquots taken at various time points (static leaching). To increase the realism of the leaching experiments performed two key changes compared to most leaching studies are implemented: 1) Leaching is performed repeatedly with a complete solvent exchange after each step, thus better representing environmental conditions where particles are repeatedly exposed to fresh water after rain events. 2) In addition to 3 CMTT materials a TRWP material produced from the same tyres as one of the CMTT materials was tested. For 6 weeks the leachates were analysed with ultrahigh performance liquid chromatography high resolution mass spectrometry to quantify 22 tire derived chemicals and assess many more through a suspect- and nontarget screening. With these experiments, this study aims to characterise differences between the four tyre materials to improve our understanding of how intrinsic properties influence leaching from tyres and increase the transferability from laboratory studies to the environment.

Varying leaching behaviour between different compounds is observed, with some having a large initial peak and then decreasing slowly and others showing a constant emission throughout. Sum concentrations for many compounds exceed concentrations measured in the extracts, demonstrating that even extraction may underestimate long term leaching for some chemicals. Initial results show many compounds will continue to leach with renewed introduction of water and could therefore be continuously emitted from tire particles for a prolonged period of time. The CMTT leachates show higher concentrations of parent compounds compared to TRWP leachates where higher concentrations of transformation products were observed. This could potentially have implications for conclusions drawn on results from studies which used CMTT as a test material, which is predominantly the case.

3.21.P-Th276 Legacy of Chemical Pollution from an Underwater Tire Dump in Alver Kommune, Norway

*Adrian Jaen-Gil[1], Amandine Tisserand[1], Lucia Santos[2], Sara Rodriguez-Mozaz[3], Alessio Gomiero[1], Eirik Langeland[4] and **Farhan R. Khan**[1], (1)NORCE, Norway, (2)Institute of Natural Resources and Agrobiology of Salamanca, Spain, (3)Catalan Institute for Water Research, Spain, (4)Clean Oceans, Norway*

The long-term environmental impact of tire pollution has been rarely studied. The site of Hjelmås, a small bay outside Bergen in Alver Kommune, provides such an opportunity. In the 1970s a producer of blast mats (which use tires to contain explosions) went bankrupt and dumped their tire stock into the bay. On the seabed there remains a dump of old tires. This study investigated the legacy of this pollution source. First the area was mapped by multi-beam sonar for bathymetry and ROVs based QC Blueye Pro revealing a 12 m x 32 m area of tires. Sampling points were arranged along orthogonal transects from the centre of the dump and two control sites were chosen away from the tire dump. Water samples for chemicals analysis were collected at fixed depths 1 m above the sea bottom and the top 5 cm of sediments were collected by a Van Veen grab. Metal concentrations (Cd, Co, Cr, Ni, Pb) measured by ICP-OES were negligible in the water samples, but Zn was significantly greater at some of the tire dump sites compared to controls. In sediments, Ni, Cr, Cu, Pb and Zn were present in all samples, but greater in the tire dump compared to control sites with Zn the major contributor to the total metal load. GC-MS/MS and LC-HRMS were employed to analyse semi-volatile and non-volatile organics, respectively. The latter method tentatively provided approximately 300 chemical entities annotated with the mzCloud database with some sites in the tire dump showing distinction from the control sites. Phthalate acid esters were a pronounced cluster of chemicals that was further investigated. Although phthalates, particularly DEHP, were found in seawater, they were more consistently found across the sediment samples suggesting the long-term stability of the sediments for both organics and metals. In sediments, DEHP was the most prevalent phthalate, but DMP and BBzP also contributed to the sediment loads. DEHP being the most prevalent phthalate found in both environmental compartments agrees with previous findings of DEHP as the most leachable phthalate from tire crumb rubber in seawater. Our study shows that the legacy of pollution remains in Hjelmås especially in sediments. Any efforts for remediation should ensure minimal disruption of the sediments as this may lead to increased mobilization of pollutants.

Disclaimer/Disclosure: This study was funded by Regionale forskningsfond (RFF Vestlandet grant #337686).

3.21.P-Th277 Characterization of Deposited Inhalable Fraction from Recycled Rubber Flooring Degradation

***Daniel Rozua**, Ines Gonzalez, Ethel Eljarrat and Teresa Moreno, Institute of Environmental Assessment and Water Research - Spanish Council for Scientific Research (IDAEA-CSIC), Spain*

Recycled rubber flooring, widely used in playgrounds, sports tracks, and other recreational surfaces, offers a sustainable solution for managing rubber waste. However, its extensive application raises concerns about potential environmental and health risks due to the presence of different contaminants and additives like plasticizers, flame retardants, and metals. The degradation of these surfaces by various physical and chemical weathering processes results in the formation of rubber particles, some of which are small enough to be inhalable (PM2.5). These remain deposited on the ground surface until they are resuspended by wind or human activity.
This study involves the characterization of potentially inhalable particles (PIP) deposited in synthetic rubber surfaces found in playgrounds and running tracks in the city of Barcelona. A total of 8 sites were sampled using a patented field resuspension chamber, that allows for the selective separation of PM2.5 without the issues of electrostatic charge and resuspension related to traditional methods of dust collecting. A total of 47 organic compounds were analysed, including 30 plasticizers like organophosphate esters (OPEs) and phthalates, as well as 17 flame retardants, like polybrominated diphenyl ethers (PBDEs), along with a wide range of short-chain chlorinated paraffins (SCCPs). A total of 57 metals were monitored as well.
Results vary greatly depending on the family of compounds. Plasticizers like OPEs were found at low concentrations, 18.4 ng/m2 at maximum, while others like phthalates were found at up to 3039 ng/m2, with compounds like diisononyl phthalate (DiNP) being the greatest contributors. Flame retardants were found at low concentrations, while SCCPs were at considerable levels, 205 ng/m2 at maximum. Metals were present at great concentrations, up to 1.87·10^5 ng/m2, with elements like Ca, Mg or Zn being the greatest contributors.
Overall, this study seeks to emphasize the presence of high quantities of concerning or regulated compounds in inhalable particles coming from parks and playgrounds. Although PIP is not directly inhalable, it can resuspend easily, as well as be absorbed by the body through ingestion and dermal contact.

3.21.P-Th278 Human Exposure Assessment to Tire-Related Chemicals Through Urine and Silicone Wristbands: Method Development

*Nicola Montemurro, **Francesca De Angelis**, Merce Gari and Antonia Merola, IDAEA-CSIC, Spain*

Tire-road wear particles (TRWPs) are generated through tire-road friction and are a significant source of non-exhaust emissions. Their accumulation in the environment raises concerns about human health due to the toxicity of Tire-Related Chemicals (TRCs), which include additives and their transformation products. Human exposure to TRCs occurs primarily through inhalation, ingestion, and dermal contact. This study aims to develop and validate methods for quantifying TRCs in urine and silicone band passive samplers. Urine, commonly used in exposome research, and silicone bands, which mimic dermal exposure, offer insights into skin exposure and internal concentrations.
Sample preparation protocols were optimized for recovery and reduced matrix effects. For silicone bands, the solvent volume, number of extractions, and reconstitution volumes were refined, with a final protocol requiring two 15-minute extractions with methanol-ethyl acetate (1:1 v/v) and reconstitution in methanol-water (1:1 v/v). Urine samples were hydrolyzed with ?-glucuronidase to process metabolites, and ?-gone® filtration and liquid-liquid extraction (LLE) methods were compared. While ?-gone provided cleaner samples, its dilution limited detection sensitivity. LLE, with 10-fold concentration and internal calibration, allowed the detection of low-sensitivity compounds despite matrix challenges.
Silicone band extraction yielded quantitative recovery for most compounds after two extractions, validated at three concentration levels. For urine samples, LLE enabled the quantification of low-sensitivity

compounds despite matrix effects. Preliminary findings on healthy volunteers detected benzothiazoles benzotriazoles, and cyclic amines in both matrices, with more compounds identified in urine. These validated methods provide a framework for assessing human exposure to TRCs, identifying biomarkers of TRWPs, and evaluating health risks. By comparing innovative silicone bands with traditional urine sampling, this study enhances understanding of the environmental and human health impacts of tire-related chemicals.

3.21.P-Th279 May Saprophytic Fungi Help in the Rehabilitation of Soils Impacted by Tire Wear Particles? - A Preliminary Study

*Laura Carvalho[1], **Isabel Lopes**[2], Joao Pinto da Costa[2], Teresa Rocha-Santos[2] and Catia Venancio[2], (1)Department of Biology, University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal*

Agricultural soils are perceived as one of the major sinks for tire wear particles (TWP). The TWP may reach soils by air, storm, or drainage water, and their deposition is potentiated by the proximity to road networks. All pathways contribute to gradual buildup of TWP in soils, with potential impacts on soil health, plant growth, and ecosystem services. Saprophytic fungi may be a promising cleansing strategy because of their natural role as decomposers. This work aimed at addressing the potential biodegradation of TWP by two saprophytic fungi (*Trametes versicolor* Tv and *Pleurotus sajor caju* Psj). For that, a 56-day experiment was conducted using a minimal medium (MSM) and a medium that simulates agricultural soil conditions (LUFA soil elutriates-ELU). The following treatments were carried out: (i) TWP in MSM or ELU with the presence of one of the fungal species; (ii) TWP in MSM or ELU without the presence of any fungal species (to allow identification of any influence of the media on its degradation); and (iii) MSM with fungi alone or ELU with fungi alone (to control for the presence of metabolites that were due to the metabolism of the fungi alone). Each treatment had four replicates with sampling points on days 0, 14, 28, 42, and 56. The biodegradation process was tracked by the production of ammonia and enzymatic activity (acid phosphatase, alkaline phosphatase and pectinase activity) in rot fungi exudates, and alterations on TWP weight loss. A higher degree of biodegradation was found in ELU than in MSM, possibly related to the presence of humic substances or the provision of a more nutrient-rich environment for fungi growth. A 7% TWP weight loss was observed in Psj+ELU on day 28. In general, the production of ammonia and the activity of the enzymes was higher in exudates of elutriates, probably for being a more nutrient-rich environment. The ammonia production and pectinase activity were higher in treatments involving the exposure of TWP to the fungi, but in those treatments, the activity of acid and alkaline phosphatase was hampered. These findings suggest the ability of fungi to tolerate possible harmful effects of the substances composing TWP and their capacity to biodegrade these particles. The primary limitations of this study are the media type and experiment duration, which may have restricted the degree of plastic breakdown. However, rot fungi have emerged as a potentially effective tactic for rehabilitating soils contaminated by TWP.

3.21.P-Th280 Ecotoxicological Impacts of Tire Wear Particles

*Manfred Feigl[1], Tobias Forster[1], Caroline Christiane Gebert[1], Alexander Brunner[1], Verena Reichart[1], Gregor Wittmann[1], Ingrid Kolar[1], **Barbara Gepp**[2] and Elisabeth Simboeck[2], (1)University of Applied Sciences Technikum Wien, Austria, (2)University of Applied Sciences Technikum Wien,Austria*

Anthropogenic pollution, including the rapid growth of plastic production and microplastic pollution since the 1950s, poses a severe threat to human and environmental health, with particles found globally, even in the cryosphere and human tissues. Tire wear particles (TWP) alone account for about one-third of primary microplastics in the environment, challenging biodiversity and Earth's system integrity. Therefore, supposedly environmental-friendly tire alternatives have recently appeared on the market
In this project, we compared two types of Continental tires, the conventional petro-based Grand Prix 5000 tire and the supposedly green and sustainable Taraxagum tire made from dandelion, and investigated their ecotoxicological impact. Leachates from both tire particles were used in a luminescent bacteria test (ISO

11348) to assess decomposer inhibition, a Daphnia Acute Toxicity Test (OECD 202) for impacts on aquatic invertebrates, a Fish Embryo Acute Toxicity (FET) Assay for developmental effects, and a MTT assay for cytotoxicity. Ready biodegradability of leachable substances was tested following the OECD 301D method.
Our results show that both Taraxagum and Grandprix TWP leachates were highly toxic to *Vibrio fischeri*, with minimal differences in IC50 values (9.1% vs. 7.6%). High toxicity was also observed for Grandprix leachates in *Daphnia magna*. FET assays indicated minimal toxicity for Taraxagum leachates, while Grandprix caused concentration-dependent developmental delays. MTT assays revealed a higher cellular toxicity for Grandprix (LC50 = 14%) versus Taraxagum (LC50 = 88%). Interestingly, biodegradation tests showed active bacterial metabolism of Grandprix leachates, but negligible degradation for Taraxagum. These data demonstrate a significant ecotoxicological risk of both TWP leachates in the environment. Grandprix TWP leachates revealed high toxicity and were biodegradable. In contrast, Taraxagum leachates were slightly less toxic, however showed negligible biodegradability, raising concerns about long-term environmental persistence. Therefore, sustainable tire materials with no ecotoxicological risk and mitigation strategies of TWPs are urgently needed.

3.21.P-Th281 Deciphering the Estrogenic Activity of Aqueous Leachates from Elastomers by Effect-Directed Analysis (EDA)

Rebecca Sussmuth[1]*, Timothy Rosenberger*[1]*, Peter Schweyen*[1]*, Georg Dierkes*[1]*, Anna Maria Bell*[1]*, Arne Wick*[1]*, Sebastian Buchinger*[2] *and Thomas A. Ternes*[1]*, (1)Federal Institute of Hydrology (BfG), Germany, (2)Biochemistry / Ecotoxicology, Federal Institute of Hydrology (BfG), Koblenz, Germany*
Elastomers used in tires or membranes of hydraulic constructions contain complex mixtures of a variety of chemicals, which can be released into the environment and are potentially toxic. The aim of this study was to identify the main drivers of estrogenicity by effect-directed analysis (EDA) and to quantify their estrogenic potential. Therefore, aqueous leaching of an elastomer membrane was applied and estrogenicity was tested in a planar yeast estrogen screening (p-YES) after chromatographic separation on high-performance thin-layer chromatography (HPTLC) resulting in two active spots on the plate. For compound identification, a non-target screening approach using LC-ESI-HRMS was used. In total, 2389 features were detected in the aqueous leachate. Due to low concentrations and limited amounts, reduction of candidates by fractionation was not praticable. Thus, an exhaustive extraction of the membrane was performed using isopropanol. The organic extract was fractionated by preparative column chromatography. Fractions showing estrogenic activity were analyzed by LC-ESI+-HRMS and detected features were compared with those from the aqueous leachate. Thereby, the candidate list could be reduced to 14. Three of those were identified by library search. Authentic standards of these three substances were analyzed by p-YES and 4-hydroxydiphenylamine (4HDPA) was found to cause the same spots as observed for the aqueous leachate. 4HDPA is a transformation product of p-phenylenediamines, commonly used antiozonants in elastomers. By quantifying 4HDPA and measuring its estrogenic activity by estimating dose response relationships it was shown that about 120±30% of total estrogenicity of the aqueous leachate can be explained by 4-HDPA. In our EDA approach, it was also possible to identify 4-(phenylimino)-2,5-cyclohexadien-1-one (QMI). Our results suggested a rapid and reversible transformation of QMI into 4HDPA resulting in a complex equilibrium between these two substances and explaining the two spots in the p-YES. This together with the environmental relevance of the leaching of 4HDPA in real waters will be elucidated in follow-up studies. Moreover, further research is needed to explain further observed specific toxic effects caused by elastomers and their additives. Overall, our EDA approach is a promising tool for an efficient way to identify toxic substances released from complex materials by linking different extraction methods, HPTLC tests and chemical analysis.

3.21.P-Th282 Sorption Dynamics of Tire-Derived Compounds to Soils is a Determinant Factor for Plant Uptake

Valerie Wilkeit*, Thilo Hofmann and Thorsten Huffer, University of Vienna, Austria*
Tires consist of diverse materials including rubber (40-50%), softeners (15%), vulcanisation agents (2-5%) and other inorganic and organic additives (2-15%). During driving, tires abrade due to mechanical and thermal stress, resulting in the emission of tire and road wear particles (TRWP). Like all plastic additives, tire-derived compounds (TDC) leach from TRWP (4-6) and may exhibit severe adverse environmental effects, for example 2-anilino-5- [(4-methylpentan-2-yl)amino]- cyclohexa-2,5-diene- 1,4-dione (6PPD-Quinone), the transformation product of N-(1,3-dimethylbutyl)-N -phenyl-1,4-phenylenediamine (6PPD).

TDCs have been detected in agricultural soils and can be taken up by plants; thus, the understanding of sorption processes of TDCs to soils is important for determining the bioavailable fraction of TDCs in soils. Therefore, we investigated the sorption processes of tire-derived compounds in soil, a topic of increasing concern due to the potential environmental and health impacts.
We investigated the sorption kinetics of selected TDCs, including aniline, 6PPD-Quinone, hexa(methoxymethyl)melamine (HMMM), 1,3-diphenyl guanidine (DPG), 5-methyl-1h-benzotriazole (5-Me-1H-BTR) and benzothiazole (BTH) using two reference soils with distinct organic carbon contents and cation exchange capacities. Sorption isotherms were generated for four well-characterised reference soils along with two soils from Israel. The experiments followed OECD guideline 106 for batch sorption experiments. TDC concentrations were quantified using triple quadrupole liquid chromatography-mass spectrometry. To elucidate the soil properties influencing TDC sorption, soil mineral composition was characterised through X-ray diffraction analysis.
The sorption kinetics revealed that all compounds followed pseudo-second-order kinetics, indicating that TDC sorption in soil involves dynamic processes, consistent with literature on the sorption of organic compounds in soils. In this model, chemisorption is the dominant mechanism, suggesting the involvement of intermolecular interactions such as covalent bonding, ?-? interactions, or cation exchange. The sorption behaviour of TDCs in soils is crucial for determining their bioavailability, which can be assessed through distribution coefficients that allow to estimate the potential risk of plant uptake.

3.21.P-Th283 Monitoring of Tire-Derived Compounds in Commercial Leafy Vegetables and Associated Dietary Exposure

Anya Sherman[1]*, Luzian Hammerle*[1]*, Evyatar Ben-Mordechay*[2]*, Benny Chefetz*[2]*, Thorsten Huffer*[1] *and Thilo Hofmann*[1]*, (1)University of Vienna, Centre for Microbiology and Environmental Systems Science, Department of Environmental Geosciences EDGE, Austria, (2)Department of Soil and Water Sciences, Institute of Environmental Sciences, Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel*

The toxicity of tire particles has been linked to leachable organic additives and associated transformation products (tire-derived compounds). Tire particles, and tire-derived compounds are introduced to the agricultural environment via atmospheric deposition, irrigation with treated wastewater, and biosolids (treated sewage sludge) application as fertilizer. In the agricultural environment, tire-derived compounds may be taken up by edible plants, leading to human exposure. Sixteen tire-derived compounds were measured in twenty-eight commercial leafy vegetable samples grown in Switzerland, France, Spain, and Israel. In commercial leafy vegetables, six tire-derived compounds were detected: benzothiazole (maximum concentration 238 ng/g dry weight), 2-hydroxybenzothiazole (maximum concentration 665 ng/g dry weight), 1,3-diphenylguanidine (maximum concentration 2.1 ng/g dry weight), N-(1,3-dimethylbutyl)-N?-phenyl-p-phenylenediamine (6PPD,maximum concentration 0.4 ng/g dry weight), N-Isopropyl-N-phenyl-4-phenylenediamine (IPPD, maximum concentration 0.1 ng/g dry weight), and N-phenyl-N-cyclohexyl-p-phenylenediamine (CPPD, maximum concentration 0.3 ng/g dry weight). At least one compound was present in 71% of samples analyzed. Statistical analyses did not reveal correlation between known growth conditions and tire-derived compound concentrations in the leafy vegetables. Based on measured concentrations and dietary survey data, the estimated daily intake due to leafy vegetable consumption of these tire-derived compounds under a mean and maximum concentration scenario was calculated. The estimated daily intake for 1,3-diphenylguanidine ranged from 0.05 ng/person/day in the mean scenario to 4.0 ng/person/day in the maximum scenario; benzothiazole ranged from 12 to 1,296 ng/person/day; 6PPD ranged from 0.06 to 2.6 ng/person/day; IPPD ranged from 0.04 to 1.1 ng/person/day; CPPD ranged from 0.05 to 2.6 ng/person/day. The estimated daily intake via leafy vegetable consumption was generally lower than or comparable to exposure via other known sources, although leafy vegetables represent only a fraction of total dietary exposure. Future studies should elucidate pathways of tire-derived compounds from road to field, assess the exposure to transformation products, and investigate the biological effects associated with this exposure.

3.21.P-Th284 Toxicity of Plastic Additives to *Daphnia magna* and *Lemna minor* and the Temporal Trends of their Leaching from Microplastics

Onni Sirkia[1]*, Pius Kinoti Kairigo*[2]*, Elina Kalenius*[2]*, Jussi V.K. Kukkonen*[1] *and Victor Carrasco Navarro*[1]*, (1)University of Eastern Finland, Finland, (2)University of Jyvaskyla, Finland*

Microplastics (MPs) are a complex group of environmental contaminants with varying physical and chemical properties. They consist not only of the polymer chains but also of many different kinds of

additives that are used to modify the properties of plastic mass. The additives are not chemically bonded to the polymer chains and can leach out of the plastic mass over time, thus causing potential harm to the organisms in the surrounding environment. Still, the majority of MP-related research focuses on physical particles rather than the released additives.
In this study, we wanted to assess the toxicity of different plastic leachates to *Daphnia magna* and *Lemna minor* in the absence of physical MPs. Both *D. magna* and *L. minor* are common freshwater organisms and vital parts of the aquatic food web. In addition, we wanted to evaluate temporal trends of additive leaching and elucidate the molecular identity of additives released.
Leachates from nine different MPs were prepared in environmentally relevant concentrations (10 g/l) over three subsequent leaching cycles (20d, 160 rpm, ambient temperature, darkness). After each leaching, the MPs were removed via filtration (0.22 ?m pore size membrane). Then, the toxicity of obtained leachates were tested on *D. magna* neonates (<24h old) in different concentrations (5, 20, 50 and 75%) by monitoring their mobility at 24 and 48h according to the OECD (2004) guidelines as well as at 72 and 96h. Leachate toxicity data will be complemented with results from *L. minor* growth inhibition tests (OECD, 2006). Identification of the leached additives using untargeted high resolution LC MS is currently an ongoing endeavor and will later be complemented with ICP MS analyses for elemental characterization of the leachates.
Our current results indicate that tire rubber leachates can induce acute mortality on *D. magna* already at 20% concentration, thus making the determination of any ECxx values impossible. The other leachates did not show acute toxicity to *D. magna* within the 96h test period, but their toxicity cannot be ruled out before the tests with *L. minor*. Ideally, the high resolution LC MS analyses will provide us with the identity of released additives and single out possible candidate molecules responsible for the toxicity observed thus far.
Overall, our study demonstrates the important role of plastic additives in ecotoxicology and the hazards they may pose to the environment already at relatively low concentrations.

3.21.P-Th285 Toxicity of Tyre Wear Particle Leachates to Lichens
Gintare Sujetoviene[1] *and Diana Miškelytė*[2]*, (1)Vytautas Magnus University, Kaunas, Lithuania, (2)Vytautas Magnus University, Lithuania*
Tyre wear particles (TWP) are some of the dominant sources of microplastics in the aquatic and terrestrial environment. Once TWP enter ecoystems, they can leach certain plastic additives that can be potentially toxic to biota. However, little is known about the impact of TWP on non-target organisms. This study aims to determine the acute toxic effect of leachates derived from different TWP on two lichen species: the sensitive Ramalina and resistant to pollution *Xanthoria parietina*, using different physiological and biochemical endpoints. Leachates were obtained by incubating 1 g L-1 of TWP in water. Each lichen species was exposed to leachates at five different concentrations for 1 h, and endpoints were measured every 24 h over 3 days. Leachates from TWP were toxic to lichens. Our results suggest that TWP leachates adversely affect lichen viability, although more field data on TWP and their leachate concentrations are needed to fully assess the environmental impact of TWP.

3.21.P-Th286 Toxic Effects of Tire Wear Particle Leachate on Survival, Detoxification, Antioxidant System, and Energy Metabolism of Two Marine Zooplankton
Hye-Seong Lee, Je-Won Yoo, Chaerin Park and ***Young-Mi Lee****, Sangmyung University, "Korea, Republic of"*
Tire wear particles (TWPs) are particulate pollutants generated by friction between tire wear and road surfaces. TWPs on roadways can be transported to the ocean via wind or surface runoff and thus are recognized as an emerging contaminant in marine surface water. In the ocean, harmful chemicals associated with TWPs, such as heavy metals, polyaromatic hydrocarbons (PAHs), and phenolic compounds, can leach into water fraction, which can induce toxic effects on marine biota. However, toxic effects of chemicals associated with TWPs on marine organisms are not well-understood. In this study, we obtained TWP leachates (5 gTWPs/L for 3 days) from two commercially available tires (one for truck and one for sedan) and investigated toxic effects of these TWP leachates and zinc (Zn), typical pollutants in tires, on survival, reproduction, transcriptional modulation and energy reserves of two marine zooplankton, the brackish water flea *Diaphanosoma celebensis* and the marine rotifer *Brachionus koreanus*. Zinc (Zn) was identified as the dominant chemical in both TWP leachates (1.96 and 5.77 mg/L in truck and sedan leachates, respectively). Acute toxicity test showed that Zn is highly toxic to both

species (48-h LC50Zn2+: 2.13 and 2.47 mg/L for *D. celebensis* and *B. koreanus*, respectively). And both truck and sedan TWP leachates were also highly toxic to *D. celebensis* (48-h LC50: 49.31 and 24.95%, respectively, equivalent to 0.96 and 1.44 mgZn2+/L, respectively). Similarly, truck TWP leachate induced significant mortality to *B. koreanus* (48-h LC50: 65.82%, equivalent to 1.29 mgZn2+/L), but sedan TWP leachate induced less than half of mortality of *B. koreanus*, even at the 100% concentration which contain Zn more than median lethal concentration, suggesting antagonistic toxicity of Zn. Chronic toxicity test showed reproductive disorder of both species exposed to Zn and TWP leachates, and gene expression, enzyme activity, and cellular molecules related to detoxification, antioxidant system, and energy metabolism were significantly modulated following exposure to Zn and both TWP leachates. Our findings imply that TWP leachates can disrupt reproduction, antioxidant system, and energy metabolism of marine zooplankton and suggest that Zn is one of the major sources determining toxicity of TWPs but they can toxicologically interact with other chemicals in TWPs.

Disclaimer/Disclosure: This research was supported by the Risk assessment to prepare standards for protecting marine ecosystem of the Korea Institute of Marine Science & Technology Promotion (KIMST) funded by the Ministry of Oceans and Fisheries (KIMST-20220383).

3.21.P-Th287 Adverse Effects of Tyre Particles on Estuarine Invertebrates and Microbial Communities

***Matthew Cole**[1], Lucy Howarth-Forster[2], Alexander Mead[2], Rebecca Millard[1], Karen Tait[1], Richard C. Thompson[3], Michael Wilde[2] and Penelope Lindeque[1], (1)Plymouth Marine Laboratory, United Kingdom, (2)University of Plymouth, United Kingdom, (3)School of Biological and Marine Sciences, University of Plymouth, United Kingdom*

Tyre particles emanating from vehicles can be readily transported into the natural environment. Approximately 2% of tyre particles entering the environment are predicted to end up in estuaries, with mean environmental concentrations of tyre particles ranging 0.5-2 g kg-1 and highest observed concentrations >25 g kg-1. The toxicological and ecological risks posed by tyre particles remain poorly understood for a diverse range of taxonomic groups, with a paucity of chronic exposure studies using environmentally relevant parameters. To elucidate the ecological risks tyre particles pose to estuarine ecosystems, a chronic dose-response exposure study was conducted. Natural estuarine sediments were spiked with 0-100 g kg-1 of tyre particles derived from end-of-life passenger car tyres. Lugworms (*Arenicola marina*) and cockles (*Cerastoderma edule*) were exposed to 1 kg of sediment, with 1350 mL overlying seawater, for 28 days. Mortality, feeding and burial activity were monitored throughout, and gene expression, burial time, growth and shifts in sediment microbial communities were assessed post-exposure. Tyre particles caused lethal toxicity in lugworms, with 100% mortality at concentrations >25 g kg-1, and a LC5028d of 11.9 g kg-1. Tyre particle concentrations >1 g kg-1 caused significant decreases in lugworm feeding, burial and weight, and the burial behaviour of cockles. Exposure to tyre particles caused significant shifts in sediment microbial community composition and diversity, for both prokaryotic and eukaryotic organisms. The study highlights that environmentally relevant concentrations of tyre particles can have substantial ecological effects in estuarine ecosystems.

Disclaimer/Disclosure: The project was funded by the Natural Environment Research Council TyreLoss project (NE/V001868).

3.21.P-Th288 Assessment of the Toxicity of Tire Wear Particles and Their Leachates Using a Cell-Based Toolbox from Rainbow Trout (*Oncorhynchus mykiss*)

***Anna Toso**[1], Sara Isabel Bastos Gonçalves[2], Thibault Masset[3], William Dudefoi[4], Alan J. Bergmann[5], Etienne Vermeirssen[5], Florian Breider[3], Benoit Ferrari[5] and Kristin Schirmer[1], (1)Department Environmental Toxicology, Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Department Environmental Toxicology, Eawag Swiss Federal Institute of Aquatic Science and Technology, Germany, (3)Central Environmental Laboratory, IIE, ENAC, EPFL Ecole Polytechnique Federale de Lausanne, Switzerland, (4)Department Environmental Toxicology, Eawag Swiss Federal Institute of Aquatic Science and Technology & aQuatox-Solutions, GmbH, Switzerland, (5)Ecotox Centre, Switzerland*

6PPD-quinone (6PPD-Q), formed by the environmental oxidation of the tire wear antioxidant 6PPD, has been identified as one the causes of urban runoff mortality syndrome (URMS), responsible for the mass death of coho salmon on North America's western coast. Understanding the impact of Tire Wear Particles

(TWPs) and their chemicals, including 6PPD, on aquatic species is critical to assessing risks to the ecosystem. Cryogenically milled tire tread (CMTT) can be used as suitable surrogates to experimentally study the toxicity of TWPs and their associated chemicals with in vitro tests, which are innovative, fast, and efficient tools that offer a less time- and resource-consuming alternative to traditional in vivo testing. We developed a cell-based toolbox from rainbow trout (*Oncorhynchus mykiss*) to assess in vitro the potential harmful effects on fish. These cells, named RTgill-W1, RTgutGC and RTbrain, derived from the gill, intestine, and brain tissues respectively, can provide important insights into the mechanism of action of and tissue-specificity of these pollutants. This method, initially developed for the RTgill-W1 cell line and validated in the corresponding OECD Test Guideline Nº 249, was extended to the other cell lines. With these cells, we studied acute toxicity of particles and chemicals by assessing their effects on several biological endpoints: cell metabolic activity, lysosome, and cell membrane integrity.
Different types of CMTT, representative of the European and US markets, were tested on RTgill-W1 cells, revealing similar toxic effects on the three endpoints investigated. Interestingly, the 6PPD-Q, present in both types of CMTTs, was found to be particularly toxic to RTbrain but not to the other cell lines, confirming the suitability of these cell lines for determining tissue-specific modes of action.
Our next steps involve: (i) examining molecular toxicity mechanisms through transcriptomics and proteomics; (ii) expanding toxicity endpoints of CMTT and their associated chemicals; (iii) evaluate chronic exposure to CMTT and iv) study the trophic transfer effects by testing invertebrates feed with biofilm contaminated by CMTTs. These cell-based in vitro assays hold potential to advance understanding on the toxicological risks of tire wear particles and their tire-associated chemicals to aquatic organisms while considerably reducing animal testing.

Disclaimer/Disclosure: The work presented here was funded by the World Business Council for Sustainable Developments (WBCSD) Tire Industry Project (TIP), a global CEO-led initiative undertaken by leading tire manufacturing companies. The study design, execution, interpretation, and manuscript preparation were conducted solely by the authors.

3.21.P-Th289 Integrating Transcriptomic Points of Departure (tPODs) with Bio- and Chemical Analyses for Hazard Assessment of Road Runoff in Zebrafish
Markus Schmitz[1]*, Selina Seibold*[1]*, Alexander Maria Pape*[1]*, Fabian Essfeld*[2]*, Markus Hecker*[3]*, Volker Linnemann*[4]*, Martin Krauss*[5]*, Werner Brack*[5]*, Sabrina Schiwy*[1] *and Henner Hollert*[6]*, (1)Dept. Evolutionary Ecology and Environmental Toxicology (E3T), Goethe University, Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (3)Toxicology Centre and School of the Environment & Sustainability, University of Saskatchewan, Saskatoon, Canada, (4)Institute for Environmental Engineering (ISA), RWTH Aachen University, Germany, (5)Dept. Exposure Science, Helmholtz Centre for Environmental Research - UFZ, Germany, (6)Dept. Evolutionary Ecology and Environmental Toxicology (E3T), Goethe University & Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Germany*
Road runoff and tire wear particles can severely impact freshwater ecosystems, such as the Urban Runoff Mortality Syndrome in coho salmon (*Oncorhynchus kisutch*) along the northern Washington coast, USA. However, little is known about the environmental impacts of urban runoff in other regions, particularly Europe. The RoadTox project aims to address this gap by integrating bioanalytical, chemical, and molecular methods to study the effects of road runoff on zebrafish larvae. Specifically, three consecutive stormwater samples were collected from the BAB4 motorway in Aachen, Germany, and zebrafish embryos were then exposed to graded concentrations of total and particle-free runoff fractions. Our analyses included acute toxicity, enzymatic biomarkers, neurotoxic endpoints, and whole transcriptome analysis. Transcriptomic Points of Departure (tPODs) were then calculated based on benchmark concentrations of individual genes for which concentration-response models could be fitted. Acute toxicity varied highly among the three samples, with EC10 thresholds ranging from 2.3% to 28% runoff for total samples and 9.8% to 45% for filtered samples, confirming that particulate matter contributed most to toxicity. Additional effects were observed on spontaneous tail coiling, light-dark transition behaviour, and EROD activity differing in severity between samples and fractions. Transcriptional analysis revealed an increasing number of transcripts that were dysregulated with increasing concentrations of all three runoff samples. Preliminary tPOD results showed effect thresholds ranging from one-quarter of the EC10 concentration to nearly the EC10, within the single-digit percentage range of road runoff. Noteworthy, upregulation of cyp1A, linked to dioxin-like activity and oxidative stress, was consistently observed across all samples, matching previous observations of cardiovascular teratogenic effects and enzyme biomarker data. Other dysregulated genes (e.g., cyb5a, alox5b.2, cbr1l, sult6b1) were associated with

oxidative stress and xenobiotic metabolism, which may be related to exposure to PAHs and benzothiazoles as likely drivers of toxicity. The results of this study, funded by the Ministry for Environment, Agriculture, Conservation, and Consumer Protection of North Rhine-Westphalia (MULNV), Germany, demonstrate that road runoff affects gene expression at low concentrations and provide a foundation for identifying toxicity drivers through molecular pathway analyses.

3.21.P-Th290 CMTT Exposed Periphyton Induces Bottom-up Food Chain Effects in the Freshwater Grazer *Physa acuta*

***Sara Isabel Bastos Gonçalves**[1], Alexandra Kroll[2], Anna Toso[1], Thibault Masset[3], Alan J. Bergmann[2], Etienne Vermeirssen[2], Florian Breider[3], Benoit Ferrari[4] and Kristin Schirmer[1], (1)Department Environmental Toxicology, Eawag Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Ecotox Centre, Switzerland, (3)Central Environmental Laboratory, IIE, ENAC, EPFL Ecole Polytechnique Federale de Lausanne, Switzerland, (4)Ecotox Centre - EPFL ENAC IIE, Switzerland*

Periphyton communities grow on the bottom of freshwater streams, being composed of a complex mixture of microorganisms embedded in extracellular polymeric substances (EPS). These microbial communities form the base of aquatic food webs being crucial to ecosystem functioning. Consequently, changes at this level can have far-reaching effects on onward food-web relationships. They also may act as a sink for pollutants, including particles, such as tire and road wear particles (TRWP), which have been detected in streams and rivers not exceeding 10 mg/L. We have previously shown that CMTT (cryogenically milled tire tread) particles, used as proxies for TRWP, accumulate in periphytic communities though with little structural or functional impacts for these communities at environmental relevant concentrations. However, the potential threat to organisms grazing on CMTT-contaminated periphyton has not yet been explored. We hypothesized that CMTT particles associated with the periphyton matrix, will be transferred to Physa acuta, and have potential to interfere with the snail's health. To explore this hypothesis, we fed snails on CMTT contaminated periphyton: near natural periphyton was grown until mature (14d) and subsequently exposed to nominal concentrations of 50 mg/L of CMTT particles, leachates obtained from 50 mg/L CMTT and 2 µg/L of 6PPD-Q (compound highly toxic for fish) for 96h. The exposed periphyton was offered to snails in contamination-free microcosms for 14d, with medium and food renewal at 7d. After the exposure period, snails were transferred to new microcosms for a 24h depuration period. The snail's health was evaluated via feeding rate, faeces production, growth, and reproduction. About 20% mortality was observed for the leachates treatment, while particles only and 6PPD-Q did not induce statistically significant changes in mortality compared to the control. Leachates and CMTT treatments induced higher feeding rates and growth compared to control. The 6PPD-Q exposed snails tended to remain attached to the glass when not feeding, had lower feeding rates and less eggs per clutch compared to the other treatments. Moreover, snails only laid egg clutches on the biofilm in the control, while for the other treatments the egg clutches were attached to the microcosm glass. These visual observations will be analysed further in upcoming behavioral experiments. Analyses on the transfer and accumulation of particles and leachates into the snails are ongoing

Disclaimer/Disclosure: The work presented here, including the production, handling, distribution and information related to the CMTT and TRWP, was funded by the World Business Council for Sustainable Developments (WBCSD) Tire Industry Project (TIP). TIP is a global CEO-led initiative undertaken by leading tire manufacturing companies. TIP drives research on potential human health and environmental impacts of tires throughout their lifecycle. The study design, execution, interpretation, and manuscript preparation were conducted solely by the authors.

3.21.P-Th291 Evaluating the Effects of 6PPD-Quinone Exposure on Early-Life Stage Rainbow Trout Transcriptome

***Catherine Roberts**[1], Junyi Lin[1], Evan Kohlman[1], Niteesh Jain[1], Mawuli Amekor[1], Alper James Alcaraz[2], Natacha S. Hogan[1], Markus Hecker[1] and Markus Brinkmann[1], (1)University of Saskatchewan Toxicology Centre, Canada, (2)University of Saskatchewan Toxicology Centre, United States*

The rubber tire derivative N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone (6PPD-quinone), commonly found in roadway runoff, has recently been identified as a key driver of urban runoff mortality syndrome in coho salmon. Subsequent studies have shown significant variability in species sensitivity to this toxicant, even within the salmonid family. While traditional exposure studies are essential for assessing species sensitivity, transcriptomic analysis offers a broader perspective, uncovering gene expression changes and disruptions in biological pathways, as well as establishing transcriptomic points of departure (tPODs). To investigate early-life stage toxicity, a test was conducted on rainbow trout (*Oncorhynchus mykiss*) alevins starting at hatch. Treatment groups included a a solvent control (0.01%

dimethyl sulfoxide), and time-weighted average 6PPD-quinone concentrations of 0.06, 0.10, 0.20, 0.44, 1.30, and 2.35 µg/L. After 96 hours of exposure, whole-body alevins were sampled and flash-frozen for transcriptomic analysis. The results revealed over 1,200 disrupted genes at a log2 fold change of 2.0, with significant alterations in biological pathways, including osteoclast differentiation, apoptosis, necroptosis, inflammation, and immune response. Evaluation of tPODs found similarity between tPODs and sub-chronic mortality data for the same species and life stage, indicating that tPODs may be used predictive of sub-chronic mortality.

3.21.P-Th292 Transcriptomic Disruption of Northern Leopard Frog Tadpoles (*Lithobates pipiens*) by 6PPD-Quinone

Catherine Roberts*, Julie Borsa, Markus Brinkmann, Markus Hecker and Natacha S. Hogan, University of Saskatchewan Toxicology Centre, Canada*
Catherine Roberts[1], Julie Borsa [1,2], Natacha Hogan[1,2], Markus Hecker[1,3,4], Markus Brinkmann[1,3,4], (1) Toxicology Centre, University of Saskatchewan, Saskatoon, Canada, (2)Department of Animal and Poultry Science, College of Agriculture and Bioresources, University of Saskatchewan, Saskatoon,Canada, (3)School of Environment and Sustainability (SENS), University of Saskatchewan, Saskatoon , Canada, (4)Global Institute for Water Security (GIWS), University of Saskatchewan, Saskatoon, Canada

The rubber-tire derivative N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone (6PPD-q) has recently been identified as a potential cause of Urban Runoff Mortality Syndrome, which describes the widespread deaths of pre-spawn salmon near roadways. Tire-wear particles deposited on road surfaces are washed into runoff during rainfall, introducing pulses of 6PPD-q into aquatic environments. Fish species have shown widely varying sensitivity to this toxicant, and environmental concentrations often exceed sensitivity thresholds for certain species, posing a significant risk to vulnerable aquatic organisms. However, the potential toxicity of 6PPD-q to amphibians remains unexplored.

Larval-stage amphibians, such as northern leopard frog (*Lithobates pipiens*; NLF) tadpoles, frequently inhabit small, temporary water bodies near roadways, where they are exposed to roadway contaminants like copper, which is known to harm amphibian populations. To investigate, an acute 96-hour exposure was conducted with freshly hatched NLF tadpoles. Treatments included nominal 6PPD-q concentrations of 20, 2, and 0.2 µg/L, along with a 0.01% dimethyl sulfoxide control, with three replicates per treatment. At the conclusion of the exposure, tadpoles were flash-frozen, and total RNA was extracted from three pooled tadpoles per replicate. Transcriptomic analysis was performed using the EcoToxChip NLF v0.1 and analyzed with EcoToxXplorer.

Although no mortality occurred during the exposure, transcriptomic disruption was observed. At a log2 fold change of 0.5 and a p-value <0.05, nine genes were significantly dysregulated, with eight downregulated and one upregulated. These findings suggest a potential risk of sub-lethal effects to NLF tadpoles exposed to 6PPD-q. Further research is needed to better understand exposure pathways and assess the broader risks of 6PPD-q to amphibian populations.

3.21.P-Th293 Toxicokinetics and Biotransformation Products of 6PPD-Quinone Using In Vitro Substrate Depletion Assays in Salmonids

Matthew Schultz[1]*, Hohyun Jin*[2]*, Catherine Roberts*[3]*, Blake Hunnie*[1] *and Markus Brinkmann*[1]*, (1)University of Saskatchewan, Canada, (2)Seoul National University of Science and Technology, "Korea, Republic of", (3)Toxicology Centre, University of Saskatchewan, Canada*
N-(1,3-Dimethylbutyl)-N -phenyl-p-phenylenediamine-quinone (6PPD-quinone) is an oxidation product of rubber tires that is acutely toxic to select salmonid species at environmentally relevant concentrations created by stormwater runoff events. 6PPD-quinone exhibits marked species-specific sensitivity, with closely related salmonids ranging in acute toxicity thresholds by several orders of magnitude. Recent studies investigating the mechanism of action of 6PPD-quinone have suggested that differences in biotransformation rate and metabolic pathways may explain some of the stark differences in lethality observed across a relatively well conserved phylogenetic space. The present study explores the toxicokinetics of 6PPD-quinone in rainbow trout (*Oncorhynchus mykiss*) and arctic char (*Salvelinus alpinus*) to represent a sensitive and insensitive species respectively, using primary cells from liver and

gill tissue. Primary hepatocyte suspensions were isolated using a standardized guidance approach (Organisation for Economic Co-operation and Development) OECD Test Guideline 319A) to measure intrinsic clearance of 6PPD-quinone, as well as appearance of transformation products. Primary gill cells were isolated using a previously published protocol, and biotransformation was assessed with a modified 319A approach. Samples were analyzed using liquid chromatography high-resolution mass-spectrometry (LC-HRMS) to quantify parent compound depletion as well as metabolite formation. We hypothesize that differences in intrinsic clearance of 6PPD-quinone between these two species within liver and gill tissues will be predictive of overall acute toxicity differences. The quantification of 6PPD-quinone transformation products further serves to investigate these differences. This study demonstrates the adaptability of substrate depletion based primary cell assay methods by applying them to an emergent, acutely lethal contaminant with a complex toxicity outcome.

3.21.P-Th294 Assessing Epithelial Membrane Integrity and Permeability in Rainbow Trout RTgill-W1 and Atlantic Salmon ASG-10 Gill Cells Exposed to 6PPD-Quinone

***Chantel De Lange**[1], Francisco Carlos da Silva Junior[1], Anita Solhaug[2], Natacha S. Hogan[1], Markus Brinkmann[1] and Markus Hecker[1], (1)Toxicology Centre, University of Saskatchewan, Saskatoon, SK, Canada, (2)Chemistry and Toxinology, Norwegian Veterinary Institute, aas, Norway*

The compound N-(1,3-dimethylbutyl)-N?-phenyl-p-phenylenediamine-quinone (6PPD-quinone) has been linked to significant mass mortalities of coho salmon along the western coast of North America. This toxicant forms from the antioxidant 6PPD through the environmental oxidation of tire wear particles, which enter aquatic systems via urban stormwater runoff. Although the acute lethality of 6PPD-quinone at concentrations ? 1µg/L has been established in various salmonid species, sensitivity to this toxicant varies greatly among fishes. The mechanism behind its species-specific acute toxicity remains unknown. Evidence suggests that 6PPD-quinone may cause molecular dysregulation of genomic pathways related to cell adhesion and endothelial permeability. Therefore, this study aims to evaluate the impact of 6PPD-quinone on the integrity and permeability of a modeled gill epithelium using two salmonid cell lines: RTgill-W1 (rainbow trout, sensitive species) and ASG-10 (Atlantic salmon, tolerant species). Three key targets of cell viability will be assessed: lysosomal integrity using the neutral red assay, metabolic activity using the MTT assay, and cell membrane integrity using the LDH assay. Additionally, gill cells will be cultured on a semipermeable insert that separates apical and basolateral compartments. Once they reach confluence, cells will be exposed to incremental concentrations of 6PPD-quinone for specified durations in 24-well plates. Transepithelial electrical resistance (TEER, in ohms) will be measured with chopstick electrodes to quantify the barrier integrity. Additionally, paracellular flux will be measured using FITC-dextran as well as the use of targeted qPCR to assess changes in abundance of transcripts of genes coding for specific cell junction proteins. Given that the gill epithelium is a primary target site for water-borne pollutants, this research aims to reveal the effects of 6PPD-quinone on gill permeability in both sensitive and tolerant species as a potential mechanism of toxicity.

3.21.P-Th295 A broad approach to understand how 6PPD-q, combined with phenanthrene, affects thermal tolerance, hematology, and omics in three salmonid species

***Andreas N.M. Eriksson**[1], Jaden Griffiths[1], Lexie Dyck[1], Katherine Anderson-Bain[1], Justin Dubiel[1], Rayen Morales Urrutia[1], Sodiq Aremu Olawoore[1], Luis Terrazas Salgado[1], Markus Brinkmann[2] and Steve Wiseman[1], (1)University of Lethbridge, Canada, (2)University of Saskatchewan, Canada*

Because of climate change, urbanization, and hydrological manipulation of water flows, water temperatures in urban environments are increasing, which has implications for freshwater fish that inhabit cooler streams and rivers. An additional stressor that fish in urban settings must cope with is stormwater, a complex chemical mixture, including many chemicals that originate from car tires, including antioxidants and their transformation products, such as 6PPD and 6PPD-quinone, and polycyclic aromatic hydrocarbons (PAHs), such as phenanthrene. Recently, 6PPD-quinone was identified as the cause of urban-runoff mortality syndrome of Coho salmon (Oncorhynchus kisutch) in the Pacific Northwest. Since, the discovery of 6PPD-q, environmental and toxicological understanding of 6PPD-q has progressed fast and 6PPD-q is now detected ubiquitously in urban aquatic systems, while the mechanism of acute lethality has been linked to disruption of mitochondrial functions. However, we know very little about how other contaminants in stormwater runoff influence the toxicity of 6PPD-quinone. In addition, the effects of 6PPD-q alone, and in combination with other stormwater related chemicals, on thermal tolerance in fish is not known. To fill this knowledge gap, we investigated how exposure to a road-runoff surrogate-mixture of 6PPD-quinone (0.5 µg l-1) and phenanthrene (5 µg l-1) influenced the thermal avoidance behaviour of three salmonid species: brown (Salmo trutta), bull (Salvelinus confluentus), and rainbow trout (Oncorhynchus mykiss). Additionally, we investigated body burden, xenometabolome, gill and liver transcriptomes, and plasma-related parameters. Bull trout exposed to the individual components and the mixture presented thermal avoidance behaviour at significantly lower temperatures (mean range: 17.7 to 19.1°C) compared to control (20.7 ± 0.4°C). No such difference was observed among brown trout. Interestingly, a 5.7 and 7.3 percentage unit reduction in hematocrit was observed among 6PPD-q and mixture exposed brown trout, respectively. No reduction in hematocrit were observed among bull trout, although their blood was observed to be more viscous than control, suggesting altered hematology. Assays with rainbow trout are in progress. Comparative and species-specific molecular processes and biomarkers are to be investigated.

3.21.P-Th296 Assessing Ecological Impacts of 6PPD-Q in Aquatic Ecosystem Using Mesocosm: Focusing on the Fish Toxicity

Yooeun Chae[1]*, Hyungmin Kim*[2]*, Jung Eun Min*[1]*, Wonman Kang*[1] *and Sooyeon Kim*[1]*, (1)Korea Institute of Toxicology (KIT), "Korea, Republic of", (2)Korea Institute of Toxicology (KIT), "Korea, Republic of"*

6PPD (N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine), an additive used as an antioxidant and anti-degradation agent for tires, has received worldwide attention for its extraordinary toxicity. In particular, the oxidized product 6PPD-Q, which is produced by the reaction of 6PPD with ozone, is highly toxic to salmon, so it is urgent to study the effects of these substances on aquatic ecosystems. Therefore, this study aimed to evaluate the chronic effects of 6PPD-Q on native fish species living in Korea by creating a simulated ecosystem that mimics the actual water environment, and to determine the environmental behavior and biological effects of the substance. The experiment was conducted for 60 days, and the half-life of 6PPD-Q in water bodies under the experimental conditions was found to be less than 24 hours. The concentration of 6PPD-Q in aquatic plants was not found to increase significantly with exposure. This suggests that 6PPD-Q is rapidly degraded or translocated in water and does not accumulate in plants. The plankton community in the water body of the simulated ecosystem was sampled periodically during the exposure period to evaluate the effects of 6PPD-Q on plankton community characteristics, and it was found that daphnia, caddisflies, water snails, allegorical insect larvae, and invertebrate communities were formed. In addition, an omics-based chronic toxicity assessment based on different pathways was performed using carp, and it was found that 6PPD-Q had some effects on fish. This study allowed the evaluation of the effects of 6PPD-Q, an oxidized product of tire additives, on the aquatic environment, and is expected to help predict the ecological effects of long-term and continuous environmental exposure to these substances in advance, and to respond to substance use regulation and ecosystem protection.

3.21.P-Th297 Sperm Genotoxicity of the Rubber Tire Oxidant By-Product, 6PPD-Quinone

Marina Tenório Botelho[1]*, Markus Brinkmann*[2] *and Gisela de Aragão Umbuzeiro*[1]*, (1)Universidade de Campinas, Brazil, (2)University of Saskatchewan, Canada*

N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone (6PPD-q) is a transformation product of the tire rubber antioxidant 6PPD. 6PPD-q reaches the aquatic environment by stormwater and urban runoff and was associated with high mortality of salmon. Several studies evaluating acute toxicity were performed in different aquatic species showing a wide range of toxicity values. Although 6PPD-q is known to cause oxidative stress and mutagenicity to bacteria, there is limited information about other sublethal effects, especially in invertebrates. We had previously observed that 6PPD-q was not toxic to the marine amphipod *Parhyale hawaiensis*, but induced micronuclei in hemocytes after 96 h exposure. The aim of this study was to complement the genotoxicity evaluation of 6PPD-q with the marine amphipod *P. hawaiensis* using the comet assay in sperm cells. 6PPD-q was dissolved in DMSO at the limit of solubility and tests were performed using a maximum of DMSO of 0.01%. *Parhyale hawaiensis* male adults (<8 months old) were exposed to 50 and 500 µg/L 6PPD-q for 96 h then sperm cells were collected. DMSO was used as solvent control and ethyl methanesulfonate 2mM was used as positive control. Sperm cells from 16 organisms per condition were used for comet assay and from 2 organisms per condition to access sperm viability using Live/Dead Sperm Viability Kit (with SYBR-14 and propidium iodide). Sperm viability was above 90% for the two concentrations tested. DNA damage in sperm cells increased after exposure to both concentrations of 6PPD-q compared to the solvent control. We conclude that 6PPD-q was genotoxic to sperm cells of *P. hawaiensis* therefore has the potential to cause long term effects especially at population levels. Our next step will be to evaluate possible effects of 6PPD-q in the embryo development after parental exposure of males and females to this compound.

3.21.P-Th298 Assessment of Adsorption and Leaching Potential of 3H-6PPD Quinone in Soils

***Ji-Young An**, Jong-Hwan Kim, Seong-Hoon Jeong and Jung-Hoon Jung, Korea Institute of Toxicology (KIT), "Korea, Republic of"*

This study was conducted to evaluate the adsorption and leaching behavior of 3H-6PPD-quinone in three soil types with varying pH levels, clay contents, and organic matter.

The adsorption tests were performed using the indirect method with a soil-to-aqueous phase ratio of 1:5 (soil/0.01 M CaCl2). Adsorption equilibrium was achieved within 7 hours for all three soils. After 48 hours, the adsorption coefficients (Kd) were determined to be 70.8 cm^3/g for Loam soil, 43.3 cm^3/g for Silt Loam soil, and 20.4 cm^3/g for Sandy Loam soil. The organic carbon-normalized adsorption coefficients (Koc) calculated after 48 hours were 1727.6 cm^3/g for Loam soil, 1731.0 cm^3/g for Silt Loam soil, and 3350.0 cm^3/g for Sandy Loam soil. Based on the Koc values, which are indicative of mobility in soil, 6PPD-quinone was classified as having Low Mobility in Loam and Silt Loam soils and Slight Mobility in Sandy Loam soil.

Leaching tests were conducted using atrazine (Relative Mobility Factor [RMF]: 1.03) as a reference compound. For the analysis of 3H-6PPD-quinone, soil samples were extracted with various organic solvents. The percentages of the test compound detected in the 0 6 cm soil sections were 95.0% for Loam soil, 94.2% for Silt Loam soil, and 92.3% for Sandy Loam soil. Compared to atrazine, the RMF values for 3H-6PPD-quinone were 0.5 in Loam soil, 0.3 in Silt Loam soil, and 0.2 in Sandy Loam soil. Based on these RMF values, 6PPD-quinone was classified as Slightly Mobile in all three soil types.

3.21.P-Th299 Permeability and Toxicity of Tire-Derived PPDs and Their Transformation Products in Human Gut Cells

***Göksu Celik**[1], Vanessa Pap[1], Gabriela Hadrich[2], Lea Ann Dailey[2] and Thilo Hofmann[1], (1)University of Vienna, Centre for Microbiology and Environmental Systems Science, Division of Environmental Geosciences, Austria, (2)University of Vienna, Division of Pharmaceutical Technology and Biopharmaceutics, Department of Pharmaceutical Sciences, Faculty of Life Sciences, Austria*

Tires contain thousands of chemicals, many of which can become environmental pollutants upon release. Among these, N,N?-disubstituted phenylenediamines (PPDs) are commonly added to tires as anti-aging agents, protecting against oxidative degradation to maintain tire performance. However, PPDs are highly reactive with ozone and oxygen, forming transformation products (TPs) such as PPD-quinones, which can accumulate in tire and road wear particles and disperse through environmental compartments via sorption, leaching, and runoff. One widely used PPD, N-phenyl-N?-(1,3-dimethylbutyl)-p-phenylenediamine (6PPD), along with its toxic transformation product 6PPD-quinone (6PPDQ), has been linked to acute mortality syndrome in coho salmon, raising urgent concerns about adverse effects on human health. Human exposure to PPDs and their TPs occurs through ingestion, inhalation, and contaminated water, and these substances have been detected in human urine, breast milk, and blood. This study addresses the need for a comprehensive health risk assessment by investigating the cellular permeability and cytotoxicity of seven PPDs (IPPD, CPPD, DPPD, 6PPD, 7PPD, 8PPD, and 77PD) and four TPs (IPPD-Q, CPPD-Q, DPPD-Q, and 6PPD-Q) in human intestinal (Caco-2) epithelial cell line. Mitochondrial activity, membrane integrity and oxidative stress were assessed using WST-1, LDH and ROS assays, respectively, at realistic (non-lethal) concentrations. Both individual and cocktail effects were scrutinized to determine the mode of interaction, whether additive, synergistic, or antagonistic. Chemical concentrations were quantified at the beginning and end of exposure using liquid-liquid extraction with acetonitrile, followed by LC-MS/MS analysis. Structure-activity relationships were evaluated to identify structural features linked to toxicity, with a focus on the role of hydrophobicity. The findings provide critical insights into the effect of these chemicals on human cells, stressing the need for their inclusion in environmental monitoring programs to protect public health by tracking exposure levels and informing regulatory actions.

3.22 Matching Microplastic and Nanoplastic Reference Materials to Exposure Scenarios

3.22.T-01 Nano-Sized Polypropylene as a Promising Candidate Reference Material: Preparation, Characterization and Stability in Complex Matrices

Florian Meier[1], *Roland Drexel*[1], *Yosri Wiesner*[2], *Korinna Altmann*[2], *Paul-Tiberiu Miclea*[3], *Dorota Bartczak*[4], *Enrica Alasonati*[5], *Ivana Fenoglio*[6], *Francesco Barbero*[6], *Daniel Proefrock*[7], *Andy Booth*[8], *Alessio Sacco*[9], *Marta Fadda*[9] *and Andrea Mario Giovannozzi*[9], *(1)Postnova Analytics GmbH, Germany, (2)Bundesanstalt fur Materialforschung und -prufung (BAM), Germany, (3)Fraunhofer-Center fur Silizium-Photovoltaik CSP, Germany, (4)UK National Measurement Laboratory at LGC, United Kingdom, (5)Laboratoire National de Metrologie et d'Essais, LNE, France, (6)Universit di Torino, Italy, (7)Helmholtz-Zentrum Hereon, Germany, (8)SINTEF Ocean, Norway, (9)Istituto Nazionale di Ricerca Metrologica (INRiM), Italy*

The lack of nanoplastic (NPs) reference materials capable of mimicking real-world scenarios is currently hampering the development of validated extraction techniques from complex matrices (e.g. soils, sediments, biota), the development of analytical approaches for robust identification and quantification, and the ability to use environmentally relevant test materials in (eco)toxicity testing and hazard assessment.
Here, we present a strategy towards the development of a potential NP reference material based on nano-sized polyproplyene particles (nanoPP) developed within the EURAMET-funded PlasticTrace project (https://plastictrace.eu/). The strategy includes the preparation, the physicochemical characterization and the stability assessment of nanoPP in suspension both in its pristine state, but also when spiked into food (mineral water, milk) and environmental matrices (river water).
NanoPP was produced reproducibly in a top-down approach by crushing in acetone with an UltraTurrax, filtering and change of solvent to MilliQ water. The prepared nanoPP material was subjected to a comprehensive physicochemical characterization including e.g., dynamic light scattering (DLS), particle tracking analysis (PTA) and asymmetrical-flow field-flow fractionation coupled with multi-angle light scattering (AF4-MALS) for particle size distribution assessment, PTA and scanning electron microscopy (SEM) for particle number concentration determination, SEM and atomic force microscopy (AFM) for shape analysis and pyrolysis GC-MS for chemical identification. Performed studies showed that the prepared nanoPP material is irregularly shaped and highly polydisperse with a particle size of around 180 nm (e.g., Dh-z-ave from DLS) and a particle size distribution from around 15 nm up to 135 nm (radius of gyration Rg from AF4-MALS).
Storage stability studies using DLS, PTA and AF4-MALS revealed nanoPP in aqueous suspension to be stable for at least 22 months with respect to particle size distribution and number concentration rendering it a promising NP candidate reference material. However, conducted spiking experiments in mineral water, river water and milk showed a time-dependent agglomeration of nanoPP that needs further investigation with focus on dedicated sample preparation and extraction techniques, as well as enrichment protocols from complex food and environmental matrices.

Disclaimer/Disclosure: The PlasticTrace project has received funding from the European Partnership on Metrology, co-financed from the European Union s Horizon Europe Research and Innovation Programme and by the Participating States (Project no. 21GRD07).

3.22.T-02 Advancing Environmental Fate Assessments: Generation and Tracking the Fate of Realistic (UV-Degraded) Nanoplastics

Patrizia Pfohl[1], *Lars Meyer*[1], *Markus Ruckel*[1], *Svetlana Guriyanova*[1], *Iban Amenabar*[2], *Rainer Hillenbrand*[2] *and Wendel Wohlleben*[1], *(1)BASF SE, Germany, (2)CIC nanoGUNE, Spain*

Reference materials constitute an important part for nanoplastic fate studies: they ensure comparability of results between labs, are used for calibration of analytical techniques, facilitate method development and can be used as benchmarks for toxicological assessments. However, reference materials for microplastics are only rarely available and, moreover, are not representative of environmental nanoplastics.
To understand the environmental fate of nanoplastics we tested two approaches to obtain more realistic nanoplastic materials (including extensive physicochemical characterization):
1) solvent precipitation using polyamide-6 (PA-6) resulted in non-spherical fragmented particles with a particle size distribution under 500 nm
2) Ultraviolet (UV) aging of an acrylic paint followed by a re-dispersion step enabled the sampling of more realistic multi-component UV-aged micro- and nanoplastic fragments < 40 µm
The generated fragments were used for the development of methods to extract micro- and nanoplastics from compost. The extraction protocols are based on deagglomeration and size fractionation to isolate the

nanoplastics from compost components, which are then enriched using a stacked density-separation technique. To demonstrate the identification of individual micro- and nanoplastic fragments, we performed spiking tests and measurements via infrared nanoimaging using Scattering-type Scanning Near-field Optical Microscopy (s-SNOM), as well as Raman and fluorescence microscopy. The final goal is the identification and quantification of individual realistic fragments in environmental matrices. However, each material, extraction protocol and analytical technique comes along with specific challenges that need to be addressed and improved. This can only be achieved when suitable reference materials are available.

3.22.T-03 Harmonisation of Sample Preparation for the Microplastic Analysis: Recovery Rates of Tablets Containing Microplastics as Reference Material for Food and Environmental Matrix

Claudia Drago[1], Yosri Wiesner[2], Ulrike Braun[3], Andrea Mario Giovannozzi[4], Marta Fadda[4], Mara Putzu[4], Soledad Muniategui-Lorenzo[5], Carmen Moscoso-Perez[5], Paul-Tiberiu Miclea[6], Nizar Benismail[7], Carla Palma[8], Jose Vaz de Almeida[8], Monica Mattarozzi[9], Marta Barbaresi[9], Maurizio Piergiovanni[9], Matteo Masino[9], Federica Bianchi[9], Maria Careri[9], Bert van Bavel[10], Alina Maltseva[11], Markus Sillanpaa[12], Daniel Profrock[13], Dominik Wippermann[13] and ***Korinna Altmann**[2]*, *(1)Umweltbundesamt, Germany, (2)BAM Bundesanstalt fur Materialforschung und -prufung, Germany, (3)Uweltbundesamt, Germany, (4)INRIM, Italy, (5)UDC, Spain, (6)CSP Fraunhofer, Germany, (7)Nestle, France, (8)Hidrografico, Portugal, (9)UNIPR, Italy, (10)Norwegian Institute for Water Research (NIVA), Norway, (11)HORIBA, France, (12)SYKE, Finland, (13)HEREON, Germany*

Microplastics (MP) are everywhere and their impact on health and environment is still discussed, based on the precautionary principle, their presence should be monitored and emission should be reduced. The crucial point is the reduction of MP pollution but also the introduction of legally binding, standardized procedures for their analysis. The limited availability of certified reference material as well as absence of standard operating procedures to identify, characterize and quantify MP according to number and mass have generated lack of comparability between analytical methods and laboratories. First, we developed tablets of a water-soluble matrix, containing defined numbers of MP particles or mass contents. These can be solved in water and handled as reference materials in drinking water without additional sample preparation. These samples are measured using mass-based methods as thermo-analytical methods like thermal desorption-gas chromatography-mass spectrometry (TED-GC/MS) or pyrolysis gas chromatography mass spectrometry (Py-GC/MS) and using number-based methods as vibrational spectroscopy like Infrared and Raman after filtration. Our aim was to develop a standard operating procedure to measure MP in complex matrices and to harmonise and compare different detection and characterization methods. These matrices require treatments to show a reliable quantification and identification of MP. We selected baby milk powder, as food matrix, which has a high content of water soluble and organic compounds. For the identification and quantification of small microplastics (SMPs; 10-100 µm) with TED-GC/MS and Py-GC/MS, a simple and fast pre-treatment with citric acid was applied. For the assessment of the number of SMPs, with vibrational spectroscopy (µ-Raman, µ-Infrared) and with electron microscopy (SEM), a multi-enzymatic digestion and a microwave alkaline hydrolysis was tested. As environmental sample, we selected surface water. The suspended particulate matter contained in the water has a high content of inorganic compounds. In this case, no sample preparation was used for the thermoanalytical methods and a sample preparation including density separation and oxidative digestion was tested to identify and quantify SMPs with vibrational spectroscopy. Depending on matrix and on the detection procedure, sample preparations influence significantly recovery rates. This work shows various analytical results and discusses technical aspects of the different procedures.

Disclaimer/Disclosure: The authors thank the European Commission for funding the PlasticTrace project (21GRD07) from the European Partnership on Metrology, co-financed from the European Union s Horizon Europe Research and Innovation Programme and by the Participating states.

3.22.T-04 A Paint Library of Plastic Particles (PLoPP): Fourier Transform Infrared Spectral Analysis of Paint Microplastics

***Zoie Taylor Diana**[1]*, *Madeleine Milne[1], Jacob Lee Ford[2], Ron Rubinovitz[3], Andrew Turner[4] and Chelsea M. Rochman[1], (1)Department of Ecology and Evolutionary Biology, University of Toronto, Canada, (2)Solstice Power Technologies LLC, United States, (3)Thermo Fisher Scientific, Wilmington, Delaware, United States, (4)School of Geography, Earth and Environmental Sciences, University of Plymouth, United Kingdom*

The degradation of paint is thought to be one of, if not the largest, source of microplastics in the environment. However, researchers lack paint-specific spectral libraries that represent a wide variety of paint sources (e.g., roads, boats, buildings) to characterize paint microplastics in the environment and differentiate paint microplastics from non-paint microplastics. Here, we fill this gap by creating a Fourier transform infrared spectroscopy (FTIR) library of 263 spectra from 90 paints using attenuated total reflection (µATR-FTIR) called here a Paint Library of Plastic Products (PLoPP). The paints in the library are primarily used in seven sectors (architectural, automotive, consumer, general industrial, marine, road markings, and wood) and are in 15 colors and five appearances (glitter, gloss, matte, pearl, and semi-gloss). With the library, we also created a spectral analysis pipeline using machine learning to aid in the identification of paint vs. non-paint microplastics and to see if it is possible to trace back to paint sources. To assist in microplastic characterization as paints or non-paints, we also created a visual key for use with light microscopy. Using environmental microplastics, we verified the utility of these tools (visual key, ATR-µFTIR spectral searches, and machine learning model classification) to characterize paint microplastics. This research creates tools to further our understanding of paint microplastics.

3.22.T-05 Do Polymer Interactions Impact the Accuracy of Microplastic Quantification in Mass Spectrometry-Based Analysis?

Sevda Eryilmaz Soydan[1]*, Patrick Bauerlein*[2]*, Merle de Kreuk*[1] *and Kim Maren Lompe*[1]*, (1)Delft University of Technology (TU Delft), Netherlands, (2)KWR Water Research Institute, Netherlands*

Microplastic (MP) pollution is an increasing global concern, with MPs detected in air, water, soil, and biota. Accurately quantifying these microplastics is challenging due to sample variability and the absence of standardized methods for analyzing polymer mixtures. A critical challenge is selecting reference materials that reliably replicate the decomposition behaviour of environmental polymer mixtures. Most studies focus on individual polymers to identify decomposition markers and develop calibration curves; however, this approach does not consider the complex interactions found in environmental samples where multiple polymers are co-pyrolyzed. These interactions may lead to secondary reactions, potentially introducing systematic errors in quantitative analyses. This challenge is particularly evident in thermoanalytical techniques such as TED-GC/MS and PY-GC/MS, where the co-pyrolysis of polymers can interfere with accurate quantification. This study investigates the impact of polymer interactions on thermal degradation fingerprints using thermogravimetric analysis coupled with gas chromatography and mass spectrometry (TGA-GC/MS). Various polymer combinations, including polystyrene (PS), polyethylene (PE), polyethylene terephthalate (PET), polyamide-6 (PA6), styrene-butadiene rubber (SBR), polyvinyl chloride (PVC), and polypropylene (PP), are analyzed with two different internal standards to evaluate their co-pyrolysis behaviour. Preliminary results indicated that increasing PS concentrations reduce the abundance of internal standard (poly(4-fluorostyrene)) monomer while promoting trimer formation, highlighting significant polymer interactions. Final results, expected by March 2025, aim to investigate specific fingerprints to prevent analytical errors caused by polymer interactions in MP quantification. Identifying polymer interactions and understanding their chemistry is crucial to avoid interferences and improve the accuracy of microplastic analysis.

3.22.P Matching Microplastic and Nanoplastic Reference Materials to Exposure Scenarios

3.22.P-Tu252 Polystyrene Nano- and Microplastics: Are We Using Relevant Particles for Exposure, Hazard, and Risk Assessment?

Todd Gouin[1]*, Robert Ellis-Hutchings*[2]*, Mark Pemberton*[3] *and Bianca Wilhemus*[4]*, (1)TG Environmental Research, United Kingdom, (2)Dow Chemical Company, United States, (3)Systox Limited, United Kingdom, (4)INEOS Syrolution Group, Germany*

During the past two decades there has been an exponential increase in the number of studies reporting on the toxicological effects associated with exposure to nano and microplastic particles (NMPs). Nevertheless, there is currently no commonly agreed mode of action (MOA) of these particles on human health and the environment. Neither has it been established whether all NMPs share the same MOA, or whether different NMPs of different size, shape, morphology, polymer chemistry, and surface reactivity act via different mechanisms. Collecting and characterising naturally occurring NMPs in sufficient quantities for research studies has so far proven to be impractical. Consequently, most studies have used monodispersed polystyrene microspheres (PSMs) as model particles. These PSMs differ considerably from NMPs that can be generated from commercial plastics, and from those that occur naturally in the environment, raising uncertainty as to the relevance of this research to human health and the environmental hazard and risk assessment. Our study of PSMs and generated NMPs has identified properties of these particles that, if investigated in targeted research programs, may elucidate likely MOAs of both particle types and provide greater insight into the hazard and risk of naturally occurring NMPs.

3.22.P-Tu253 Optimized Reprecipitation Method for Nanoplastics and Small Microplastics as Test Materials

***Jinyoung Jeong**, KRIBB, "Korea, Republic of"*

Microplastics (generally defined as plastic fragments under 5mm) can be categorized by size, shape and polymer type. In particular, small micoplastics (sMP, <100 ?m) and nanoplastics (NPs, <1 ?m) are considered to pose high risk on organisms due to their bioaccumulation and capability to deliver adsorbing contaminants on NMPs which can cause combined toxicity. Although it is important to use well-characterized NMPs as test materials for investigating their effects, obtaining sufficient NMPs is challenging. In this work, the optimized reprecipitation method for synthesis of NPs and sMP was described. Reprecipitation method, in other words, non-solvent induced phase separation method, enables to prepare NPs and sMP with high yield and scale-up. For example, polyethylene (PE) and polypropylene (PP) are the most abundant polymer type in environment; however, the studies with PE and PP NPs and sMPs were very limited because of their lack of test materials, compared to PS NMPs which were commercially available with various sizes and homogeneity. Based on the optimized reprecipitation method, this work described three different sized (300~500 nm, 2~5 ?m, 20~50 ?m) and two different shaped (sphere and fragment) PP NMPs at a large scale (in grams) with high yield (90%). Moreover, homogenously spherical PE NPs with 100~300 nm was also obtained the modified reprecipitation method. These NPs and sMPs have been used as test materials for their biological effects on various organisms such as zebrafish larvae, plant, and mouse. It is expected to be expanded to include additive chemicals on NPs and sMP in future works.

3.22.P-Tu254 Additive Manufacturing of Monodisperse Microplastic Reference Particles Through Micro Extrusion

***Maurice Hauffe**, Lucas Kurzweg, Kathrin Harre, Thomas Himmer, Robert Mohn and Tilmann Priebe, Dresden University of Applied Sciences (HTWD), Germany*

The environmental risks of microplastics are emphasized by their inclusion in the REACH Regulation of 2023 and further EU restrictions. While analytical methods exist for detecting microplastics, there is a critical lack of suitable reference materials for standardizing and validating these methods.
Producing microplastic references primarily relies on cryogenic grinding and screen fractionation, which comes with several challenges. For example, the use of liquid nitrogen and the fact that this method results only in dispersed fractions with limited size control. Additionally, a major requirement is to know the particle number, especially as conventional techniques only determine fraction weight. The distribution over multiple particle sizes prevent direct correlation between mass and particle count, necessitating time-consuming manual counting for precise numbers. Synthetic production of microplastic references faces similar problems with size distribution and unknown particle counts while being limited to few polymer types. All these limitations highlight the need for improved microplastic reference production methods. Thus, we present a cost-efficient and routinely capable method for the production of microplastic references using an additive manufacturing process by micro extrusion. The microplastic particles can be produced in exact numbers as well as in homogeneous size and shape. The process is suitable for all thermoplastics. Therefore, our method makes it possible to compare mass-based and number-based analysis methods for the first time. 10,000 particles can be easily produced within a few hours. We plan to fully automate the process and implement inline process control. The low error and reject rate mean that manufacturing time can be reduced and resources can be saved. So far, we have produced particles reproducibly in a size range of 300 to 1000 µm from PLA, PCL, PMMA, PE and PA. In some cases, a minimum particle size of around 150 µm has already been achieved. Another goal is to reduce the minimum particle size to below 100 µm and to expand the range of polymers.
Our particles were already used in different environmental compartments for several months, for example, experiments in the Elbe River and vegetation plots, as well as in experiments on modeling microplastic transportation behavior within soil columns.

Disclaimer/Disclosure: This study was supported by the European Social Fund (ESF) and by the Federal State of Saxony (Project VEMIWA Vorkommen und Verhalten von Mikroplastik in sächsischen Gewässern; grant no. 100382142) and the European Regional Development Fund (ERDF) (Project MP-Standards - Validierung eines Verfahrens zur Herstellung von Standards und Referenzmaterialien für die Mikroplastikanalytik im industriellen Maßstab, grant no. 100689050).

3.22.P-Tu255 Influence of Fragmentation Techniques on the Biotic Aging of Polystyrene and Polypropylene Microplastics

Gabriela Kalcikova[1], *Ula Putar*[1], *Serena Ducoli*[2], *Mark Starin*[1], *Janja Novak*[1], *Barbara Klun*[1] *and Stefania Federici*[2], *(1)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia, (2)Department of Mechanical and Industrial Engineering, University of Brescia & INSTM RU of Brescia, Italy*

Microplastics are increasingly studied for their impact on the environment and preparation of tests materials are essential for laboratory experiments. However, laboratories often produce their own test materials by different methods, which can lead to significant differences in the physico-chemical properties of the produced microplastics. Recent research has revealed that the milling method used to produce microplastics can significantly influence their properties. In this study, we investigated how two commonly used milling methods by using ultracentrifugal and mixer mill affect the biofouling of microplastics. Polystyrene (PS) and polypropylene (PP) were milled under comparable conditions using both methods and then aged in natural stream water under laboratory conditions. The results showed that microplastics produced using different milling techniques age differently. In particular, PP microplastics produced with the mixer mill developed significantly more biofilm than those produced with the ultracentrifugal mill. But both PS and PP microplastics produced with the mixer mill exhibited significantly lower chlorophyll-a content and extracellular polymeric substances (EPS) compared to those produced with the ultracentrifugal mill. Furthermore, these differences in biofouling were reflected in the density changes after aging, with both PP and PS produced with the mixer mill having a lower density than those produced with the ultracentrifugal mill. These results highlight the important role of milling methods in determining the subsequent biofouling and physical properties of microplastics and emphasize the need for standardized preparation techniques to improve the comparability of different studies.

3.22.P-Tu256 Developing Reference Materials for Thermal and Vibrational Analysis of Microplastics

Huiling Liu[1], *Marie-Louise Tambo Magni*[1], *John Magnus Breivik*[1], *Amy Lusher*[2] *and Bert van Bavel*[2], *(1)Chiron, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway*

Microplastics, ubiquitous pollutants in the environment, pose significant ecological and health risks. Accurate identification and quantification of microplastics are crucial for effective monitoring and mitigation strategies. Thermal analysis such as Pyrolysis-GCMS and vibrational analysis techniques such as µFT-IR and µRaman are powerful tools for microplastic characterization. However, these techniques require reliable reference materials to ensure accurate and reproducible results.

This presentation will discuss the development of a suite of reference materials specifically designed for microplastics, highlighting the neat microplastic reference materials (RMs) and certified reference materials (CRMs) for Py-GCMS for chemical identification of polymers and mass based quantification of microplastics, as well as soda tablets for µFT-IR and µRaman, highlighting tablet format for both chemical and particle morphological information, and number of particle based quantification. These reference materials will encompass a range of polymer types, sizes, and shapes, representative of common microplastic pollutants. The RMs and CRMs are rigorously characterized using a combination of techniques, including microscopy, spectroscopy, and chromatography.

The development of these reference materials will significantly enhance the accuracy and precision of microplastic analysis, enabling more reliable monitoring and assessment of environmental contamination.

Disclaimer/Disclosure: The authors thanks to the EU commission and Innovation Norway for the fundings.

3.22.P-Tu257 Production of a 1-10 µm Polypropylene Reference Material for Development of Analytical Methods

Andy Booth[1], *Lisbet Sorensen*[2], *Marianne Molid*[2], *Tassilo Waniek*[3], *Andrea Mario Giovannozzi*[4], *Marta Fadda*[4], *Alessio Sacco*[4], *Dorota Bartczak*[5], *Aneta Elzbieta Sikora*[5], *Soledad Muniategui-Lorenzo*[6], *Veronica Fernandez-Gonzalez*[6], *Paul-Tiberiu Miclea*[7], *and Korinna Altmann*[3], *(1)SINTFE Ocean, Norway, (2)SINTEF Ocean, Norway, (3)Bundesanstalt fur Materialforschung und -prufung (BAM), Germany, (4)Istituto Nazionale di Ricerca Metrologica (INRiM), Italy, (5)National Measurement Laboratory, LGC Limited, United Kingdom, (6)Universidade da Coruña, Spain, (7)Fraunhofer CSP, Germany*

Reference materials (RMs) are needed for harmonisation and validation of microplastic (MP) and nanoplastic extraction and analysis approaches, for the development standardised methods and for (eco)toxicity assessment. From an analytical chemical perspective, plastic particles in the size range 1-10 µm represent a specific challenge; most commonly used MP analysis techniques struggle with particles <10 µm, whilst common NP analysis techniques struggle with particles >1 µm. Plastic particle RMs in the 1-10 µm size range are important for the development and optimization of analysis techniques. Here, we present a method for the production of polypropylene (PP) MP in the target size 1-10 µm with an irregular morphology. PP pellets (100 g) were placed in 100 mL of ethanol and subjected to milling by UltraTurrax in an ice bath. The resulting mixture was filtered on 500 µm, 90 µm and 45 µm filters. The material >500 µm was milled again with the UltraTurrax and re-filtered. The <45 µm fractions were combined and further filtered using a 10 µm macroporous silicon filter. The filtrate was then refiltered over a 1 µm macroporous silicon filter. The particles were re-suspended in ethanol and transfered to a preweighed vial, where the ethanol evaporated off. The final yield of 1-10 µm PP particles was 18.29 mg. The stock 1-10 µm PP material was re-suspended in MilliQ water and maintained in aqueous dispersion by addition of 0.025 wt% of BSA. Sub-samples of the PP dispersion were subject to imaging scanning electron microscopy (SEM), laser diffraction (LD), µRaman spectroscopy, MADLS, particle tracking analysis, TED-GC/MS and pyrolysis GC-MS analysis for physicochemical characterisation. SEM imaging confirmed the irregular morphology of the PP particles. The RM was tested according to ISO Guide 35:2017 with n = 10 on one property of interest, here particle size distribution. The PP particle suspension passed the homogeneity control with a particle size range between 300 nm to 7 µm, and a mean particle size of approximately 800 nm. Stability control will be performed again after 3 months. The results demonstrate that the top down production method is capable of producing irregular shape plastic particles that could be used for the development of analytical techniques targeted at MP <10 µm. Furthermore, an irregular-shaped PP RM <10 µm offers the potential to close a current gap in MP (eco)toxicological assessment.

Disclaimer/Disclosure: The authors thank the European Commission for funding the PlasticTrace project (21GRD07) from the European Partnership on Metrology, co-financed from the European Union's Horizon Europe Research and Innovation Programme and by the Participating states.

3.22.P-Tu258 Impact of UV-Induced Aging on Microplastic Composition: Identification Challenges, and Implications for Environmental Monitoring

***Isabella Gambino**[1], Serena Ducoli[2], Elisa Terzaghi[3], Laura Eleonora Depero[4], Stefania Federici[2] and Antonio Di Guardo[5], (1)DiSAT, University of Insubria, Varese, Italy, (2)University of Brescia, Italy, (3)University of Insubria, Italy, (4)Chemistry for Technologies Laboratory, Department of Mechanical and Industrial Engineering, University of Brescia & INSTM RU of Brescia, Italy, (5)Dept. of Science and High Technology, University of Insubria, Varese, Italy*

Natural weathering processes of microplastics (MPs) not only lead to the production of secondary smaller size particles but may also alter the structure of polymer chains. These changes often consist in the increase of the oxygen contained functional groups such as carbonyl and carboxyl groups. Moreover, the aging process alters the physico-chemical properties of MPs, facilitating the leaching of additives and degradation products, potentially posing ecotoxicological risks. Furthermore, degraded polymers can present difficulties in their identification due to a poor match with the spectra of the pristine polymers. This could therefore complicate monitoring plans for MPs due to their misidentification. The aim of this research was to evaluate the differences in aged versus unaged MPs produced by mechanical fragmentation techniques starting from daily-used plastic products by using different techniques. A total of 5 true-to-life MPs (white and blue PS, PET, PVC, PA66) were photo-oxidized for 8 weeks in a UV-equipped furnace box system. Aged MPs were studied and compared with the unaged ones. Samples were analyzed by Py-GC-MS in double shot mode (thermal desorption followed by pyrolysis) to monitor whether the aging processes altered the chromatographic fingerprints. Moreover, untargeted analysis was performed using LC-HRMS (Orbitrap) on sample extracts, using Methanol as extraction solvent. Acquisition was performed both in positive and negative ionization. Chromatograms were then screened by Compound Discoverer 3.3 SP. The first differences observed were a change in color and a reduction in electrostatic behaviour between unaged and aged samples, particularly for PET and PS. The analysis of pyrograms revealed the presence of changes in some of the analyzed samples. For example, PVC microparticles were affected by the photodegradation in terms of number of pyrolyzates in aged samples in respect to unaged ones and in terms of different substances found. Indeed, some chemicals were only present in aged fragments rather than in unaged. This was also confirmed by untarget analysis, where 2-Ethylhexanoic acid and Dodecanedioic acid, used as plasticizers, were only detectable in aged samples. Since the existence of degradation products could be considered an indicator of the state of deterioration, additional Py-GC-MS databases are required for identifying polymer-related pyrolytic products of environmental alteration processes.

3.22.P-Tu259 Experiments on Fragmentation and Abrasion of Plastics by Sediments and Impacts on Accelerated Chemical Leaching

Francesca De Falco[1], *Lars Michael Hildebrandt*[2], *Frank Menger*[3] *and Florian Pohl*[4], *(1)School of Biological and Marine Sciences, University of Plymouth, United Kingdom, (2)Department for Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (3)Department for Organic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (4)Department of Earth Sciences, University of Bayreuth, Germany*

Plastic waste, ubiquitous in natural environments worldwide, accumulates over time and becomes an integral component of sedimentary systems such as rivers, beaches, and the deep seafloor. Within these systems, plastic items are transported alongside natural sediments, undergoing abrasion and fragmentation due to mechanical forces from their interactions with the sediments. These processes not only generate micro- and nanoplastics but also enhance the release of chemicals by increasing the surface area available for leaching. The accumulation and progressive fragmentation of plastics, combined with the release of hazardous chemicals, contributes to the "plastic toxicity debt," posing significant risks to future generations. However, the rate and extent of plastic fragmentation in sedimentary systems, as well as its interaction with chemical leaching, remain largely unknown, making it challenging to assess the ecological risk associated with this toxicity debt. To address these gaps, this study investigates the fragmentation of plastics during sediment transport and explores the correlation between the degree of fragmentation and chemicals leaching. Laboratory experiments were conducted to simulate plastic fragmentation mechanisms by abrading polystyrene cubes through mechanical interaction with sediments in freshwater. The experiments varied sediment parameters, such as grain-size and grain angularity, as well as the duration of abrasion. During the experiments, the samples underwent abrasion, shedding microplastics. Optical and electron microscopy analyses revealed a correlation between sediment parameters and the degree and type of abrasion over time. The generated microplastics were isolated and analysed for size distribution, with coarse sediment producing microplastics with a coarser size distribution compared to medium sediment, likely due to a flakier abrasion mechanism resulting in larger plastic fragments. In addition, preliminary chemical analyses of the fluid phase suggested that the concentrations of organic and inorganic components increased with increasing plastic abrasion. This study highlights the feasibility and potential of combining abrasion experiments with leachate analysis to investigate the relationship between plastic fragmentation and chemical leaching. The findings provide valuable insights for a comprehensive hazard assessment of plastic pollution, essential for future environmental planning and mitigation strategies.

3.22.P-Tu260 Preparation and Characterisation of Representative Micro and Nanoplastic Test Materials

Luke Parker[1], *Elena Hoppener*[1], *Merel Nooijens*[2], *Arjen Boersma*[1], *Donal van Uunen*[2], *Andrea Mizzi Brunner*[2], *Maria Kloukinioti*[2] *and Ingeborg Kooter*[1], *(1)TNO, Netherlands, (2)TNO, Netherlands*

Micro- and nanoplastics (MNPs) are ubiquitous, however suitable risk assessments are still lacking due to poor quality control, the lack of standardised approaches to particle characterisation and environmental analysis, and the use of test materials that do not reflect those found in the environment for toxicity testing. Currently used test materials are often monodisperse polystyrene microbeads which are unrepresentative of environmental MNPs due to the perfectly round morphology, lack of diversity in plastic type and use of surfactants. A set of well-characterised test materials that are more representative of environmental MNPs would greatly help with the development of relevant risk assessments.

In this work, we aimed to develop a method for preparing test materials that are more environmentally representative. Such materials should: a) represent different, widely used plastics; b) possess a fragment morphology; and c) have representative bulk and surface chemistry. To achieve this we developed a four step protocol that involved coarse milling, (cryogenic) ball milling, sedimentation and sieving. The plastics used were commercial grades and particles were suspended without surfactants to ensure relevant chemistry. We successfully demonstrated the suitability of this protocol by preparing multiple different size fractions of both PP and PVC. These particles were also comprehensively characterised to provide information on contamination, chemical bonding, size and morphology.

Suspension of MNPs without surfactants is not without challenges as in water the particles have limited physical stability and will agglomerate whereas in organic solvents certain plastics may have limited

chemical stability, exhibiting either dissolution or swelling. We demonstrated that by combining descriptors for physical and chemical stability (zeta potential and Hanson Solubility Parameters, respectively) it is possible to predict suitable particle suspension media.
Current work is focused on increasing the environmental relevance of particles by including weathering processes such as UV-ageing that may play and important role in the behaviour, uptake and (eco)toxicity of MNPs.
We believe that the particle preparation protocol developed, along with the insights into surfactant-free suspension of particles, can advance the field by enabling research groups to study the effects of MNPs using more environmentally relevant materials thus leading to improved risk assessments.

Disclaimer/Disclosure: This research was supported by funding from ZonMw and Health-Holland (MOMENTUM project, grant agreement No 458001101) and PlasticsEurope (Brigid Project).

3.22.P-Tu261 Processing Tablets as Reference Material for Microplastics Quantification in Environmental and Food Matrices

Mara Putzu[1]*, Yosri Wiesner*[2]*, Marta Fadda*[1]*, Alessio Sacco*[1]*, Andrea Mario Giovannozzi*[1]*, Andrea Mario Rossi*[1] *and Korinna Altmann*[2]*, (1)National Institute of Metrological Research, INRiM, Italy, (2)BAM Bundesanstalt fur Materialforschung und -prufung, Germany*
Analytical detection methods and techniques to identify and quantify microplastics in environmental and food matrices are numerous but validated and standardized methods are currently lacking. To close this research gap, representative reference materials (RMs) and sample preparation approaches are urgently needed. Homogeneity and stability are two crucial characteristics for the certification process of the reference materials. For this purpose, we aim to present ways to prepare reference materials containing very low masses of close-to reality plastic particles with broad size distribution (10-100 µm) that are homogeneously distributed in tablet-to-tablet variation and stable over time. RMs were prepared by choosing polypropylene (PP) as polymer due to food and environmental relevance and a water soluble matrix composed by lactose and polyethylene glycol (PEG). The PP powder was obtained by cryogenic milling from pellets and sieved afterwards to isolate size fraction within a certain range focusing our analysis on the size fraction < 50 µm. For the production of homogeneously distributed PP particles in the individual tablets, polypropylene (< 50 µm), lactose and PEG were added step by step and mixed in between before tabletting. In order to develop a validate method to produce RMs, four different approaches will be carried out by changing two variables: (i) matrix size distribution (sieved or unsieved to the same sizes as PP) and (II) homogenization mixer instrument (Thumble mixer or Y mixer). The results of polypropylene particle size distribution measurements by laser diffraction show that most particles are in the wishes size range between 10 and 100 µm with a D50 of 48.382 ± 0.045 µm, therefore the powder is homogeneous. Thermogravimetric analysis measures the mass loss of PP and its decomposition temperature; the TGA curves obtained from the first tests confirm that the lost mass between 350 and 490 ºC corresponds to the concentration of PP present for each tablet.
This work is based on the ISO Guide 30:2015 and ISO Guide 35:2017 to fulfil the criteria set in future standards ISO/DIS 16094-2 and ISO/DIS 16094-3. The property of interest is the mass detected by thermogravimetric analysis (TGA) but the future prospective of this project also aims at integrating spectroscopic analyses (Raman microscopy or µFTIR) to obtain particle numbers by size class and chemical identification as informative values.

3.22.P-Tu262 Advanced Approach to Collect Small Microplastics in Environmental Water Samples Using Automatic Sample Preparation Technique

Yoshio Ikezawa*, Shimadzu Corporation, Japan*
The occurrence of microplastics(MPs) and nanoplastics (NPs) in the environment is a global issue that requires the collaboration of multiple stakeholders to ensure the life cycle of plastics is properly monitored and managed. Most international efforts have focused so far on the standardization and validation of detection techniques, including Raman and FTIR spectroscopy and Py-GCMS. However, now that regulations for MPs are being developed and more environmental laboratories are starting their routine analysis, effective sample preparation is crucial for their success. Current approaches for eliminating organic content from samples or for separating inorganic materials rely on manual digestion and density separation, and the performance of these steps depends on the operator's proficiency. To obtain more accurate data between laboratories, the homogenized method must be required. In addition, converting from manual to automatic operation would be a solution to improve the accuracy in the data. The

automatic preparation device, providing a universal sample preparation process suitable for the follow-up analysis by Raman, FTIR or Py-GCMS, has been available. But it still has some challenges in the treatment of smaller microplastics. This presentation will provide some experiments data using automatic preparation device for isolating smaller microplastics in environmental water samples.

3.22.P-Tu263 Extracting and Quantifying Nanoplastics in Food Matrices

Enrica Alasonati[1]*, Korinna Altmann*[2]*, Yosri Wiesner*[2]*, Dorota Bartczak*[3]*, Florian Meier*[4]*, Roland Drexel*[4]*, Carine Chivas-Joly*[1]*, Andy Booth*[5]*, Thierry Caebergs*[6]*, Claudia Drago*[7] *and Andrea Mario Giovannozzi*[8]*, (1)National Metrology Institute of France (LNE), Paris, France, (2)Bundesanstalt fur Materialforschung und -prufung (BAM), Germany, (3)UK National Measurement Laboratory at LGC, United Kingdom, (4)Postnova Analytics GmbH, Germany, (5)SINTEF Ocean, Norway, (6)FPS Economy - Metrology Division (SMD), Belgium, (7)Umweltbundesamt (German Environment Agency), Germany, (8)National Metrology Institute of Italy (INRiM), Turin, Italy*

Due to their smaller dimensions and specific colloidal properties, small microplastic (sMPs; 1-10 µm size range in this work) and nanoplastics (NPs; < 1µm in this work) are likely to cross biological barriers, increasing the potential for accumulation and the possibility of negative effects on living organisms. Recent studies have highlighted the potential presence of sMPs and NPs in bottled drinking water and in milk powdered infant formulas, raising concerns about exposure during early development.
Here, we address the quantification of NPs in food-related samples such as drinking water and milk, establishing the lower detection limit as a function of particle size and aiming to achieve precise and reliable characterization.
In the framework of the Plastic Trace Project (plastictrace.eu), sub-micron and nano-sized plastic particles, representative of common industrial polymers like polyethylene (PE) and polypropylene (PP), were produced and characterised. These materials, designed to mimic real-life particles in terms of size, shape, and aging, were then spiked into bottled drinking water and infant formula. This work focuses on developing optimized sample preparation strategies for the extraction of NPs from complex food matrices, with an emphasis on maximizing particle recovery rates while preserving the original characteristics of the particles. The stability of nanomaterials spiked in these complex matrices is also addressed. Different strategies for the enrichment of nano-polypropylene (nanoPP) dispersed in bottled drinking water are currently being tested. This includes (i) nanoscale filtration of nanoPP and recovery in surfactants assisted by probe ultrasonication; (ii) Cloud Point Extraction (CPE) methods based on Triton X-45, and (iii) freeze-drying. Multi-detector Asymmetrical Flow-Field Flow Fractionation (MD-AF4) is used for the separation and characterization of nanoPP before spiking and after extraction from the matrices. Fit-for-purpose fractionation methods for separation of NPs dispersed in milk matrices are also currently studied to provide an alternative to more invasive extraction methods.

Disclaimer/Disclosure: The PlasticTrace project has received funding from the European Partnership on Metrology, co-financed from the European Union's Horizon Europe Research and Innovation Programme and by the Participating States.

3.22.P-Tu264 A Roadmap for Harmonized Microplastic Analysis in Textile Wastewater Treatment Plants

Serena Ducoli[1]*, Alberto Zoccali*[2]*, Isabella Gambino*[3]*, Giulia Pezzoli*[3]*, Elisa Terzaghi*[3]*, Benedetta Villa*[3]*, Roberta Bettinetti*[4]*, Enrica Baldini*[5]*, Augusta Silva*[6]*, Giovanni Bergna*[7]*, Francesca Malpei*[2]*, Antonio Di Guardo*[3]*, Laura Eleonora Depero*[1] *and Stefania Federici*[1]*, (1)DIMI, University of Brescia and INSTM, Italy, (2)DICA, Politecnico di Milano, Italy, (3)DiSAT, University of Insubria, Italy, (4)DiSUIT, University of Insubria, Italy, (5)Centro Tessile Serico Sostenibile, Italy, (6)CITEVE, Portugal, (7)Lariana Depur, Fino Mornasco (CO) Italy, Italy*

The growing concern over microplastic pollution in aquatic environments highlights the need for harmonized methodologies, particularly for complex matrices such as textile wastewater. Current approaches lack harmonization, leading to inconsistent results that hinder reliable assessments. This study proposes a robust roadmap for the extraction and analysis of microplastics from textile wastewater. The framework begins with optimized extraction methods tailored to complex wastewater matrices, ensuring minimal interference from co-contaminants. Analytical pathways include optical microscopy visual inspection, Fourier-transform Infrared spectroscopy, and Pyrolysis GC-MS for identification and quantification, supported by comprehensive uncertainty budget estimation. Key elements of the protocol involve the systematic analysis of blanks, evaluation of subsampling techniques, and the use of replicates to ensure data reliability. Furthermore, an interlaboratory comparison among multiple facilities validates

the developed protocols.
The focus on harmonization across these steps aims to establish reproducible and comparable results, thereby advancing the field of microplastic research. This study's roadmap provides critical insights into improving protocol harmonization and ensuring robust data generation. These findings are not only essential for understanding microplastic pollution from textile wastewater but also provide a foundation for policy-making and mitigation strategies. The methodology's adaptability further enhances its relevance for broader environmental applications.

Disclaimer/Disclosure: This contribution is based upon work from LIFE-2022-SAP-ENV - LIFE-PJG Action LIFE22-ENV-IT-LIFE CASCADE Project Grant Management Number 101113942.

3.22.P-Tu265 Developing a Protocol for Accurate Qualitative Assessment of Paint-Derived Microplastics in the Environment: Density and FTIR Analysis

***Taekhyun Kim**, Soeun Eo, Wonjoon Shim and Moonkoo Kim, Korea Institute of Ocean Science & Technology (KIOST), "Korea, Republic of"*

Paint particles, particularly those derived from antifouling and other marine coatings, are a significant but under-recognized source of microplastic pollution in the environment. Due to their complex composition of polymers (binders), pigments, and additives, paint particles exhibit diverse physical and chemical properties, such as higher densities compared to pure polymers, which complicates their identification and environmental analysis. This research aims to address these challenges by improving the qualitative assessment of microplastics derived from paint through two critical approaches: density analysis and FTIR spectrum interpretation.
This study investigates the environmental fate of paint particles by measuring their densities and predicting sedimentation behavior using Stokes' Law. Comparisons were made between pure polymers, commercially available paint particles, and those sampled from environmental matrices, revealing density variations due to pigments and additives. Additionally, FTIR spectra of paint particles were analyzed to identify functional groups and molecular motions, focusing on fingerprint regions that distinguish paint particles from other microplastics.
Results indicate that paint particles have significantly higher densities than standard polymers, often leading to their omission in density-based separation processes (e.g., 1.6 g/cm^3 cutoff) commonly used in microplastic research. Furthermore, FTIR analysis identified unique peaks corresponding to polymers such as acrylate, rosin, PDMS, epoxy, urethane, and alkyd, facilitating the development of a protocol for the accurate identification of paint-derived microplastics.
This study emphasizes the importance of integrating density-specific methods and FTIR fingerprinting to enhance the detection and characterization of paint particles in environmental samples. By addressing critical gaps in current methodologies, these findings provide a foundation for more accurate monitoring and risk assessment of paint-derived microplastic pollution.

Disclaimer/Disclosure: This research was supported by the Korea Institute of Marine Science & Technology Promotion (KIMST), funded by the Ministry of Oceans and Fisheries, through the following projects: Land/sea-based input and fate of microplastics in the marine environment (RS-2022-KS221604) and Techniques development for management and evaluation of biofouling on ship hulls (RS-2021-KS211530).

3.22.P-Tu266 Development of Analytical Methods for Polymers (Unique Plastics) That Cannot be Analyzed by Hydrogen Peroxide Oxidation Treatment

***Emiko Fujita** and Yutaka Kameda, Chiba Institute of Technology, Japan*

Microplastics (MPs) are a global environmental concern, with ongoing research improving our understanding of their distribution and characteristics. However, existing methods for accurately detecting all types of plastics remain insufficient, particularly for biodegradable plastics and those with unique properties, such as Polyvinyl Alcohol (PVAl) and Super Absorbent Polymers (SAP). PVAl, widely used in products like detergent pods, has seen its global production grow from 3.7 million tons in 2018 to 4 million tons in 2022. While considered biodegradable, its high water solubility raises questions about persistence in aquatic environments. Studies like Rolsky et al. (2021) indicate PVAl degradation requires specific conditions, such as specialized microorganisms, optimal temperature, pH, and oxygen levels. In their absence, PVAl may persist longer than anticipated.

SAP, with an annual production of 3 million tons, is non-biodegradable but exhibits high water absorption capacity, which decreases in saline conditions. SAP distribution in aquatic environments remains poorly documented. Existing methods face challenges in detecting PVAl and SAP. For example, at the standard 55°C used in hydrogen peroxide oxidation, over 99% of PVAl becomes undetectable by micro-FTIR analysis. SAP particles often fragment during analysis, leading to underestimation of particles smaller than several hundred micrometers. Thus, traditional methods may underestimate these plastics in environmental waters.

In river surveys conducted in Japan (2022 2023), a 300/350 ?m plankton net collected 2,897 MPs, of which 22 were identified as PVAl via FTIR analysis. Follow-up studies using a 10 ?m net detected no PVAl and few SAP particles. These results contrast with reports of PVAl and SAP as macroplastic debris on beaches, raising concerns about their degradation into smaller particles and behavior in aquatic environments. Like other plastics, PVAl can adsorb pollutants, posing ecological risks. This highlights the need for improved monitoring of PVAl and SAP to assess their environmental impact.

This study introduces a novel method for quantifying PVAl and SAP in environmental waters, addressing limitations of traditional approaches. By providing a more accurate assessment of their concentrations, this method enhances understanding of their distribution and impact.

3.22.P-Tu267 Innovations in Microplastic Measurement: A Pyrolysis-Gas Chromatography/Mass Spectrometry for a Polyethylene Terephthalate Reference Material

Veronica Fernandez-Gonzalez[1], Carmen Moscoso-Perez[1], Yosri Wiesner[2], Purificacion Lopez-Mahia[1], Korinna Altmann[2] and ***Soledad Muniategui-Lorenzo***[1]*, (1) University of A Coruña, Spain, (2)Bundesanstalt fur Materialforschung und -prufung (BAM), Germany*

In the framework of the PlasticTrace project, in which a reference material for PET microplastics will be proposed, a method using pyrolysis and gas chromatography coupled with mass spectrometry detection (Py-GC-MS) is developed to quantify the mass of PET microplastics (10-100 µm) in tablets at two different concentration levels.

The overall aim of this project is to develop international metrological capacity that enables the traceable measurement and characterization of SMPs and NPs in environmental and food samples and the production of suitable reference materials, according to the metrological requirements (https://plastictrace.eu/).

The proposed method consists of dissolving the tablet containing the PET microplastics in milli-Q water and filtering the solution using a glass microfiber membrane 13 mm filter size, 1.6 µm pore size (Whatman). After filtering and several washes to ensure complete dissolution of the tablet and recovery of all PET microplastics, the filter is removed, folded, and placed in a capsule of the pyrolyzer for direct Py-GC-MS analysis.

Two main markers were selected for PET quantification: vinyl benzoate and benzoic acid, with consistent concentrations found for both at high PET concentrations (?400 µg) (24% RSD, n = 17), but interferences with the matrix and vinyl benzoate were found at low concentrations (?17 µg PET), with only benzoic acid being valid as a marker in this case (22% RSD, n=10).

As an alternative to the quantification of PET microplastics in tablets at low concentrations, derivatization is proposed, for which tetramethylammonium hydroxide solution (TMAH) is added directly into the pyrolysis cap. The PET marker in this case is dimethyl terephthalate, with which good results have also been found (19.6% RSD, n = 10).

The proposed method is robust, simple, with high automation and very little sample handling and treatment, and allows the analysis of PET microplastics (10-100 µm) in tablets with excellent accuracy and precision even at very low concentrations.

Disclaimer/Disclosure: The authors thank the European Commission for funding the PlasticTrace project (21GRD07) from the European Partnership on Metrology, co-financed from the European Union s Horizon Europe Research and Innovation Programme and by the Participating states. The Program Consolidación e Estructuración de Unidades de Investigación Competitivas (Xunta de Galicia) is also acknowledged (Grant ED431C 2021/56).

3.22.P-Tu268 Identification of Microfibers Released from Textiles in Simulated Accelerated Washing Using International Standards: Implications for Comparative Analyses

Ana Costa[1], Andrea Marinho[1], Alcina Pimenta[1], Ana Paula Fonte[1], ***Ana Luisa Patrício Silva***[2]*, Antonio Fernandes[3], Florinda M. Costa[4], Damia Barcelo[5], Lucia H.M.L.M. Santos[6], Armando Duarte[7], Joao Pinto*

Microplastics, including plastic microfibers, are increasingly recognized as a significant environmental issue. Their ubiquitous presence in various environmental matrices, coupled with their complex composition and morphology, implies the need for standardized methodologies for their accurate detection and quantification. This study aimed to contribute to the development of such standardized approaches by investigating the release of microfibers from different fabrics during simulated washing processes, adhering to established international standards.
By adopting these standardized protocols, researchers can generate reliable and comparable data on microfiber release, enabling a more comprehensive understanding of the factors influencing their prevalence and environmental fate. This knowledge is crucial for developing effective strategies to mitigate microplastic pollution and protect ecosystems.
Our findings emphasize the importance and requirement of careful data analysis, particularly when relying on automated software-based identification techniques. While these techniques offer potential advantages in terms of efficiency and high-throughput, they may introduce biases and inaccuracies, especially for complex samples. Therefore, a combination of analytical techniques, including manual verification and complementary methods, is recommended to ensure accurate and reliable results.
By promoting the use of standardized methodologies and critical data analysis, this study contributes to the advancement of microplastic research and the development of evidence-based solutions to address this emerging environmental challenge.

3.22.P-Tu269 Approaches and Strategies for the Detection and Quantification of Nano and Microplastics by Single Particle Inductively Coupled Plasma Mass Spectrometry

*Chady Stephan[1], David Price[2], Helmut Ernstberger[3], **Tom Hey**[1] and Michael Petrich. [4], (1)PerkinElmer, Canada, (2)PerkinElmer, United Kingdom, (3)PerkinElmer, Italy, (4)PerkinElmer, Germany*
Plastic is the most prevalent type of marine debris found in our ocean and lakes. Plastic debris can come in all shapes and sizes, but those that are less than five millimeters in length are called microplastics. Microplastics enter the environment from a variety of sources, environment weathering of large plastic items, additive manufacturing used in cosmetics and release from consumer products.
Currently FT-IR microscopy is the most common approach used for microplastic research. Here we show that single particle inductively coupled plasma mass spectrometry (SP-ICP-MS) can be utilized for the analysis of micro-sized plastics by monitoring carbon isotopes. We discuss the use of specific introduction parts, to ensure an even transport efficiency of both dissolved and micron-sized particles into the plasma, as well as strategies using specific gases and cell conditions to obtain the best detection limits. This approach can be used for fast scanning of microplastic particles in environmental matrices or consumer products without needing to concentrate or alter the samples matrices.

3.22.P-Tu270 Detection of Nanoplastics in Liquid Using Surface-Enhanced-Raman-Spectroscopy-tags

Moritz Haffner[1]*, Barbara Rothen-Rutishauser*[1]*, Patricia Taladriz-Blanco*[1] *and Alke Petri-Fink*[2]*, (1)Adolphe Merkle Institute, University of Fribourg, Switzerland, (2)Adolphe Merkle Institute, University of Fribourg, Switzerland & Chemistry Department, University of Fribourg, Switzerland, Switzerland*

Nanoplastic detection (defined here as plastic particles smaller than 100 nm) has become critically important due to its widespread presence, persistence in various ecosystems, and potential toxicity to wildlife and humans. Despite this concern, the analytical techniques available for detecting and quantifying nanoplastics, especially at environmentally relevant concentrations (µg/L ng/L), remain significantly limited.

Surface-enhanced Raman spectroscopy (SERS) has shown promising potential for achieving the necessary sensitivity to detect nanoplastics below the conventional Raman resolution limit (~500 nm), even at concentrations as low as ng/L. However, many existing SERS approaches, which rely on aggregated plasmonic particles, suffer from weak reproducibility and the inability of quantification in environmental contexts.

To address these limitations, we adopted a strategy that employs SERS tags to indirectly detect nanoplastics. By conjugating gold nanostars with a reporter molecule with an inherently strong Raman signal, we are able to measure signal changes of the reporter molecule in the presence of plastic particles. This signal change depends on the plastic concentration and, therefore, allows us to quantify the nanoplastics in an artificial aqueous sample at low concentrations. This method could enhance our ability to detect nanoplastics at realistic concentrations in natural freshwater and marine environments and more complex aqueous environmental matrices.

3.22.P-Tu271 Advancing Microplastic Research through True-to-Life Micro- and Nanoplastics for Environmental and Biological Studies

Stefania Federici*, Serena Ducoli, Annalisa Zacco, Michele Speziani and Laura Eleonora Depero, Chemistry for Technologies Laboratory, Department of Mechanical and Industrial Engineering, University of Brescia & INSTM RU of Brescia, Italy*

Micro- and nanoplastics have become significant environmental pollutants, posing potential threats to aquatic ecosystems and human health. Despite growing concerns, there is a lack of harmonized methods for accurately identifying and assessing the impact of these particles. A major challenge in developing more relevant test microplastics is finding processes that closely replicate their environmental counterparts. To address this, we have developed "true-to-life" micro- and nanoplastics, along with comprehensive analytical protocols for their identification, characterization, and impact assessment. This approach aims to enhance our understanding of the sources, fate, and effects of these particles. In particular, we explored and compared three mechanical fragmentation techniques for preparing true-to-life materials, examining how each method affects the morphology and structural properties of the resulting microplastics. Through centrifugation protocols, we successfully isolated nanosized fractions from micrometric plastic powders. Nanoplastics were then characterized using both chemical and imaging techniques, revealing unique morphological features for each nanoplastic type. This diversity in particle characteristics led to distinct bio-interactions with proteins and environmental compounds. Lastly, we investigated the dynamics of microplastic uptake, accumulation, and egestion in biota by exposing mussels to true-to-life microplastics. Our findings underscore the importance of employing materials with greater environmental relevance, bridging the gap between laboratory experiments and real-world observations.

Disclaimer/Disclosure: This contribution is based upon work from COST Action CA20101 Plastics monitoring detectiOn RemedIaTion recovery PRIORITY, supported by COST (European Cooperation in Science and Technology, www.cost.eu). 3.22.P-Tu272 Investigation of Fluorescent Polystyrene Uptake in Caco-2 Cells Using Microplate Readers

Xiaohui Lin[1]*, Jun-Li Xu*[1] *and Aoife Gowen*[2]*, (1)University College Dublin, Ireland, (2)School of Biosystems and Food Engineering, University College Dublin,Ireland*

Microplastics (MPs) are a growing concern due to their potential impact on human health, including their uptake by cells and accumulation in tissues. Detecting MP uptake by human cell lines is critical for understanding exposure pathways, but current techniques such as transmission electron microscopy, flow cytometry, and Raman microscopy are labor-intensive, time-consuming, and require specialized skills. This study aims to develop a fast and user-friendly detection method using a microplate reader, which could offer a high-throughput alternative for studying MPs-cell interactions. Fluorescent polystyrene (PS, 1 µm) was selected due to its prevalence in consumer products and the ease of size control during synthesis. Caco-2 cells were incubated with different PS concentrations (0, 10?, 10?, 10? particles/mL) for 24 hours, followed by washing, fixing, and measuring fluorescence using a microplate reader. Results showed a correlation between increasing PS concentrations and fluorescence intensity, but the microplate reader failed to detect uptake at the lowest concentration (10? particles/mL), as values were indistinguishable from the control group (0 particles/mL). These findings suggest that microplate readers can provide a fast and efficient means of detecting MP uptake by cells at higher concentrations (?10? particles/mL), offering a practical tool for high-throughput studies. This method advances the field by simplifying detection protocols, making it more accessible for broader use, and contributing to a better understanding of MP exposure risks and mitigation strategies.

Disclaimer/Disclosure: This project received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 101034345 and the Science Foundation Ireland (SFI)-Irish Research Council Pathway Programme Proposal ID 21/PATH-S/9290.

3.22.P-Tu273 Leaching of Plastic Additives from Custom-Made Polymers into Artificial Gut Fluids

*Mara Romerscheid, **Karla Schmitz**, Annika Jahnke, Nico Jehmlich, Ulrike E. Rolle-Kampczyk, Zheng Chen and Alexander Bohme, Helmholtz Center for Environmental Research (UFZ), Germany*

Microplastics are pervasive in the environment, including their presence in the food web. Humans can ingest microplastics through beverages and food, and are exposed not only to the microplastic particles themselves, but also to the plastic additives. These additives can leach into human intestinal fluids during passage of the gastrointestinal tract, where they may be transformed and bioaccumulate, thus posing a risk to human health.

As the composition and concentration of additives in plastic products are generally not disclosed, this study used custom-made polymers with known and realistic additive mixtures. The additives were chosen to cover different categories such as UV stabilizers, plasticizers, and flame retardants. We used UV-weathered plastic as UV-light may cause surface alteration, degradation and structural modification of the plastic.

The study investigated material-specific leaching across different polymers and additives, comparing weathered and unweathered plastics and varying incubation times. By utilizing plastics with known additive concentrations, the extent of leaching was determined, providing critical insights into plastics with unknown compositions.

To simulate human digestion, microplastics were exposed to artificial gut fluids representing saliva, gastric juice, duodenal juice, and bile, with conditions reflecting physiological temperature, pH, and residence time in each digestive phase. To provide a more holistic understanding, a simplified human intestinal microbiota (SIHUMIx) was applied followed by metabolome and proteome analysis. Finally, the additives were extracted using hexane, and their concentration in the solution was measured.

These findings aim to improve risk assessments and inform regulatory agencies regarding plastic additives, particularly with respect to human gastrointestinal exposure.

3.22.P-Tu274 Influence of Additives on the Abiotic Degradation of Polyethylene Plates

***Hulya Markl-Hahn**[1], Anika Mauel[2], Jurgen Senker[2] and Holger Ruckdaschel[1], (1)Polymer Engineering, University of Bayreuth, Germany, (2)Inorganic Chemistry III, University of Bayreuth, Germany*

Secondary microplastics in the environment are mainly caused by the ageing of macroplastics. However, the extent to which this ageing is influenced by the addition of additives still needs to be clarified. Accelerated abiotic weathering was used to investigate the mechanisms that lead to the degradation of additivated, semi-crystalline low-density polyethylene (LDPE). For this purpose, LDPE plates were produced with different, realistic concentrations of additives and weathered in a test chamber. Oxidation products from photooxidation and fragmentation processes were detected on the surfaces of the LDPE plates. Analyses of the aged plates clearly showed the influence of the additives on the ageing of the macroplastics. Based on these results, it should be possible to model the degradation process of additivated plastics in the future.

3.22.P-Tu275 Investigation of the Photo-Oxidation and Casein Interaction of Polystyrene Microplastics

***Emine Merve Canga*[1]*, Aoife Gowen[2] and Jun-Li Xu[2], (1)University College Dublin, Ireland, (2)School of Biosystems and Food Engineering, University College Dublin, Ireland*

Ultraviolet (UV) radiation might cause photo-oxidation of plastic polymers driven by free radicals. Comprehending the effects of UV-induced photo-oxidation on microplastics (MPs) is essential for assessing their ongoing environmental impact and interactions with other molecules. In our study, 1 ?m polystyrene (PS) MPs were exposed to 36 W UV-C light for 10 days in a dry state and subsequently analysed for interactions with casein to explore the altered behaviour of photo-oxidized MPs. Chemical characterisation of samples (casein-interacted pristine MPs and casein-interacted UV-aged MPs) was conducted using optical photothermal infrared (O-PTIR), obtaining infrared (IR) spectra. This novel method enables the detection of submicron particles with 500 nm spatial resolution and addresses some challenges posed by Raman and Fourier Transform Infrared Spectroscopy (FTIR). Our preliminary result showed that characteristic peaks related to carbonyl groups (~1743 cm-1) exhibited slight shifts after 10 days of UV exposure. Following casein interaction, protein-related peaks between 1600 1700 cm-1 were also observed in the IR spectra. Scanning electron microscopy (SEM) images showed the altered surface after UV exposure and the formation of a protein corona following casein interaction. Dynamic light scattering (DLS) analysis revealed that UV exposure led to the formation of smaller PS MPs of approximately 150 nm in size compared to untreated samples. Furthermore, the particles exposed to UV had a diameter about 100 nm larger after interacting with casein compared to unexposed particles, although this difference was not statistically significant. This could be attributed to the formation of functional groups on the particle surface due to photo-oxidation. Zeta potential analysis indicated that the zeta potential of both untreated and UV-treated samples closed the zeta potential value of casein after the interaction. Moreover, atomic force microscopy (AFM) analysis showed that the stiffness of PS MPs decreased after casein interaction. In conclusion, our preliminary findings suggest that UV radiation changed both the physical and chemical properties of 1 ?m PS MPs, and this alteration might affect the protein interaction of the particles. These insights are critical for understanding the environmental fate and biological impact of aged microplastics, particularly in systems where protein interactions play a significant role, such as food systems and human health.

Disclaimer/Disclosure: This research was supported by the Science Foundation Ireland (SFI)-Irish Research Council Pathway Programme with the proposal ID 21/PATH-S/9290. In addition, Emine Merve Canga acknowledges the Study Abroad Program (YLSY) funding of the Ministry of National Education of the Republic of Turkey for her doctoral studies.

3.22.P-Tu276 Bioprocessing of Printed Circuit Board Microplastics

***Diogo A. Ferreira-Filipe*[1]*, Leila Oliveira[2], Ana Maria Paço[1], Antonio Fernandes[3], Florinda M. Costa[3], Armando Duarte[1], Teresa Rocha-Santos[1] and Ana Luisa Patrício Silva[4], (1)Centre for Environmental and Marine Studies (CESAM) & Department of Chemistry, University of Aveiro, Portugal, (2)Department of Chemistry, University of Aveiro, Portugal, (3)I3N & Department of Physics, University of Aveiro, Portugal, (4)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal*

Electronic waste (e-waste) is the fastest-growing waste stream globally, comprising a complex mixture of hazardous materials, including metals, plastics, flame retardants, and plasticizers. Despite advances in recycling technologies, challenges persist in sorting and decontaminating the polymer fractions (over 27% of e-waste), leading to their frequent unregulated disposal. In this context, building up approaches with increased sustainability towards processing these plastic constituents becomes essential, ensuring both efficient resource recovery and mitigation of environmental impacts.
Microorganisms such as fungi have demonstrated a broad ability to degrade and metabolize a variety of plastics. Still, their use for the biodegradation of e-waste plastic fractions has yet to be attempted. In this context, this study explored the potential of the fungus *Penicillium brevicompactum*, a species previously found to have plastic biodegradation potential (including polymers used in electronics) for the biodegradation of the plastic fraction of printed circuit boards (microplastics 1-2 mm in size). Exposure to *P. brevicompactum* over 28 days in a liquid medium, under stirring, was associated with a concurrent increase in the number and decrease in the size of microplastic particles and mass reductions of up to 75% (specifically in the first 14 days). A further indication of this fungus capacity for PCB microplastic

biodegradation is the occurrence of chain scission and oxidation events, as assessed through attenuated total reflectance Fourier-transform infrared (ATR-FTIR) spectroscopy. On the other hand, regarding fungal biomass, absorption intensities were observed in regions attributable to functional groups associated with carbohydrates (assessed through ATR-FTIR), which signals these microplastics' potential use as a fungus carbon source.
These results highlight the promising role of fungi such as *Penicillium brevicompactum* in the biodegradation of e-waste-derived microplastics, which further represents a basis for research into broader and more sustainable e-waste bioprocessing strategies.

3.22.P-Tu277 Rethinking Biofilms on Plastics as Environmental Defenders

Isabel Gossmann[1]*, Barbara M. Scholz-Boettcher*[2]*, Heinz Wilkes*[2]*, Jes Vollertsen*[1]*, Thomas S. Quaade*[3]*, Morten E. Simonsen*[4]*, Hery Mitsutake*[1] *and Fan Liu*[1]*, (1)Department of the Built Environment, Aalborg University, Denmark, (2)Institute for Chemistry and Biology of the Marine Environment, Carl von Ossietzky Universitat Oldenburg, Germany, (3)Department of Materials and Production, Aalborg University, Denmark, (4)Department of Chemistry and Bioscience, Aalborg University, Denmark*
Plastic pollution introduces a range of harmful chemical additives into natural environments due to physicochemical aging and subsequent leaching processes. However, the role of biofilms microbial communities that form on plastic surfaces remains largely unexplored in this context. This study proposes that biofilms may act as a natural barrier, capturing and potentially metabolizing these additives before they disperse into the environment, while also protecting the plastic itself from environmental degradation. Such interactions could fundamentally change our understanding of plastic persistence and toxicity in ecosystems.
To test our hypotheses, we conduct controlled experiments exposing consumer plastics of various polymer types to natural water to induce biofilm formation. Plastic samples are maintained in both biofilm-supportive and biofilm-inhibited environments, enabling direct comparison. Plastics from both sets are then exposed to UV radiation, to evaluate the potential protective role of biofilms on plastics against photoaging.
The fingerprints of biochemical alterations from the uppermost plastic surface along particle’ s depth is characterized using Raman micro-spectroscopy, with a depth resolution down to 5 µm. Concurrently, alterations in surface chemistry, including wettability, zeta potential, and surface energy, are also analyzed. Changes in surface morphology are monitored by scanning electron microscopy and atomic force microscopy coupled with Raman micro-spectroscopy. To characterize and measure leachates and potential metabolites generated within the biofilm, we employ gas chromatography and liquid chromatography coupled with mass spectrometry on nominal and high resolution mode.
The findings from this study are expected to provide valuable new insights into plastic risk assessment, promoting a more realistic evaluation of plastic's environmental impact and fate. By reframing biofilms as potential defenders of both the environment and plastic materials, this research aims to enhance our understanding of plastic pollution and its mitigation within natural ecosystems.

3.23.A Plastics in Terrestrial Ecosystems: Balancing Applications with Impacts, Fate and Hazards

3.23.A.T-01 (Micro)Plastics in Soils: From Sampling Strategy to Source Identification and Conclusions for Regulation

Helene Walch[1]*, Sebastian Koppel*[1]*, Ievgeniia Lomako*[1]*, Andreas Kreuzeder*[2]*, Thomas Bauer*[3]*, Sonja Marhold*[3]*, Thomas Peham*[4]*, Katharina Sexlinger*[5]*, Walter Wenzel*[6]*, Maria Uhl*[1] *and Wolfgang Friesl-Hanl*[1]*, (1)Environment Agency Austria, Austria, (2)Land Salzburg, Austria, (3)Amt der Oo. Landesregierung, Austria, (4)Amt der Tiroler Landesregierung, Austria, (5)Umweltinstitut Vorarlberg, Austria, (6)University of Natural Resources and Life Sciences, Vienna, Austria*
(Micro)plastics are ubiquitous in our environment, including the soil. Reliable monitoring data help to

understand input pathways, to assess potential risks, and to derive recommendations for action. In the context of soil protection, robust cost-effective sampling and analytical methods are needed. Within the project PLASBo "harmonised methods for plastics and microplastics in soils," we developed a soil sampling strategy for subsequent (micro)plastic analysis and evaluated a visual method for routine analysis of plastics >1 mm in an inter-laboratory comparison. Moreover, we generated a first comprehensive database on micro(plastics) in soils and identified major input pathways. Samples from 113 sites of different land use types across Austria (non-representative selection) were collected and analysed by visual inspection (>1 mm) as well as by micro-FTIR (0.05-1 mm), detecting the 10 most common plastic types. For 25 sites, tire wear was additionally analysed by TED-GC-MS. A complementary site characterization allowed identification of factors influencing the concentrations, sizes, shapes, and types of plastics identified.
The sampling strategy proofed fit for various land use types and can be used in combination with visual analysis to reliably quantify concentrations of large (micro)plastics (>1 mm) >10 n/kg. Visual analysis was found to be robust, with a low error rate, despite some impact of analytical experience.
Small microplastics (0.05-1 mm) were virtually omnipresent, with concentrations about 3 orders of magnitude higher (mainly ~10^2-10^4 n/kg) than for large (micro)plastics (mainly 1-10 n/kg). The concentrations decreased with decreasing use intensity. Impacts of fertilizer applications (sewage sludge, compost, manure, none) and plasticulture (e.g., mulch foils in vegetable farming) were reflected in (micro)plastic concentrations and compositions. Some hotspot sites were related to closeby emitters, and for roadside/commercial and leisure areas impacts of littering were evident. Tire wear was detected at 16/25 sites at concentrations of <1.1-61 mg/kg and coincided with the proximity of roads, urban areas, and sewage sludge application. For forests, deposition and the impact of the humuslayer on the transfer of microplastics into underlying mineral soils was evident.
The results provide a valuable basis for method harmonisation and the priorisation of recommendations for action in the regulatory context of soil protection.

Disclaimer/Disclosure: The authors thank the Federal Ministry of Agriculture, Forestry, Regions and Watermanagement for funding the Project via the research plattform DaFNE (https://dafne.at/projekte/plasbo) and the Austrian federal provinces for funding and active participation.

3.23.A.T-02 Assessment of Sampling Approaches for Representative Quantification of Microplastics in Soil

Denise M. Mitrano, Roman Schefer and ***Samuel James Cusworth****, Department of Environmental Systems Sciences (D-USYS), Switzerland*

Microplastics (MPs) concentrations and accumulation in soils are highly spatially variable and are dependent on proximity to sources, land-use and natural processes. The entire analytical chain for quantifying and characterizing MPs in soils is challenging, particularly in terms of accurately capturing the variations of a heterogeneously distributed particulate contaminant, which is the foundation for all future steps in assessing MPs exposure. Current approaches for MPs sampling rarely consider the sampling design, matrix characteristics and the spatial representativeness of each sample. Using metal-doped MPs to more quickly assess sampling strategies by circumventing the time needed for traditional MPs analysis, we produced a reproducible and representative hypothesis-driven sampling framework from which MPs can be quantified from a diverse range of soil environments. MPs of different morphologies (fragments, fibers) and concentrations (0.001 0.1 %) were mixed into different model systems (100 x 100 x 5 cm and 40 x 40 x 30) at distribution patterns mimicking clustered or homogenously polluted systems. We created a multi-factorial experiment to determine the most effective combination of the individual components (sampling design, frequency, sample mass, homogenization and separation techniques, as well as composite aliquot factors) to accurately represent different distributions and concentrations of MPs in soils. Initial results highlight that techniques to reduce a sample mass by an order of magnitude must have > 90% recovery for integration in the sampling framework. Similarly, a higher composite aliquot factor of 5:1 (aliquots:composite) returned higher recover rates than direct analysis of individual samples, for both fragments and fibers. From 0.02 0.09 wt.% (MPs/soil), recovery rates of direct digestion were 91.3% ± 10.1%, compared to density separation (85.7% ± 4.5%). However, when two density separation cycles were performed, recovery rates were comparable to direct digestion (94.6% ± 3.1%). The development of this sampling framework is critical for the accurate assessment of MPs in different soil environments, which ultimately facilitates comparability of data between studies. Using this approach can provide guidance for MPs monitoring in soil, which is urgently needed for the accurate assessment of MPs exposure in the terrestrial environment and to better understand the mechanisms governing MPs fate, mobility, behavior and impacts.

3.23.A.T-03 Fate of Microplastics Derived from Agricultural Plastics in Soil Systems: Insights from Mesocosm and Field Experiments

Rachel Hurley[1]*, Chiara Consolaro*[2]*, Sam van Loon*[3]*, Salla Kristiina Selonen*[4]*, Hafeez Ur Rehman*[2]*, Lotte de Jeu*[3]*, Laura J. Zantis*[5]*, Helena Soinne*[6]*, Johanna Nikama*[6]*, Virtudes Martinez-Hernandez*[7]*, Raffaella Meffe*[8]*, Paula E. Redondo*[7]*, Andreu Rico*[7]*, Melanie Braun*[9]*, Wulf Amelung*[9]*, Cornelis A.M. van Gestel*[10] *and Luca Nizzetto*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Amsterdam Institute for Life and Environment (A-LIFE), Faculty of Science, Vrije Universiteit Amsterdam, Netherlands, (4)Finnish Environment Institute (SYKE), Finland, (5)University of Leiden, Netherlands, (6)Natural Resources Institute Finland (Luke), Finland, (7)IMDEA Water Institute, Spain, (8)IMDEA Water Institute,Spain, (9)Institute for Crop Science and Resource Conservation (INRES) - Soil Science and Soil Ecology, University of Bonn, Germany, (10)Vrije Universiteit Amsterdam, Netherlands*

Soils have been identified as one of the main environmental recipients of microplastic pollution, where the fragmentation of mulching films during and after use has been highlighted as an important source. Yet, little is known about the environmental fate of mulching film fragments once they enter soil ecosystems. This is important as, if microplastics remain in the soil, then the successive use of mulching films may lead to increasingly high concentrations over time. If they are instead effectively mobilised, then soils may act as a release pathway for microplastics to connected environments. This study addresses this critical knowledge gap by combining multiple experiments across different scales.

First, a series of mesocosm experiments were conducted using the CLIMECS (CLImatic Manipulation of ECosystem Samples) facility at Vrije Universiteit Amsterdam, which comprises 40 soil columns that simulate soil ecosystems and are individually controlled for different environmental conditions. Different treatments investigated included a range of microplastic concentrations, high and low watering regimes, and the presence and absence of earthworms. Insights from this experiment were further investigated under field conditions, as part of multi-season field plot experiments conducted in Finland, Germany, and Spain. Experimental plots were established in fields with known histories of plastic exposure. The experiments were maintained from the onset of the growing season in each country in 2022 until the end of the growing season in 2023. Samples were taken at the end of both growing seasons. Two polymer types (linear low density polyethylene and polybutylene adipate terephthalate), produced from conventional and biodegradable mulching films, respectively, were tested across both experiments. Microplastics were analysed in soil and earthworm samples to track particle fate.

Vertical transport of microplastics was noted, where the critical role of earthworms was revealed. High soil water inputs exerted a lesser but observable influence. Different earthworm species take up particles to a different degree. However, despite vertical migration, the majority of particles remain in the upper layers where they are more available for lateral transport processes. Together, these experiments help to identify important mechanisms governing microplastic fate in soils systems. These insights are valuable in assessing the sustainable use of mulching films in soil-food systems.

3.23.A.T-04 Incorporation of Microplastics into Water-stable Soil Aggregates: Dependencies on Particle and Soil Characteristics

Mike Rohling*, Denise M. Mitrano, Daniel Iso Christl and Oliver Klaus, ETH Zurich, Switzerland*

Agricultural practices like irrigation, mulching, and fertilization are closely associated with the pollution of soils by microplastics (MPs). In these environments, MPs can be transported both vertically and horizontally, with the potential to ultimately reach groundwater or surface water sources. While vertical MPs transport has gained considerable attention, horizontal transport remains underexplored. In soil systems, MPs exhibit interactions with other particles and form aggregates. The incorporation of MPs into these aggregates might strongly change their later transport behaviour, particularly when these aggregates show water resistance (water stable soil aggregates, WSAs). This study attempted to understand the incorporation of MPs into WSAs with regards to both MPs and soil properties. To do so, polyethylene terephthalate (PET) and two BASF seed coating fragments were spiked at 0.5% (wt/wt) into a soil that was sieved to <250 µm. All materials contained rare metals to facilitate tracing. MPs were milled to 150

250 µm while PET was additionally milled to <63 µm. For one variant, PET fragments 150-250 µm were mixed with the same soil that was re-combined with the sand fraction (250-2000 µm). All soils were incubated in triplicates at 60% of their maximum water-holding capacity for 2 weeks. To provoke faster aggregation, 2% (wt/wt) glucose was added through the water. After the incubation phase, soils were removed from the cylinders and broken down by drop-shattering until they passed a 1 cm mesh. Then, they underwent a wet-sieving procedure on a 1000 and 250 µm mesh, respectively. The respective fractions were dried, and the weight determined. For further analysis, subsamples from the homogenized fractions were analysed by inductively coupled plasma mass spectrometry. The PET <63 µm incubation showed that 72.9 ± 7.2 % of the recovered MPs were detected in the fractions >250 µm. Using different MPs sizes of the same polymer (PET) will elucidate the effect of size on their incorporation into WSAs. Contrastingly, different MPs polymers of the same size range will shed light on the influence of the MPs chemical composition. Finally, testing two distinct soil textures with the same MPs polymer and size will lead to a better understanding of the importance of soil properties in this context.

3.23.A.T-05 Impact of Polyethylene Microplastics on the Vertical Migration of Pesticides in Soil
Siqi Wu[1], *Alexander Bohme*[1], *Nadin Ulrich*[1], *Andreas Schaffer*[2], *Zhongli Chen*[3] *and Annika Jahnke*[1], *(1)UFZ - Helmholtz Centre for Environmental Research, Department of Exposure Science, Germany, (2)Institute for Environmental Research (IFER), RWTH Aachen University, Germany, (3)Key Laboratory of the Three Gorges Reservoir Region's Eco-Environment, Ministry of Education, Chongqing University, China (Mainland)*
With the revelation of microplastic contamination in soil, their interaction with organic chemicals has received increasing attention due to their hydrophobic surfaces, substantial sorption capacity, and large specific surface area. Our study aimed to extend the focus on single compounds to complex contamination by 20 pesticides which we applied to reference sandy soil. Stainless steel columns were filled with soil with or without the addition of 1% w/w polyethylene (PE) microplastics cryo-milled and sieved to a size of 200-600 µm of irregular shape. The columns were continuously rinsed with ten soil column pore volumes (PVs) of the pesticide-contaminated solution. The leachates were collected and measured every 0.2 PV using liquid chromatography-tandem mass spectrometry to derive breakthrough curves. The results showed that migration was positively correlated with hydrophobicity (as DOW and KOC), while the leaching order of multiple compounds was unaffected by PE microplastic contamination. However, PE microplastics promoted the vertical migration of pesticides in the soil, as previously reported in the literature. Overall, our results indicate that the sorption capacity of soils contaminated with microplastics for such chemicals may be decreased, enhancing the potential of groundwater contamination.

3.23.B Plastics in Terrestrial Ecosystems: Balancing Applications with Impacts, Fate and Hazards

3.23.B.T-01 Micro-Nanoscale Polystyrene and Polyvinyl Chloride Co-Exposure Impacts the Uptake and Translocation of Toxic Elements and Pesticides by Lettuce and Wheat
Jason C. White[1], *Mandeep Kaur*[1], ***Nubia Zuverza-Mena***[1], *Manavi Yadav*[2], *Glen Deloid*[3], *Omowunmi Sadik*[2] *and Phil Demokritou*[3], *(1)The Connecticut Agricultural Experiment Station, United States, (2)New Jersey Institute of Technology, United States, (3)Rutgers University, United States*
Micro-nanoplastics (MNPs) are widespread emerging environmental and food contaminants. The ability of MNPs to influence the fate and effects of other environmental pollutants (EPs) in terrestrial environments and in edible plants is a topic of great concern. Investigations were conducted to evaluate if co-exposure to MNPs (polystyrene, PS; 20 or 1000 nm; or polyvinyl chloride, PVC, <10 µm, unaged or aged) had an impact on the accumulation of other EPs (arsenic, lead, chromium, boscalid, PFOS) in lettuce or wheat. Under hydroponic conditions, lettuce was co-exposed to PS at 10 or 50 mg/L, and to 1 mg/L of each EP. In a soil study with lettuce, the PS and EPs were at 50 and 10 mg/kg, respectively. Phytotoxicity was enhanced by PS under both growth conditions, particularly nanoscale PS (nPS), although impacts were less in soil-grown plants. Nanoscale PS had a greater impact than microscale PS (µPS) on As fate; the As translocation factor from roots to shoots was increased 3-fold in plants co-exposed to nPS (50 mg/L). PS dose and size had a variable impact on boscalid uptake and translocation. Fluorescent microscopy analysis of lettuce co-exposed to MNPs and EPs suggests that nPS enters the roots and translocates to the leaves, while µPS remains mostly in the roots. Pyrolysis-GC/MS showed that in soil, EPs significantly increased the translocation of nPS in lettuce shoots from 4.43±0.53 to 46.6±9.7 mg/kg, while the concentration of µPS in the shoots was unchanged with EPs. Separately, co-exposure to unaged PVC increased the root and shoot accumulation of As, Cr, and Pb by 3.1-, 2.1-, and 1.5-fold,

respectively; for aged PVC, the toxic element increases were 3.9-, 2.6-, and 2.1-fold, respectively. Soil-based experiments with wheat under similar co-exposure conditions are ongoing, as are molecular analyses to elucidate key mechanisms of action. These findings demonstrate that co-exposure of MNPs with other EPs can significantly impact co-contaminant accumulation and toxicity, presenting an unknown risk to humans and other receptors.

3.23.B.T-02 Single- and Multigenerational Toxicity of Seven Mulching Film – Derived Microplastics in Single Species Tests with Nine Soil Invertebrates

*Sam van Loon[1], **Anita Jemec Kokalj**[2], Klára Šmídová[3], Vili Saartama[4], Sarmite Kernchen[5], Salla Kristiina Selonen[6], Jakub Hofman[3] and Cornelis A.M. van Gestel[1], (1)Vrije Universiteit Amsterdam, Netherlands, (2)University of Ljubljana, Ljubljana, Slovenia, (3)RECETOX, Masaryk University, Czech Republic, (4)Finnish Environment Institute (Syke), Finland, (5)University of Bayreuth, Germany, (6)Finnish Environment Institute (SYKE), Finland*

Agricultural plastics like mulching films and plastic fleece are beneficial for increasing yield while decreasing resources, causing a rise in their use over the past decades. However, their degradation and/or fragmentation causes microplastics (MPs) to accumulate in agricultural soils, where their effect on soil invertebrates remains largely unknown. Single species toxicity tests were therefore performed, using seven different MP materials derived from agricultural plastics and nine soil invertebrates: *Eisenia andrei*, *Enchytreaus crypticus*, *Ceratophysella denticulata*, *Folsomia candida*, *Heteromurus nitidus*, *Sinella curviseta*, *Porcellio scaber*, *Tenebrio molitor* and *Lasius niger*. Concentrations up to 5% (w/w dry soil) were included in all tests, with exposures done in or on Lufa 2.2 natural soil for all animals except *T. molitor*. Survival was assessed in all single species tests and different sublethal endpoints like reproduction, establishment of brood chambers or growth and moulting were included. Multigenerational exposures were performed using four of the nine animals and multiple MP materials. Generally, MPs did not affect the survival of the tested soil invertebrates in a dose-dependent manner, up to the highest tested concentration of 5% (w/w dry soil). Sublethal effects were also not always observed up to the highest test concentration, but they were observed for animal growth, oxidative stress induction in *E. andrei*, colony founding in *L. niger* and immune response in *P. scaber*. Besides the direct impact of MPs on soil invertebrates, physicochemical properties of the soil were also assessed. Multigenerational exposure did not increase effects compared to the single-generation exposures, but did show long-term effects on earthworm biomass at the highest exposure level in the 2nd generation. Profound changes in water holding capacity (WHC) and pH (0.01M $CaCl_2$) were observed, with some plastics causing a WHC increase of at least 50% and a soil pH increase of at least 1.2 pH units at 5% MPs (w/w dry soil). These changes in physicochemical properties may be indicative of soil structure and abiotic property changes in the soil, which may have an indirect impact on soil invertebrates and may impact soil communities over generations. Generally, annelids (*E. crypticus* and *E. andrei*) appeared slightly more sensitive towards MP exposures than the tested arthropods (Collembola and *P. scaber*); however no clear explanation for this can currently be provided.

3.23.B.T-03 Microplastics Originated from Agricultural Mulching Films Affect Eenchytraeid Multigeneration Reproduction and Soil Properties

***Klára Šmídová**[1], Jakub Hofman[1], Salla Kristiina Selonen[2], Cornelis A.M. van Gestel[3] and Petr Fleissig[4], (1)RECETOX, Masaryk University, Czech Republic, (2)Finnish Environment Institute (SYKE), Finland, (3)Vrije Universiteit Amsterdam, Netherlands, (4)Institute of Geochemistry, Charles University, Czech Republic*

Microplastics (MPs) are increasingly entering agricultural soils, often from the breakdown of agricultural plastics (e.g., mulching films). This study investigates the effects of six realistic MPs from different mulching films: two conventional polyethylene (LLPE-1 and LLPE-2) and two biodegradable (starch-blended polybutylene adipate co-terephthalate; PBAT-BD-1 and PBAT-BD-2), and two fabrics: ribbon fabric for direct cover (PPDE-black) and mulching fabric (PPDE-white). MPs were mixed into Lufa 2.2

soil at concentrations of 0.005%, 0.05%, 0.1%, 1%, and 5% (w/w dry soil) to reflect both realistic environmental levels and worst-case scenarios. Effects on *Enchytraeus crypticus* reproduction over two generations and six important soil properties were studied. PBAT-BD-MPs notably reduced enchytraeid reproduction in the F0 generation, with a maximum decrease of 35.5 ± 9.6% at 0.5% concentration. F1 generation was unaffected by PBAT-BD contamination. LLPE-MPs had a more substantial reproductive impact, with up to a 55.3 ± 9.7% decrease at 5% LLPE-1 concentration compared to the control, showing a dose-related effect except for 1%. PPDE-MPs impacted the enchytraeid reproduction significantly at the highest MP concentration, with a maximum reproduction decrease of 56.6% compared to the control. All MP types also significantly affected soil water holding capacity, pH, and total carbon. The most significant impact was recorded for PPDE-MPs, which increased the water-holding capacity by 71.8 and 52.7% compared to the control for PPDE-black and PPDE-white, respectively. PPDE-white also caused a significant increase in pH from 5.18 in the control to 7.41 at the 5% of MPs. These differences may explain the reduction of enchytraeid reproduction. On the other hand, although the MP addition of LLPE and PBAT-BD also significantly and dose-relatedly changed soil WHCmax and pH, these changes in soil properties were considered too small to affect enchytraeid reproduction substantially. The reproduction of enchytraeids was, in this case, probably influenced by the release of additives and/or small molecular compounds from MPs, having adverse effects. In summary, our results highlight the potential negative impacts of MPs originating from real agricultural plastics on soil health and raise concerns about the role of agricultural plastics in sustainable agriculture and food safety.

3.23.B.T-04 Microplastic Effects on Soil Nematodes: Main Factors and Species-Specific Differences
***Xuchao Zhang*[1]**, *Ralph Menzel*[2] *and Liliane Ruess*[2], *(1)Institute of Biology, Ecology Group, Humboldt-Universitat zu Berlin, Germany, (2)Institute of Biology, Ecology Group, Humboldt-Universitat zu Berlin*
Microplastic (MP) is becoming an emerging threat to biodiversity and function of terrestrial ecosystem. Although soil is the primary sink for MP, the effect on the soil microfauna is not fully understood, especially in regard to the difference between biodegradable and non-biodegradable plastics.
The impact of MPs on the ecotoxicological model, the nematode *Caenorhabditis elegans* was investigated following a modified protocol of ISO 10872. Different fitness parameters including growth, fertility, and reproduction were evaluated. Nonbiodegradable low-density polyethylene (LDPE) and a biodegradable plastic mixture with 85% polylactic acid (PLA) and 15% polybutylene adipate-co-terephthalate (PBAT) were tested two size classes and four concentrations in three soil substrates (loamy sand, sand, loam). Also, effects of light and microbial degradation of MP were tested. The results show that toxicity varied with the MP concentration and soil types. Before aging, only LDPE inhibited the fitness of *C. elegans* while PLA/PBAT did not. Under aged conditions, both plastic types showed negative effects on nematodes, indicating that biodegradable MPs can become toxic after aging.
To investigate how different nematode species respond to MPs in a semi-natural soil environment, four bacterial-feeding nematodes, i.e., *Acrobeloides buetschlii*, *C. elegans*, *Cephalobus* sp., and *Diploscapter coronatus*, were tested in a modular system. The nematode behaviors of movement, food foraging and choice were tested, with LDPE and PLA/PBAT mixed with soil and loaded into the module according to the experiment setup. Both MP types reduced nematode movement, and had a potential to influence food foraging and choice in soil. These behavioral changes differed among nematode species. The difference between soil and agar were compared for food choice. The latter was related to MP amount and type, nematode species, and observation time, on agar plate, while in soil condition the impact on nematodes was minor.
Overall, the fitness of *C. elegans* can be negatively affected by MP, with impact differing due to soil and plastic types and concentrations. Moreover, species-specific response influences the impact of MP on nematode behavior in soil.

3.23.B.T-05 Effects of Microplastics from Mulching Films on Soil Invertebrate Communities in Agricultural Field Plots from Three Different Geographical Regions

Cornelis A.M. van Gestel[1], *Vili Saartama*[2], *Jari Haimi*[3], *Lotte de Jeu*[1], *Helena Soinne*[4], *Johanna Nikama*[4], *Paula E. Redondo*[5], *Andreu Rico*[5], *Raffaella Meffe*[5], *Virtudes Martinez-Hernandez*[5], *Melanie Braun*[6], *Wulf Amelung*[6] *and Salla Kristiina Selonen*[7], *(1)Vrije Universiteit Amsterdam, Netherlands, (2)Finnish Environment Institute (Syke), Finland, (3)Department of Biological and Environmental Science, University of Jyvaskyla, Finland, (4)Natural Resources Institute Finland (Luke), Finland, (5)IMDEA, Spain, (6)University of Bonn, Germany, (7)Finnish Environment Institute (SYKE), Finland*

The use of plastics has increased dramatically over the last decades, and so has emission to terrestrial ecosystems. In the environment, physical and chemical processes may cause fragmentation of plastic, leading to particles smaller than 5 mm, so called microplastics (MPs). A main pathway for MPs into soil is the use of plastic mulching films in agriculture. Knowing that MPs could pose a risk for soil biota, an increasing number of studies has recently assessed their toxicity to soil invertebrates, mainly in laboratory single-species toxicity tests, using unrealistic high concentrations. Such tests, however, cannot account for the complexity of interactions between MPs and soil organisms due to their controlled conditions and limited duration. Therefore, the main aim of this study was to unfold the long-term direct and indirect ecological effects of MPs on soil biota, under realistic environmental conditions.

Field-plot experiments were conducted at three sites representative of different agricultural and bioclimatic zones across Europe (Spain, Germany, Finland). Micronized pellets made from two recycled mulching films, conventional polyethylene (PE-MP), and biodegradable polybutylene adipate terephthalate-starch-blend (PBAT-BD-MP) were applied to the top 10 cm soil layer of 3.5 m x 4.5 m field plots and mixed with a rotavator to obtain nominal environmentally relevant concentrations of 0.005% and 0.05% (w/w). Each treatment had five replicates. Barley was sown on the fields for two consecutive years (2022, 2023). At the end of both growing seasons, the crops were harvested, and soil invertebrate samples were taken to assess the soil invertebrate community composition.

The number of earthworms per plot varied considerably between and within countries. In 2022, Spain suffered from severe drought and hardly any earthworms and no enchytraeids were found. In Germany and Finland, no differences in earthworm numbers were seen between treatments, but in Finland less juvenile earthworms were present at the high PE dose. In both countries, in 2022 enchytraeid numbers were lower at the high PE-level (0.05%), but only slightly decreased in other MP treatments. In 2023, no MP effects were found. In Spain, in 2023 enchytraeid numbers were reduced especially at the high BAT-MP and PE-MP concentrations. Microarthropod (springtails, mites) samples are still being analyzed, and results will be presented at the SETAC Europe meeting in Vienna.

3.23.P Plastics in Terrestrial Ecosystems: Balancing Applications with Impacts, Fate and Hazards

3.23.P-Th315 The Impact of Microplastics on Nematode *Caenorhabditis elegans*

Anna Ireinova *and Jakub Hofman, Masaryk University, Czech Republic*

Plastic waste has been found in the environment since the 1960s and even the most remote areas of the world have been polluted by it. While this problem is quite well described in Earth's oceans, other regions are just now starting to be investigated. As a result, micro- and nanoplastics (MNPs) are found in many more matrices, and soil is one of the largest global reservoirs of those particles. Yet research into the effect of MNPs on soil ecosystems is currently greatly insufficient. This work is part of the international PAPILLONS project Plastic in Agricultural Production: Impacts, Life-cycle and LONg-term Sustainability which plans to address this knowledge gap. Animals from phylum Nematoda are among the most numerous multicellular organisms on Earth, and their presence in soil is key to the biogeochemical cycles of several essential nutrients. That's why the soil reproductive test with nematode *Caenorhabditis elegans* was extensively optimized to culminate in the testing of four different kinds of plastics identified as most frequently used in European agricultural mulch films.

Two conventional materials consisting of polyethylene (PE-1 and 2) and two biodegradable ones made of polybutylene adipate terephthalate (PBAT-BD-1 and 2) were tested in standard soil LUFA 2.2 in concentrations 0; 0.005; 0.05; 0.1; 0.5; 1 and 5% (w/w) of particles per 0.5 g of soil, the average size of these particles being 24,7 107,8 ?m. The results indicated that with an increased amount of PE-1, the average reproduction of nematodes decreased up to the lowest number of juveniles at 5% of MNPs added. Conversely, for PBAT-BD-2, the reproduction was highest at concentrations of 1 and 5%. During literary research, a significant data gap was identified on the effect of microplastics on the nematode *C. elegans* in soils. To assess the potential impact of using conventional and biodegradable plastics in agriculture on these and other organisms, determine the associated risks, and take the necessary protective measures, having enough relevant information is vital. Research focused on the impact of agriculture on soil ecosystems represents one of the steps we need to take to ensure the proper function and fertility of soils for future generations.
